The first step in removing the toxins in pneumonia is a soap and hot water bath and as vigorous rubbing as the patient can have with a coarse towel. The second step is the washing out of the colon with a magnesium sulphate solution—one rounded tablespoonful to a quart of hot water. This solution is to be thrown into the bowel until the latter is thoroughly cleansed. This gets rid of the fecal matter, one of the marked sources of poison, and as the magnesium sulphate has special affinity for the carbon in the toxin, it lessens its virulence. The third step, bathe the patient from head to feet with a hot magnesium sulphate solution—one heaping tablespoonful to one quart of hot water; place a compress about the neck of the patient, also over the inflamed lungs, the compresses to be wet in the hot magnesium sulphate solution. Then dissolve 1-125 grain of aconitine in a half glass of water and give one teaspoonful every hour; give what cold water the patient calls for, in small quantity, but often. Also change compresses about the neck and chest every half hour. This is a treatment that eliminates and withdraws poison from the blood, and is as certain in its action as that water will quench thirst. After the fever abates, I should continue the hot compresses and baths three or four times a day and give 1-67 grain of bryonine dissolved in one-half glass of water, one teaspoonful every hour, until soreness is gone from the lung; then as a nerve tonic use strychnine arsenate, 1-134 grain, every three hours. For nourishment, as much cold or hot water as the patient may desire for three days; then meat juice and grape juice until the patient is ready for more solid food. Such a treatment as this, intelligently applied, will purify the blood, lessen complications, and lower the death rate. Quinine, morphine, and whiskey have no place in the treatment of pneumonia.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL SOCIETIES—POSITION OF JUNIOR SURGEONS—TROPICAL SCHOOL—OLD AGE—CANCER RESEARCH—BROMPTON'S PRIZES—SCHOOL INSPECTION—FEEBLE MINDED—HUNTERIAN MUSEUM—ROYAL WATERLOO HOSPITAL—OBITUARY.

London, October 16, 1908.

The societies, as well as the schools, are now at work. As all cannot be mentioned at once, I will send you a note to begin with on the venerable Medical Society of London, which met on Monday, when the president, Mr. C. B. Lockwood, delivered a specially interesting address. The great increase in the number and arduous nature of modern operations, he said, entailed an amount of exhausting labor that few realized. Recent deaths among junior hospital surgeons suggested that they might have succumbed to the strain and stress of their work. Some were certainly strong men, but long hours in the out-patients' rooms, in the wards and in teaching, with night work and insufficient rest or recreation, were not calculated to fortify them to withstand the influences to which they were exposed. Some of his own friends had become victims to tuberculosis and other infectious diseases. The surgical out-patients' departments in which so much good work and teaching was done, were always crowded—often ill ventilated and dust laden. Operating theaters unless scientifically ventilated and lighted become highly prejudicial on account of the scarcely supportable atmosphere. The overworking of the juniors was having a bad effect not only on their health, but on their scientific work. If British surgery was to maintain its position its makers must have time to think, to work and to record their achievements. They also needed recreation in the open air. This involves an outlay not always at command. The public who support hospitals fancy these posts are profitable, and hospital committees often imagine that the emoluments of teaching are handsome and all-sufficing. He did not see a remedy in an increase of the staffs, as there was not space enough at present for their work, and the multiplication of hospitals would not alleviate the lot of men who were expected to work gratuitously. Some would invoke state or municipal aid. Others would restrict the numbers of admissions, especially to the out-patients' departments, and this seems to me the proper first step.

After the address Mr. R. Morison read a paper, in which a portion of lung had been excised in order to remove the stump of a tooth which had slipped down the air passage. After long distress and expectoration of thick, green sputum operation was essayed, although Roentgen rays did not show a foreign body. The stump was not removed in the portion of lung excised. The post mortem specimen of the part of the lung containing the tooth was shown and some varying opinions expressed on the case.

The Earl of Crewe presided on Wednesday at the London School of Tropical Medicine and paid a graceful tribute to his distinguished predecessor, Mr. Joseph Chamberlain, to whom the school owed its foundation. He said the ever increasing usefulness of the school would cause his name to be never forgotten. At the Colonial Office their interest in this and the kindred Liverpool school was a very direct one, for in East and West Africa alone they had some two hundred medical officers, all of whom found it part of their duty to study tropical diseases before taking up their posts in those districts. He commended the interchange which had taken place between this school and the Royal Veterinary College, and had always been impressed with the thought that doctors might advantageously study more animal pathology than sometimes they did.

Sir Clifford Allbutt then gave an address, in which he dwelt upon the great place which preventive medicine was assuming in the mind of society generally, and said it was of enormous importance, not merely that the medical profession should be expert in research, but that they should make their purpose understood by the great lay public, without whom no progress could be made. Referring to the fact that the spread of disease was very largely brought about by traffic, he said he spoke of this because an exceedingly important event was taking place in the East—the making of the

railway to Medina, Mecca and Bagdad. The religious pilgrimage, as was well known, acted as one of the strongest possible carriers of infectious disease. The slow pilgrimages on foot had been carefully watched and every possible step taken to prevent the carriage of disease, but that would be difficult with swift railway communication. If a great pestilence followed the opening of the line it must not be said they did not know. They did know. The tropical schools knew all about it. It was for the lay people to insist on that knowledge being so applied as to prevent the railway from becoming a means of propagating possibly more than one dire pestilence.

Sir R. Douglas Powell gave a pleasant little address at the West London Postgraduate College on the conditions of old age, which, he said, were too often regarded as disease conditions. He thought to speak of old age as disease was quite a misnomer, although, in a sense, they might say they were not living so much as dying all their time. But he spoke of healthy old age. Changes gradually took place as age came on—conditions which should not be regarded as disease and still less treated as such, if these conditions had not been hastened by riotous living, too strenuous labor, or hereditary disease, they should only be regarded as natural changes. He then pointed out some of the changes incidental to old age and gave suggestions as to treatment when needed. The doctor must know his medicine, but he must also learn his patient. Not a few of the ailments which old people suffer from would seem trivial in the young, but that is no reason for neglecting them. They require treatment of a very light hand with very gentle medicine.

The third report of the Cancer Research Fund appeared on Tuesday. Dr. Bashford remarks in the introduction we are still at the beginning of systematic experimental investigation and caution is as necessary as pertinacity and enthusiasm. Since the second report was issued a year ago work has continued in the laboratories steadily and profitably, and the researches are more specialized than those described in the two preceding reports. The volume is well arranged, starting with more general papers giving the evidence on which the comparative biological and experimental study of cancer is based, followed by those dealing with particular problems. Dr. Bashford contributes an interesting paper dealing with points of general interest as to the incidence of the disease and its association with different forms of chronic irritation in mankind. Dr. Seligmann gives an account of new growths met with in New Guinea. Dr. Murray writes on the zoological distribution of and records some new observations on cancer. "The Nature of Resistance to the Inoculation of Cancer" is considered by Dr. B. R. G. Russell, and other papers deal at length with the tumors of mice, the features of their growth and the means by which it can be modified, or even inhibited. Drawings and photographs are added to the report, and there is a list of the contributions issued by the Fund. Rigid rules for making and recording experiments have been adopted from the first, so that such can be repeated as may be desirable and the results compared. In reference to this, imperfect records have too often reduced the value of some experimenters' results to a minimum and have prevented an accurate repetition of their experiments. No indications of a curative serum or a prophylactic vaccine have been discovered, and the rationale of early resort to removal of malignant tumors is amply justified by experiment. Alleged empirical remedies are useless.

Our Brompton Hospital friends are elated at the prizes awarded their institution by the International Congress on Tuberculosis held at Washington. They have been informed by cable that they have gained the prize for the best hospital exhibit for treatment and that their sanatorium wins the prizes for the curable cases. This is very encouraging to them. The building of their sanatorium at Frimley cost £70,000 and exhausted their exchequer. Patients are taken only from the hospital, so that proper care is exercised in their selection, only those likely to receive the most benefit being transferred. One of the distinctive features is the system of graduated exercises which is adopted. Frimley is our largest sanatorium. Its "cures" so far are estimated at 80 per cent. It may interest you to learn that the model of it which gained the prize was almost completely made by the patients, who took the greatest pleasure in constructing it. A third prize has been awarded, the cablegram says, to the Women's Health Association of Ireland for their work in preventing tuberculosis.

How best to meet the obligations imposed by the medical inspection of school children is exercising the minds of a number of local authorities. It is admitted that inspection can be of little value except as a matter of statistics unless some method of supply treatment be provided. The plan of school clinics proposed I have already reported, but the local bodies are by no means anxious to adopt it. In London it is suggested that everything which could reasonably be required could be supplied by the numerous provident dispensaries, that the local bodies might contribute at first the trifling payment and that the parents, as a rule, would soon be ready to continue this form of insurance against sickness if its purpose were properly explained to them.

Dr. W. A. Potts, late investigator to the Royal Commission on the Feeble Minded, read a paper on Tuesday at the Society for the Study of Inebriety, in which he maintained that his investigations proved that alcoholism was twice as common in the antecedents of children in special schools as in those of ordinary schools. Further, it established the great injuriousness of maternal drinking, leading to the conclusion that, combined with other bad influences, alcohol was a most unfavorable factor, and maternal drinking continued through more than one generation was a potent cause of degeneracy. The Royal Commission stated that the mentally defective amounted to 1 in 200 of the population.

To-day is the 115th anniversary of the death of John Hunter, and a series of demonstrations by the conservator of the Hunterian Museum and by the pathological curator is to be begun, and will be continued in the theater through the present session. The object of the Council of the Royal College of Surgeons in arranging for these demonstrations is to increase the recognition of the value of the museum by showing specimens of the collection and illustrating their bearing on general and surgical pathology and practice.

On Saturday the Princess of Wales opened a new ward in the Royal Waterloo Hospital for children and women. This is the oldest hospital for children in London, having been founded in 1816 under the auspices of their Royal Highnesses the Dukes of Sussex and Kent, and it has enjoyed the support of the Royal Family ever since, this new ward being named the Duchess of Albany. Several enlargements have taken place during its history, and in 1904 it was practically rebuilt at a cost of £45,362, which has been wholly paid. With the new ward completed thirty beds and sixty cots are available, but to carry it on about £3,700 a year is required beyond its fixed income.

The Local Government Board has informed the Hammersmith Borough Council that their Medical Officer of Health has accepted appointments at the Franco-British Exhibition which seem to be incompatible with his duties as Medical Officer of Health. In 1902, the letter states, the Board had expressed the opinion that the Council should engage the whole services of their Medical Officer. The Council reply that they then decided to make no alteration and they now see no reason for any other decision in view of the fact that Dr. Collier has continued to perform his duties in a manner so satisfactory as to enhance rather than diminish the Council's confidence in him.

The death is announced of Surgeon-Major T. Holmested, late of the Indian Medical Service. He had charge of the field force at Renn Kanta in the operations against the Bheels in 1868. He retired in 1878 and practised for a time at Hyderabad.

Another Indian medical officer's death took place in September—that of Lieutenant H. A. Knight, M.B. He entered the service only two years ago and died at Mooltan in the 29th year of his age.

Wm. Treves, F.R.C.S., of Margate, died on Wednesday, aged 65. He was known to an immense number of practitioners as a skillful surgeon at the popular watering place where he had practised for many years. He was as popular with the visitors as with the profession all through the southern counties. He was a brother of Sir Frederic Treves.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 22, 1908.

A Case of Pyonephrosis and Renal Calculi in a Pregnant Woman. Induced Labor, Nephrectomy, Recovery.—The patient of J. M. Wheeler was a woman of 37 years, with symptoms dating back five years in the middle of the fourth month of her eighth pregnancy. A firm, elastic, tender, rounded tumor extended from

the right loin up under the ribs to the tip of the tenth costal cartilage, inward nearly to the umbilicus and downward to the McBurney point. As it did not seem probable that the pregnancy would run a normal course, the uterus was emptied. Shortly after the tumor grew rapidly and she developed fever with nausea and severe lumbar pain. Abdominal incision showed the tumor was an enlarged right kidney, which was removed. The mass was in the shape of a sac, dividing into four compartments, distended with about a pint of purulent fluid. The renal pelvis contained a large stone and eight others were found in other parts of the sac. The large one weighed 768 grams and the others combined 192 grams. Recovery was without incident and the patient subsequently bore two more children. The case was a typical one as to symptoms, viz., pain, pyuria, renal colic, hematuria, tumor, urinary disturbances and tenderness. Its special interest lies in the fact of a complicating pregnancy. It was necessary to dissect away from the sac the inferior vena cava, which was adherent over the whole length of the tumor about half an inch from the inner border. There were two renal veins, about half an inch long. In the course of the operation the left kidney was palpated, but nothing abnormal was discovered, while the appendix, which was clubbed at the tip and somewhat adherent, was removed.

New York Medical Journal, October 24, 1908.

The Alcoholic Psychoses.—S. E. Jelliffe discusses this question under the headings of history, pathology, general, special and focal symptoms, clinical forms, diagnosis, course, and treatment. The histories of two personal cases are given by the author, who draws freely on the observations of various neurologists. Under the heading of clinical forms, he refers to Dupré's classification into the amnesic, confusional, delusional, anxious, and demented forms, and to Knapp's more expanded classification into the delirious, stuporous, demented, hallucinatory with and without systematization of ideas, paranoid, anxiety, expansive, maniac and melancholic forms, the polyneuritic mobility psychosis of Wernicke, and anomalous cases. The paper is a general clinical study of the entire subject. The treatment is in general the same as for multiple neuritis. The author cautions against too great zeal in therapeutics We must not overdo the matter. We must bear in mind that excessive physical work calls for an amount of nervous functioning just as mental work, that no adaptation to hit even a golf ball correctly can be carried out without an immense amount of nervous functioning, and that therefore in the earlier stages those games or occupations should be chosen which do not call for a high degree of nervous tension—such as the lazy lolling about of swimming—and that no exercise treatment should be overdone. Hard muscles, ruddy cheeks, ability to run twenty-five miles after a dog cart, these may be the delusive signs of a healthy musculature at the expense of mental restitution. It goes without saying that all alcohol-containing tonics must be avoided.

A Summary of the Results Obtained by the X-Ray Treatment of Exophthalmic Goiter.—A review of the literature is made by G. E. Pfahler, who has found records of 51 cases. His deductions from the material collated are as follows: (1) Decided improvement may be expected in about 75 per cent. of cases. (2) This improvement consists of an increase in weight and strength, and gradual disappearance of the Basedow symptoms. (3) Some improvement should be noticed within a month, and after six to a dozen treatments. (4) When this treatment is properly given there appears to be no danger. The permanency of the results is still an open question. The reports here presented were carried out to periods varying from a few months to three years after the cessation of treatment. The earliest and most noticeable improvement is in body weight. The symptoms most obstinate to treatment are the thyroid enlargement and the exophthalmos. If some improvement is not shown after one month of treatment, the latter should be discontinued for one month and then resumed. The rays should be localized upon the goiter and may be carried to the point of producing a mild dermatitis, but no farther. The author believes that this plan of therapy deserves a more general trial than it has yet received.

The Diagnostic Value of Perverse Secretion of Hydrochloric Acid by the Mucous Membrane of the Stomach.—G. Chambers cites certain well-known facts bearing on gastric physiology. He notes that the native juice free from food obtained from a gastric fistula during "sham feeding" has an acid content more than twice that of gastric contents after a test breakfast. There are so many factors taking part in the genesis of the acid content of the gastric contents that it is very difficult in some cases to determine the kind and degree of perversion of gastric secretion by chemical analysis. The author says he can easily imagine cases of diminished secretion of gastric juice as a whole (subsecretion) diagnosticated, by our present methods of examination, as hypochlorhydria; and similarly hyperchlorhydria may be mistaken for oversecretion. This view is, he thinks, supported by his observation in cases of chronic gastritis, carcinoma of the stomach, and achylia gastrica, in which the absence of marked motor insufficiency, diminished percentage of hydrochloric acid is usually associated with greater consistency of the gastric contents; and similarly hyperchlorhydria with diminished consistency. As a rule diminished percentage of hydrochloric acid is associated with an abnormally high and increased percentage, in the absence of much mucus with an abnormally low specific gravity. He refers to perverse secretion especially as regards carcinoma, acid gastritis, and achylia gastrica. According to his observations all the cases of cancer of the stomach, in which free hydrochloric acid was present in advanced stages of the disease, gave a history of having suffered from gastric ulcer or acid gastritis, affections usually characterized by excess of free hydrochloric acid in gastric contents, and frequently by a large excess. Acid gastritis is especially apt to occur in alcoholics, and predisposes to both ulcer and cancer. When the latter complicates acid gastritis or ulcer free HCl may be present in advanced stages of the disease. In achylia gastrica a common symptom is chronic diarrhea. Under these circumstances HCl is a valuable remedy in checking the bowel flux.

Journal of the American Medical Association, October 24, 1908.

Hemorrhagic Nephritis.—C. F. Wahrer gives an account of an unusually mild epidemic of scarlet fever occurring in Lee County, Iowa, in which a much larger proportion of the patients than usual had albuminuria and nephritis, a considerable percentage of these showing the diffuse form with hematuria and hemoglobinuria. Nearly all, however, recovered in spite of the usually considered seriousness of the complication, and none has since relapsed or shown any late had effects after the lapse of about two years. None of the usual factors to which such a complication is ascribed could be invoked as the cause, and the etiology of the epidemic is obscure. The treatment, so far as ascertained, was prophylactic against such complications from the beginning of the scarlatinal symptoms, and greater care was, of course, used after the hematuria appeared.

Fibroid and Anemia.—The question of anemia as affecting the operation for fibroid of the uterus is discussed by B. R. Schenck. He finds that anemia is frequently associated with fibroid, and it is often grave and even threatening to life. He is not satisfied with the theories offered to account for the frequency of cardiovascular changes in connection with fibroid. It is his belief that uterine myomata are congenital, and cannot, therefore, be secondary to alterations of the vascular system, aortic tension, or toxin. The cases on which these theories are based are those either in which degenerations have taken place or in which there has been hemorrhage. Hemorrhage he considers to be the underlying factor in a vast majority of the cases, and anemia the cause of cardiovascular changes in the larger proportion. If this is the case, the practical deduction is that all fibroids showing the slightest tendency toward an increase in the menstrual flow should be promptly removed. These patients are often seen, however, only after the anemia has become marked, and the question arises, What is then to be done? It has long been held that a hemoglobin percentage of less than 30 contraindicates operation. Certain recent writers, however, have held that we can put no arbitrary limit below which it is unjustifiable to operate, and this position, Schenck holds, is the correct one. Of course, a percentage below 30 is a grave complication and calls for special attention to numerous details, both before and during operation. When there is active bleeding, no radical measures should be attempted until every effort to stop hemorrhage and build up the patient has been exhausted. If everything fails, and the bleeding continues active, with a low blood count and bad action of the heart, he believes ligation of the uterine arteries, as advocated by F. H. Martin, is advisable as a preliminary to hysterectomy. Myomectomy should never be done, and when hysterectomy is undertaken every measure possible must be employed to shorten the time of operation, minimize the hemorrhage, maintain body heat, and sustain the blood pressure. Neglect of

these is never excusable. There is great danger of thrombosis and embolism as a postoperative complication in these cases. Histories are given of four patients operated on when the hemoglobin percentage was very low, 23, 26, 30, and 20 per cent., respectively. All but one recovered. This one seemed to improve, but died some months after the operation, apparently from typhoid infection.

Cutaneous Epithelial Tumors.—J. A. Fordyce says that the division of cutaneous epithelial tumors into basal cell and prickle cell is justified by their histological structure and clinical course. In one the basal cells of the epidermis and the outer root sheath of the hair are chiefly or solely active, this class including the well-known rodent ulcer. The prickle cell type, on the other hand, originates in the layers above the basal cells, and reproduces its own kind; it is much more malignant than the other, as a rule, since it tends to involve the lymph nodes and to produce metastases. In this form there is not so much divergence from the type of growth. In some cases the cells do not proceed to the formation of pearls, but retain their spinous or polygonal form. There are gradations between the two types. In the basal cell variety of tumors the clinical picture is as diverse as the histological one. The so-called cylindromas probably belong to the basal cell group, though an endothelial origin has been attributed to them. Fordyce describes several varieties of this type. Other conditions noted by him are carcinomatous lymphangitis secondary to cancer of the breast, and extramammary Paget's disease, of which he gives illustrative cases. These epitheliomas, he thinks, do not differ essentially from those of the nipple, except, perhaps, in degree. Multiple epitheliomas of the arms and chest in one case are also reported; the patient had been treated for syphilis by various physicians, misled by a history of lues many years before. The microscopic examination, however, revealed the true character of the growths unmistakably. A case of trichoepithelioma is also reported, which was diagnosed only after microscopic examination, there being nothing in the clinical appearance of the lesion to suggest the real nature of the growth. A case of prickle cell epithelioma occurring in the same individual, with rodent ulcer, and a case of epithelioma of the lip in a woman are also reported. Fordyce says that the *x*-ray treatment of skin epitheliomas has been more beneficial in his experience after the growth had been thoroughly curetted, thus enabling the rays to reach the actively developing cells. He has also found its prolonged use contraindicated in malignant cutaneous growths as a rule, and he believes that in certain cases it renders the tissue more vulnerable. He thinks its use should be reserved mainly for growths in locations not accessible to other treatments.

Gonococcus Vaccine.—N. E. Aronstam finds that the gonococcus vaccine acts beneficially in acute cases of gonorrhea, and the time required to cure the disease does not exceed four weeks. It is also useful and may be considered curative in some of the complications, such as epididymitis, Cowperitis, acute prostatitis, gonorrheal adenitis, enlargement of lymph channels on the dorsum penis, and in posthitis of the same origin. He has also used it lately with success in gonorrheal iritis. No other treatment, systemic or local, is necessary. In chronic cases it is inert and acts indifferently, owing to the mixed infection in these cases, and the conjoined use of other bacterins suggests itself. It is a valuable diagnostic agent, bringing to light latent or dormant conditions and showing whether a given case has actually been cured, an especially important point for sociological reasons. In dormant gonococcic arthritis it will bring about a recrudescence of the disease. It materially shortens the duration of this complication, and brings about a speedy cure. No exact rule can be given as regards dosage and intervals of administration; each case must be treated individually. Aronstam considers that the future possibilities of gonococcic vaccine and opsonotherapy in general are unlimited. Its bearing on prophylaxis in this disease, which must be recognized as a systemic and not a local infection, should be considered.

Children of the Tuberculous.—T. B. Sachs has investigated the incidence of tuberculosis in the children of tuberculous parents in the city of Chicago. One hundred and forty-six families were taken, in which one or both parents were tuberculous; all were of the average working class and largely living under unfavorable hygienic conditions. The findings are given in detail. He concludes that the infection of children by tuberculous parents must necessarily depend on several factors, and the unhygienic conditions and crowding of the poor favor its occurrence. While detection of the well-developed forms is possible with ordinary methods, the infection with the germ doubtless is more general than the diagnosed cases would indicate. Hereditary predisposition as a factor cannot be properly estimated until the factor of infection is completely eliminated, and the question of connection between tubercle infection in childhood and the manifestations of the disease in later life is still unsolved. The present trend of medical opinion is toward the interpretation of the term "predisposition" as a susceptibility of the tissues dependent upon previous infection. It is probable that a vast majority of these early infections remain unrecognized, but the eradication of tuberculosis in the human race can never be accomplished until the child is protected. At the time of their birth and for the first few years of life the vast majority of children of tuberculous parents may show no deviation from the normal type, but later, with unfavorable environment, the so-called "habitus phthisicus" may appear.

Heart Maladies.—A. G. Brown notes the increasing prevalence of heart troubles, and credits the infective diseases with the largest part in their production. The prophylactic phase of the heart problem, he says, can be outlined in one sentence. The infectious diseases and other conditions, such as derange metabolism, occupation, habits, etc., affecting the viscera must constantly be kept in mind by the physician. He divides cardiopaths into three general classes: (1) Those in whom the compensation is perfect; (2) those in whom compensation is waning; (3) those in whom compensation is lost. The main question is by what means can the first group be kept as such, and how can the largest number of those falling under the second and third group be reclaimed and placed in the first group. In other words, the duty of the physician to the patient is to support the musculature. He specially discourages any secrecy on the part of the physician toward the patient in regard to these matters. The first and most fundamental step to be taken to protect the cardiopath from an untimely end is publicity. Candor and careful explanation will do much to correct the state of affairs. Those cardiopaths in whom the compensation and the conductivity of the auriculoventricular bundle is good, and in whom the cardiac muscle is fairly strong, may need little or no medicine, but they should have medical advice as to exercise, vocation, habits, baths, the danger of intercurrent disease, the use of drugs, changes of climate, etc. The second and third group must be treated with the same candor, but more skilfully and carefully. Those of the second group should have more constant supervision, frequent cardiac examinations, and proper remedial measures to restore the waning compensation. The cooperation of the patient in these cases is of the utmost importance. The third group presents a syndrome comparable to the last stages of cancer or phthisis, but, unlike these conditions, heart disease, with all its discomforting symptoms, offers a chance of striking medical success. The two points especially insisted on in this paper are a more careful treatment of the infectious diseases to protect the heart, and more candor and public education in regard to those disorders.

The Lancet, October 17, 1908.

A Diphtheria "Carrier."—T. Strain reports the case of a girl nursemaid who went through a severe attack of diphtheria and discharged from hospital with a free record as to absence of baccili in the throat. After she had resumed the care of children, one of the latter contracted diphtheria. A culture from the maid's throat now showed the Klebs-Loeffler bacillus. She was isolated and again declared free. Still again one of her charges, this time in another family, became ill. The maid was readmitted to hospital and subjected to steady treatment with antiseptic sprays, scrubbing, etc. She remained in hospital for six weeks, by which time the throat was free, but the nose still harbored the bacilli, yet only intermittently, from which it was conjected that they might come from one of the accessory sinuses which previously discharged its contents into the nares. It was nine months before the air passages were baccili free.

Unusual Cause for Rupture of the Rectum.—The patient of C. L. Franklin, a lad of 17 years, was crushed between some machinery in a cotton mill. On admission to hospital he was apparently moribund, suffering from shock and severe hemorrhage from the rectum. The rectum was firmly plugged with gauze and the hemorrhage ceased, saline solution was infused into the median basilic vein, and the usual treatment for hemorrhage carried out. However, the patient died within two hours of admission. The only marks of external injury were slight contusions in the left hypochondriac region and over the forehead. At the post-mortem examination the pelvic peritoneal cavity was found to contain a large quantity of blood. There were a slight laceration of the liver and a vertical tear on the anterior surface of the rectum three-quarters of an inch in length and situated at a distance of three and a half inches from the anus. There was no fracture of the pelvis, sacrum, or coccyx, nor sign of injury about the region of the anus. The other organs were normal. The gauze packing was projecting into the peritoneal cavity through the rent in

the rectum. The main interest of the case lies in the possibility of a rupture of the normal rectum from increased abdominal pressure. Cases of vertical rupture of the rectum due to straining in order to pass hard scybalous masses have been recorded, but in these cases the rectal walls are undoubtedly abnormally thin and ruptured without great difficulty.

Treatment of Acute Appendicitis as It Comes Under the Care of the General Practitioner.—In mild cases J. Phillips advises rest in bed, abstinence from food, plenty of hot water, but nothing which can leave any residue. He gives no calomel, but if flatus is present orders a turpentine enema. An alkaline carminative comforts the patient. If pain is felt, a little morphine may be called for in pill, suppository or enema. If the foregoing does not relieve the patient in two or three days, and if the pain continues, we probably have a more severe case with which to deal. We now begin to look for a more or less irregular mass in the right iliac fossa. The author counsels delay in operation. To operate at once means, he says, tedious dissection through acutely congested and friable tissues down to what is usually quite a minute collection of pus around an appendix so soft and glued down that its removal is extremely difficult. Moreover, the pus is full of colon bacilli and infection of the abdominal wound becomes practically certain. If, on the other hand, rest and starvation are persisted in, the temperature will come down and the lump disappear in the great majority of cases. Then, in a week or two, operation may be done. The adhesions are easily separable, the appendix sufficiently firm to be easily dealt with, and if a little pus remains about the appendix tip, the colon bacillus is probably absent and primary union will result in the abdominal wound. When there is evidence of acute peritonitis without any iliac mass, indicating that the inflammation is well localized, immediate operation may be indicated. The question is whether the pus is efficiently or inefficiently shut off around the appendix. The author lays great stress on a condition of the abdomen which he thus describes, considering it practically pathognomonic of diffused purulent periappendicitis. If the patient's whole abdomen is bared it will be found to be more distended than normal, and if well diffused or generalized peritonitis is present there will be general immobility and rigidity (except when the patient is poisoned by morphine in the early stages or towards the end of the case by the products of the peritonitis) and all the regular signs of well-developed peritonitis. If, however, the pus is confined to the region of the appendix and is only threatening to generalize, but has not already done so, careful observation will reveal some slight movement at any rate in the epigastric region and sometimes also of the left half of the abdomen. If the surgeon's warm hand is now gently placed on the abdominal wall, care being taken not to exert any pressure, the epigastrium being palpated first, the rectus abdominis will be found to give slightly with each respiration. Carry the hand down over the left rectus to the pubes and the same slight movement will be observed. Now glide the hand back to the epigastrium (it should not be raised from the abdominal wall until the examination is completed) and down the right side of the abdomen. When the appendix region is reached if there is pus present the segment (not the whole muscle) of the rectus abdominis over the appendix will be found to be firmly contracted and board-like. All that is needed to demonstrate this sign is great gentleness during the examination in order not to excite general contraction of the recti muscles. Such a condition indicates immediate operation.

British Medical Journal, October 17, 1908.

Use and Misuse of Iron Remedies.—Eustace Smith says that to take anemia as a sure guide to the immediate use of iron is to fall into one of the commonest of errors. To get any benefit from such a remedy, the tongue must be clean and the digestive organs in a healthy state. Preliminary antacids and stomachics are called for and then the iron will be beneficial. Often in chlorosis there is considerable tenacious mucus in the stomach, and the use of an emetic will help far more than the routine administration of aloes and iron. Any benefit which may result from the latter combination is probably due to the laxative ingredient. It is often advantageous to begin the treatment of anemia with the ammoniocitrate in some bitter infusion, changing to a stronger iron preparation as the tongue grows cleaner. The author then enumerates certain of the B. P. iron preparations which he has found useful in various clinical conditions. He closes by saying that the chalybeate salts, when given with judgment, are remedies which we could ill spare, but the indiscriminate use of these preparations is to be deprecated. Iron must not be regarded as an infallible specific in every form of anemia. The cases for which it is curative must be chosen with judgment, and every care must be taken to see that the digestion is in a condition to profit by the remedy. Any sign of irritability of stomach is to be taken as an indication that the stronger preparations are to be avoided, and even the milder salts—the tartrate and the ammoniocitrate—should be prescribed timidly, and only in conjunction with an alkali, such as citrate of potassium or the aromatic spirit of ammonia, in a freshly-made bitter infusion. If the tongue be clean, or merely flabby and pale, showing indentations of the teeth at the sides, the stronger salts may be prescribed with confidence, and the dose may often be pushed with advantage if aperients are given from time to time as already recommended.

The Analogy Between Spontaneous Recoveries from Cancer and the Specific Immunity Induced by X-Ray Irradiations of the Lymphatic Glands Involved.—Four cases are recorded by H. D. McCulloch, who has endeavored to induce autovaccination by the *x*-ray. At first he tried the procedure in tuberculosis, gauging his method by the opsonic index. More recently he has tried the same method in treating the lymphatic glands involved in cancer and its secondary infections, but as the cancer microorganism, if such there be, is not cultivable, it has not been possible to make use of the opsonic index in the cases here reported. The clinical symptoms of these cases were, however, sufficiently marked and progressive to be depended upon. It should be noted that the glands in these cases, which are usually remote from the site of the lesion, were alone exclusively irradiated, the rest of the body, including the lesion, being effectually screened from the influence of the rays. The author says that in the diseases which involve the production of an immunizing agent, the lymphatic involvement in its early stages is physiological and not pathological, therefore, not manifested to our senses either subjectively or objectively. A microbic attack necessarily involves the initiation of the formative process of an immunizing agent, this process being completely carried out in those cases in which a certain adequate dose of the infection is successfully repelled. Hitherto, lymphatic glandular involvement in the infectious processes in the animal body has been looked upon most unfavorably both by the physician and the surgeon, as "a spreading of the disease into the most vulnerable parts of the system," and not as an extended response of the body in the mechanism of bodily defense. These glands which are usually conspicuous in the neck and armpits are therefore cut out as completely as possible; it is said, "to prevent further spread," or "recurrence" of the malady. It should, however, be noted that there is this serious inconsistency in what has been called the "radical operation" in cancer, that these glands are usually left undisturbed, when they are not easily accessible to the fingers, as in operations for cancer in the abdominal organs. The fact that these glands have been estimated to number from 800 to 900 in the human subject, and that they exist for the purposes of a most important function, seems to have been entirely overlooked.

Berliner klinische Wochenschrift, September 7, *and October* 5, 1908.

Leucocytosis in Appendicitis.— Kothe says that according to Arneth the number of fragments composing the nuclei of neutrophile leucocytes undergoes certain definite changes in disease. In health the cells containing one, two, three, four, and five fragments reach certain constant percentages of the total number of leucocytes, while in disease the cells with fewer fragments of nuclei quickly increase in number at the expense of the cells with the larger number of fragments. This is explained by the supposition that the cells with many nuclear fragments are the older cells many of which perish in carrying out their phagocytic activities and in their place the younger mononuclear cells and cells with only two or at most three nuclear fragments appear. Kothe has found that the normal percentage of mononuclear neutrophiles is six. He has examined eighty-six cases of appendicitis in reference to any changes in this percentage and has found that the cells of this character reached from eight to twenty-five per cent. of the total leucocytes in cases of simple acute appendicitis; in cases of suppurative appendicitis, on the other hand, with empyema or gangrene of the organ, the percentage of the mononuclear neutrophiles reached from twenty-three to sixty-five per one hundred cells. The curves of temperature and pulse ran parallel to the percentage of mononuclears, and the three together gave in most cases valuable indications for the prognosis and treatment of the cases. Mononuclear percentage over thirty should be a strong argument for an immediate operation.

The Cause of Scarlet Fever.—Gamaleia says that the excitants of scarlatina are to be sought among protozoa and not among bacteria. He has examined 25 scarlet fever patients and has succeeded in finding definite protozoa-like structures in the skin, pharynx,

blood, and the internal organs The typical form of the organism consists of five rounded elements grouped about a sixth central body. They are found free in the tissues or included in polynuclear leucocytes, and are in no wise similar to products of cell degeneration. In places they are grouped in very regular colonies that resemble those observed among the radiolaria. The forms observed by Mallory are probably stages in the development of the parasite.

Atrophy of the Kidneys in Ureteral Fistulæ.—Asch has observed several cases of ureteral fistulæ opening into the vaginæ of patients, which gradually discharged less and less urine, though the communication between the ureter and the bladder was not reestablished. In no case were there any symptoms present that could point to hydronephrotic distention of the kidney on the side of the fistula. Finally the secretion stopped altogether, while the usual amount of urine was passed from the bladder. Asch suspected that in these cases gradual atrophy of one kidney took place and was able to confirm this view in operating upon one patient with ureteral fistula. Her kidney proved to have much diminished in size and microscopically showed an advanced grade of atrophy in all elements. His observations are of importance in connection with the therapy of ureteral fistulæ. They should be cured by implanting the injured ureter into the bladder as soon as possible after their development. If several weeks or months have passed and the secretion has been progressively diminishing they may be left alone, for the kidney on that side is probably undergoing rapid atrophy.

Münchener medizinische Wochenschrift, September 8 *and* 29, 1908.

A New Test Meal.—Schlaepfer recommends the use of a soup made of flour, egg albumin, and butter and colored by the aniline dye, neutralized. The first opening of the pylorus is shown by the appearance of the dye in the urine, and this phenomenon observed for the time of its duration gives a measure of the motility of the stomach. The secreting function is easily judged by the relative amount of the colored liquid and of the gastric juice in the fluid obtained by the stomach pump. The peptic digestion of the stomach may be estimated by the color of the fluid, while the usual titration methods may be applied to the mixture obtained just as in case of other test meals.

Acute Thyroiditis.—Dunger reports seven cases of this rare affection, all of which occurred in young females. The diffuse swelling of the gland was a predisposing cause. The onset was always acute and was sometimes accompanied by a chill. High fever was present in the course of six out of the seven cases and a relapse occurred in one. The constant subjective symptom was sore throat, which was aggravated by attempts at swallowing, which is explained by the movements of the gland in the act of swallowing. In addition there were radiating pains involving the ears and the occiput. Respiration was interfered with in several cases. The swelling was very often localized in the isthmus portion of the gland. A leucocytosis was observed in one case. The thyroiditis usually accompanied some other disease, oftenest influenza, and ran a mild course in all patients.

Diuretics.—Romberg says that at present diuresis is called for in edema, in localized hydropic conditions, and in inflammatory exudates; in nephritis without exudation it is not to be used. Diuresis may be produced by improving the general circulation or by directly influencing the action of the kidneys. The first measure is effective probably because of the more rapid stream of blood produced, and not by the raising of blood pressure. Cardiac stimulants are to be used to attain this effect. To stimulate the activity of the kidneys themselves the derivatives of the purin group of substances are the best preparations. Their action depends upon an increased supply of blood to the kidneys, and is not observed if this is made impossible by pathological changes in the glomeruli. Dimethylxanthin or theocin is the most effective drug, and is to be given in gradually increased doses. Theobromin sodium salicylate or diuretin is less effective, but is useful in other cases; theobromin itself and caffeine may likewise be used. Other diuretics are very weak in comparison with the purins. Calomel and sodium salicylate have some diuretic action, but are apt to damage the kidneys when given in efficient dosage. Salts and water are older diuretics that are seldom of use, as their action is best seen in the presence of healthy kidneys and not in disease. The number of diuretics is thus seen to be very limited. A special lack is felt of a diuretic that could be administered subcutaneously or intravenously.

Unilateral Rise in Temperature.—Vogel says that Peter was the first to note that in pulmonary inflammations the temperature in the axilla of the same side as the affected lung is higher than that of the opposite side. Such difference is easily explained by the rise in temperature produced by the local inflammatory phenomena, and the thickness of the parietes in the axilla does not seem to interfere much with the transmission of heat to the surface. Vogel's examinations have shown that such differences in temperatures are quite frequent, and may be observed not only in acute affections of the lungs, but even in long-standing diseases involving one side of the thoracic contents. The phenomenon is of some diagnostic value in helping to point out the lung affected; the rise of temperature upon the other side is a valuable indication that that side is beginning to be attacked by the inflammatory process. In tuberculous patients the difference in temperatures gives a clue to the side in which the process is more active.

Deutsche medizinische Wochenschrift, October 1, 1908.

Operation in Exophthalmic Goiter.—Riedel says that medicine, as theology, has its own dogmas, and one of these insists upon the great danger of operations upon goiter in cases of Graves' disease. This is correct only in late conditions, with existence of severe bronchitis and stenosis of the trachea, or when edema of the extremities is present together with obstinate diarrhea. While medical treatment may be tried in cases accompanied by a small goiter, it should not be carried on too long if the goiter is growing larger and little improvement of the symptoms is noted. Otherwise the best time for operating may be allowed to pass by. Riedel has operated upon 80 patients with exophthalmic goiter, among 876 persons suffering from all kinds of struma. Of the last 30 cases but one died of bronchopneumonia, while of the preceding 50, seven died from the effects of chloroform or from bronchopneumonia. It is Riedel's principle, however, to operate whenever a good chance of cure or improvement is present, however bad may have been the statistical results of earlier operations; the life of an exophthalmic patient is so miserable, and death from the disease so sure that operation is fully justified. A different standpoint is advisable in cases of malignant tumors of the thyroid gland; operation should be performed only if there is a good chance of removing the tumor completely, otherwise the patient undergoes the unpleasantness of the operation and still retains the fatal disease that he had previous to surgical interference. The existence of Graves' disease has little effect upon the prognosis of operations upon goiter; the condition of the lungs at the time is the most important feature in any kind of enlargement of the thyroid. Riedel's figures show that many physicians nowadays advise operating in exophthalmic goiter, which serves to show that medical treatment offers little chance of success. No surgeon should refuse to operate in this disease, if his technique is well developed, and the condition of the patient is such as to give reasonable promise of freedom from complications on the part of the lungs.

Cesarean Section.—Pfannenstiel says that the indications for cesarean section should be much widened in view of the good results obtained with the operation with modern surgical technique. It ought to take the place of operations involving the bony pelvis whenever the condition of the patient is such as to call for as short a post-operative stay in bed as possible. In most cases, the patient, after a cesarean section, may be allowed to sit up in bed three or four days after the operation, especially if the Pfannenstiel abdominal incision has been made use of. Cesarean section could also be performed with advantage in dangerous conditions calling for an immediate emptying of the uterus; eclampsia and acute nephritis may be counted among such cases if any difficulty may be expected with the more usual methods of quick delivery of the patient. In cases of living child in a transverse position with threatening rupture of the uterus both the child and the mother may be saved by a properly performed cesarean section.

Conservation of the Ovaries in Hysterectomy.—Doleris thinks it of doubtful value to leave a portion of an ovary in the pelvis after hysterectomy. Its value must depend on the theory of an internal secretion by the ovary. The author has made use of ovarian extracts in the natural and the artificial menopause without getting any effect other than that of suggestion. In the patients in whom he has operated by hysterectomy either they were near the natural menopause and there was absolutely no unfavorable effect, or they were young patients and alike experienced no trouble. In the cases in which pain continued after removal of the uterus and adnexa he found a nervous heredity, and considers them to have belonged to the class of women who are not benefited by any treatment.—*Annales de Gynécologie et d'Obstetrique.*

Book Reviews.

The Extra Pharmacopeia of Martindale and Westcott. Revised by W. Harrison Martindale, Ph.D., F.C.S., and W. Wynn Westcott, M.B. (Lond.), D.P.H., H.M.'s Coroner for Northeast London. Thirteenth Edition. London: H. K. Lewis, 1908.

Those who are familiar with this incomparable therapeutic manual will welcome the appearance of another edition, and to those who are not familiar with it, it may unhesitatingly be recommended as in many respects the best work of its kind in existence. It treats of every form of remedial measures, medicinal and nonmedicinal, of radiotherapy, hydrotherapy, electricity, pharmacopeal and proprietary medicines. This thirteenth edition has been extensively revised and in part rewritten. The work has increased in contents out of all proportion to its size, and in the present edition the endeavor to keep the book of the same dimensions has necessitated the use of type so small and paper so thin as seriously to impair its usefulness. It would be much better to make the book of larger form with larger type and opaque paper, for the work is important enough to warrant its publication in this shape.

The Principles of Pathology. By J. George Adami, M.A., M.D., LL.D., F.R.S., Professor of Pathology in McGill University, Montreal. Volume I, General Pathology. With 322 Engravings and 16 Plates. Philadelphia and New York: Lea & Febiger, 1908.

It is impossible in the limits of a brief review to give the reader an adequate notion of this work and all it contains. In his preface the author says that his idea of a textbook of pathology is that it should not be a mere record and description of the phenomena of disease, but rather an analysis of these phenomena in an orderly manner, and it is upon this plan that the book is written. Throughout, the writer is not content to state facts, but he gives the reason for everything and demonstrates the dependence of one fact on another, thus stimulating the reader to think for himself and to reason out, with the book for a guide, the causes of morbid actions and their results. Recognizing the cell and its changes as the basis of all pathology, Dr. Adami begins with a study of this, deferring a consideration of circulatory disturbances, which so often serves as an introduction to general pathology, to the volume of special pathology. While not ignoring the work of European pathologists, the author dwells with special emphasis upon what has been done by English-speaking workers, and thereby furnishes an excellent corrective to the fault of depreciation of what we may call "home talent," to the myopia which obscures the view of what is being done close at hand and allows a clear sight only of what is "made in Germany" or France or Italy. There is much pathological work of the first order done in the laboratories here and in England, and the student who neglects to inform himself of this is depriving himself of indispensable knowledge. In proof of this is the book before us, than which there is no better work in any language. It is written so well and in so clear a style, and every point is so lucidly reasoned out and so impressively stated, that the reader's attention is held from the first page to the last, and when he puts the book aside he feels that he has had a most enjoyable mental exercise, has made his own the fundamental facts of disease action, and has acquired a grasp of pathology in such a way as to make it appear almost like a new science. He sees more clearly than ever before that pathology is not an independent study, but rather the foundation of all medical knowledge, without which all the other branches of our science, and especially, perhaps, therapeutics, can but rock in the morass of empiricism without stability or sound basis.

Glandular Enlargement and Other Diseases of the Lymphatic System. By Arthur Edmunds, M.B., M.S., B.Sc. (Lond.), F.R.C.S. (Eng.), London: Henry Frowde, 1908.

This small volume makes no pretensions as an exhaustive treatise on the lymphatic system, inasmuch as there are few diseases in which this system does not take some active part, and hence a full description of such would exceed the limits of a handbook. However, Mr. Edmunds holds some interesting views and records some facts not commonly known. For instance, ligation of the thoracic duct has been performed nine times with no fatalities—a statement which seems almost incredible, but is explainable because of the abundant collateral lymphatic circulation. Mr. Edmunds states that deaths from wounds of the thoracic duct are due to sepsis, not to inanition. He believes also that infection of mediastinal glands with abscess formation and rupture is responsible for the general systemic diffusion of tuberculosis.

The Opsonic Method of Treatment. By R. W. Allen, M.B., B.S. (Lond.), Philadelphia: P. Blakiston's Son & Co., 1908.

The prominent place which opsonic therapy has assumed and the mass of scattered literature concerning it are the basis of this endeavor to collect such facts as shall give a general idea of the subject. There are chapters on the nature and source of opsonins, determination of the opsonic index, its value in diagnosis and prognosis, scope for the employment of tuberculin, and the treatment of urethritis. An especially interesting section shows what can be done by this method in diseases of the eye, ear, nose, and throat. The little volume will serve as a fitting introduction to the theoretical principles of opsonic treatment.

Chirurgie für Zahnärzte, von Prof. Dr. Med. Ludwig Brandt. Berlin: August Hirschwald, 1908.

At first glance it is rather surprising that a book of this size could be written on the subject of dental surgery, but upon further examination it becomes evident that surgery of the teeth occupies in reality only a very small portion of the text. German dentists are required to be surgeons in the best sense of the word, hence we find in this volume a complete treatise on wounds and their treatment, hemorrhage, healing of wounds, hemostasis, ligature of vessels, transfusion, salt infusion, and the principles of asepsis and antisepsis. Then follow a description of general and local anesthesia, infection, inflammation of soft parts, erysipelas, sepsis, putrid infection, etc.

Specific acute inflammations, such as diphtheria, tetanus, anthrax, and glanders, and specific chronic inflammations such as tuberculosis, actinomycosis, rhinoscleroma, lepra, and syphilis, are examined in detail. Various plastic procedures are also described, *e.g.* cheiloplasty, rhinoplasty, and staphylorrhaphy. There are excellent chapters on the connection of dental disease with eye and ear disease including empyema of the antrum of Highmore. Tumors of the mouth and face are described in detail, and cysts, such as ranula and dermoid, receive due mention. There is much in this book that the eye, ear, nose and throat specialist may read with profit.

Preventable Blindness. An Account of the Disease Known as the Ophthalmia of the New-born, and of its Effects; With a Plea for its Suppression. By N. Bishop Harman, M.A., M.B., Cantab., F.R.C.S. Eng., Ophthalmic Surgeon to the Belgrave Hospital for Children; Chief Clinical Assistant, the Royal London Ophthalmic Hospital, Moorfields; Senior Ophthalmic Assistant, the Middlesex Hospital; Oculist (with Care of Blind Children), London County Council Schools; Demonstrator of Pathology, Middlesex Hospital Medical School; Late Examiner, Natural Science Tripos, Cambridge University. New York: William Wood & Co., 1908.

This is a small volume of 109 pages devoted almost entirely to the consideration of ophthalmia neonatorum and the questions that concern it. An historical sketch of ophthalmia neonatorum is followed by a chapter on the causes of blindness in which statistics figure largely. Short chapters on the "Incidence of Ophthalmia Neonatorum," clinical characters, risk of permanent injury to the eye, contagiousness, bacteriology, treatment and prophylaxis follow. Methods for preventing the disastrous results of neglected ophthalmia neonatorum, such as notification requirements by legislative act, particularly affecting midwives, and the distribution of leaflets for the education of the public to the importance of all diseases of the eye affecting the new-born are discussed. The subject is well presented. The volume should have a wide distribution, particularly among general practitioners.

Cataract Extraction. Being a Series of Papers with Discussion and Comments Read Before the Ophthalmological Section of the New York Academy of Medicine, 1907-1908. Edited by J. Herbert Claiborne, M.D., Formerly Adjunct-Professor of Ophthalmology, New York Polyclinic; Instructor in Ophthalmology, Cornell University Medical College; Surgeon, New Amsterdam Eye and Ear Hospital. New York: William Wood & Co., 1908.

The volume edited by Dr. Claiborne is a very attractive one of 169 pages, well printed, and with a number of illustrations in the text. There are thirteen chapters, presenting as many articles by twelve authors. The various phases in the extraction of cataract are described from the point of view of the author and the principal methods of extraction are discussed. Some of the subjects considered are, the most suitable stage in the development of cataract for its removal, preparation of the patient, technique of the "simple" and the "combined" operations for the extraction of cataract, extraction by means of a lance-shaped keratome, after-treatment, extraction of cataract in its capsule, operations for artificial maturation of cataract, extraction of the crystalline lens in high myopia, results of cataract extraction.

Society Reports.

THE AMERICAN THERAPEUTIC SOCIETY.

Ninth Annual Meeting,

Held in Philadelphia, Pa., May 7, 8, and 9, 1908.

THE PRESIDENT, DR. JOHN V. SHOEMAKER, OF PHILADELPHIA, IN THE CHAIR.

Thursday, May 7—First Day.

AFTER prayer by the Rev. THOMAS C. EASTON, D.D., Brooklyn, N. Y., an address of welcome was made by the Hon. JOHN E. REYBURN, Mayor of Philadelphia, and the response by the Hon. HENRY F. WALTON, President of the Medico-Chirurgical College and Hospital, Philadelphia.

Dr. NOBLE P. BARNES, Washington, sent an obituary notice of Dr. McLain, a charter member of the Society, and concluded with memorial resolutions which were adopted by the Society.

Address by the President: Therapeutics in the Light of Ecology.—Dr. SHOEMAKER in his address considered the relation of therapeutics to the comparatively recent science of ecology, which included the study of all external conditions, whether meteorological, economic, social, or individual, relating to man. Success in therapeutics materially depended upon the recognition of the effects of the external conditions upon the individual, especially taking into account the personal equation. The various phases of the subject were considered, and in conclusion he referred to the recent development of therapeutics in connection with State medicine, especially the action of the authorities, through health boards and sanitary officials, in deliberately getting to work to change the environment of the individual with a view both of placing the sick under improved conditions and of limiting the spread of contagious disease.

The Therapeutics of Cardiovascular Disease.—Dr. F. P. HENRY of Philadelphia spoke of the hygienic and dietetic management of arteriosclerosis and referred briefly to balneotherapy and the benefit to be derived from massage and electricity. In the medicinal treatment of the condition as a whole, the persevering use of the preparations of iodine had shown itself of distinct service. In the symptomatic treatment the nitrites were most highly esteemed. In addition to these, the theobromine preparations, strongly recommended by Von Noorden in stenocardiac attacks, were worthy of a trial. The indications for the employment of digitalis and its succedanea were the same as those of failing compensation in general.

Cactus Grandiflorus as a Therapeutic Agent in Cardiac Diseases.—Dr. ROLAND C. CURTIN of Philadelphia spoke of cactus as in a class by itself, not like any other heart remedy. It was a mild tonic stimulant, acting especially on the inhibitory nerves and useful in relieving the heart of some of the unpleasant symptoms, met with particularly in the nervously disturbed heart; steadying and supporting it, even, at times, in serious nervous disease of the organ. In any case it might relieve the discomfort and pain in the region of the heart. It was a valuable adjunct to other heart remedies; but it was to be borne in mind that it was not a strong cardiac tonic or stimulant, and therefore not to be depended upon singly in a seriously diseased heart.

The Pharmacology of Heart Stimulants.—Dr. H. C. WOOD, JR., of Philadelphia confined his remarks to drugs of the digitalis group, and in speaking of digitalis said that its effect in slowing the pulse he believed to be a much more important factor in its beneficial influence than was generally supposed. In cases of chronic heart disease, when it was essential to make the burden thrown upon the feeble organ as light as possible, the slowing of the pulse was highly important, and here the inhibitory stimulation of digitalis was of the greatest service. The influence of digitalis was exerted especially on the left ventricle. This fact became of importance in certain cases of mitral regurgitation where the ventricular muscle had undergone a larger degree of hypertrophy than the auricle. The vasoconstricting action of digitalis had frequently been regarded as harmful and consequently to be avoided or combated; he believed this had, at times, led practitioners to adopt irrational or even injurious measures. While it was true that it required more force to drive the blood through narrow arteries than it did dilated ones, it was equally true that in many cases the vascular contraction was a conservative effort on the part of nature to maintain the circulatory equilibrium. He did not mean to take the ground that the vascular effect was never detrimental. When as a result of either degenerative changes in the muscle or of an extreme degree of dilation, the muscular tissue of the ventricle was too scanty to properly respond to the tonic influence of digitalis, it could scarcely be doubted that the increased resistance to the flow of blood might work great damage. He believed, however, that these cases were much less frequent than was generally supposed. Clinicians should not be too hasty in their efforts to dilate the vessels, and especially since almost the only agents we possessed for this purpose, the nitrites, were substances which increased the rate of the pulse and must tend therefore to counteract the beneficial influence of digitalis in slowing the heart. The only reason that more harm was not accomplished by the use of nitroglycerin in heart disease was because the long intervals between the doses of this evanescently acting drug, as it was habitually administered, precluded the possibility of its having a serious influence upon the circulation. Squill and apocynum, on account of their irritant action upon the gastrointestinal tract and the kidneys, were of practical utility only in selected cases. While there was a widespread belief that strophanthus differed essentially from digitalis in that it exercised little or no influence upon the blood-vessels, there appeared to be no convincing evidence of the truth of this. On the contrary, it had been clearly demonstrated by Gottlieb and others that the vasoconstricting action of this drug was a very marked one, and that even if this influence was a less powerful one than that of digitalis, the difference was very slight. It was, however, well established that strophanthus was less likely to give rise to cumulative toxic symptoms than digitalis. Adonidin was a remedy of promise, but although it had been before the profession for nearly thirty years, it still remained in the stage of only promise, since our knowledge of its effects was as yet far from satisfactory. In cases of chronic heart weakness, where merely the cardiac action of this group was desired, digitalis still maintained its supreme position. In conclusion, he spoke briefly of the digitalis glucosides, and expressed the opinion that none of these at all adequately represented the therapeutic virtues of the drug itself.

Some Instruments of Precision and Their Use in Cardiac Therapeutics.—Dr. THOMAS E. SATTERTHWAITE of New York said his purpose was to give the reasons why the sphygmograph had fallen into comparative disuse and, on the other hand, show the growing, though still restricted, field of the sphygmomanometer. In addition to the difficulty of securing a good tracing with the sphygmograph, clinicians were agreed neither upon the standard normal curve nor upon the standard for the several valvular diseases. Hence it was readily apparent that no absolute value could be attached to any tracings employed for the differential diagnosis of valvular diseases. The same statement could be made with even more emphasis in regard to cardiograms. This instrument could, however, demonstrate the rhythm and pulse-rate; so that in the very rare instances in which the pulse could not otherwise be counted it was of service. While we had been preparing to discard the sphygmograph the sphygmomanometer was being gradually developed for the purpose of determining vascular pressure in health and disease. He had

found Dr. H. W. Cook's modification of the Riva Rocci instrument fairly well adapted for clinical work and the von Recklinghausen for laboratory work. He narrated a series of laboratory experiments conducted in his presence by Dr. Haven Emerson, which illustrated some of the uses to which the latter might be applied, and stated that in line with these were some experiments recently reported by Dr. Cook with his modified Riva Rocci. In three experiments recently reported by Dr. R. C. Kemp at the Manhattan State Hospital, the effect of acute dilatation of the stomach in reducing blood-pressure was well shown, illustrating the danger to a weak heart from a dilated stomach. In Dr. Satterthwaite's experience, in from 6 to 8 per cent. of sudden deaths in cardiac disease the immediate cause was some acute gastric disorder. Among the conclusions which appeared to him to be justified in regard to the sphygmomanometer were the following: No one of the instruments in use was absolutely accurate. At present their utility appeared to lie chiefly in determining the comparative value of remedies and the effects of posture, different physical exercises, and baths upon the blood-pressure. Here, relative accuracy would usually suffice. In these directions, and especially in the study of the pharmacodynamics of cardiac remedies, the sphygmograph appeared to offer a large field of usefulness. The ideal instrument was still to be made; this must eliminate the personal equation, which was still the chief source of inaccuracy.

Venesection and Cardiovascular Affections.—In this paper Dr. Judson Daland of Philadelphia expressed the opinion that this "lost art" still had a legitimate and, indeed, most important field. In cardiovascular affections it might be employed with advantage both as a palliative and as a life-saving measure. Usually it was required in conditions where the patient's life was threatened, but it was apt to be postponed until too late to be of service. If promptly done, it might at times avert otherwise certain death. It was essentially indicated in valvular diseases of the heart with well-marked failure of compensation, where the patient presented extreme dyspnea, cyanosis, tumultuous cardiac action, a rapid, small, feeble pulse, distention of the veins of the head and neck, feeble apex-beat displaced to the left and extending over a wide area, increase in the area of cardiac dulness, and perhaps accentuation of the pulmonic second sound. If degeneration of the myocardium were not extreme, the relief afforded by venesection was immediate and satisfactory. In pronounced myocardial degeneration, however, it was useless. In failure of compensation in arterial sclerosis it was frequently of great value. In acute pulmonary edema, it might be palliative, and in some instances was followed by recovery, and in aneurysm of the arch of the aorta dyspnea or pain might often be temporarily relieved by it. When in acute croupous pneumonia the symptoms and signs of right heart dilatation were present, the abstraction of 20 to 24 ounces of blood was not only a palliative measure, but was occasionally life-saving.

A Few Conditions Requiring Caution in the Use of Digitalis.—Dr. Alexander D. Blackader of Montreal urged the importance in cardiac disease of maintaining the muscular nutrition of the organ. While digitalis, he said, was a drug with very definite therapeutic indications, and one which, judiciously employed, might prove a veritable gift of the gods, much harm might result from its incorrect use. In aortic regurgitation, it was indicated only when symptoms of dilatation had occurred. In the stenoses, until the signs of failure in the right ventricle had supervened, harm, and not good, might result from it. While the medical attendant might make judicious use of the increased power resulting from digitalis, he would be wise at the same time to abolish all undue overstrain by ordering rest in bed, or at all events moderation of exertion. It should be borne in mind that when once compensation had been lost, time was required for its restoration. Prolonged rest in bed, with the judicious employment of digitalis, might secure this in many instances, but in others it would often be found advisable to supplement the very moderate stimulation by digitalis with gradually increased resistance exercises, while the patient spent most of his time in bed. In acute endocarditis especially, but also in acute myocarditis, the use of digitalis was always to be deprecated.

Dr. James C. Wilson of Philadelphia said that from the time of Laennec there was a long period when the revelation by the stethoscope of the presence of a cardiac murmur was equivalent to writing the death warrant of the patient. From the time of Fothergill we came into a more hopeful view, the period of digitalis and its group of analogous remedies, followed by the abuse of digitalis. In the third period, that of broad conceptions of diseases of the heart, we were making great advances, and this statement, he thought, was well borne out by the paper of Dr. Blackader, in which he pointed out that the way to take care of our patients was not simply by the use of stimulants, but by the careful clinical management of the case. The careful study of the individual case was the main point, and this involved the painstaking search for the remedies or method of treatment appropriate to it. We had, therefore, come to a time when brilliant results attended the management of cardiac diseases, and he knew of no field of clinical medicine, no large aggregate of varied cases, in which more satisfactory results were achieved than in chronic valvular diseases. In conclusion he referred to three classes of cases illustrating such results: (1) Those in which compensation had developed hand-in-hand with the lesion and was still maintained; (2) those in which compensation failed; (3) those in which compensation had so ruptured that it was only a question of palliation for the rest of the patient's life.

The discussion was continued by Drs. O. T. Osborne, C. De M. Sajous, F. H. Gerrish and Robert Reyburn. Most of the speakers were in accord with Dr. Daland as to the value of venesection. Dr. Osborne said that it was very important to give the right dose of nitroglycerin, sometimes very large and sometimes very small doses being required; and he could not agree that, because the laboratory said that the effect of the drug lasted but an hour or so, we should necessarily give it every two hours.

The U. S. Pharmacopœia from a Physician's Standpoint.—Dr. James M. Anders of Philadelphia said that the increasing use of proprietary remedies had given rise in recent times to unfavorable comment, both in the lay and medical press, and now the profession had clearly entered upon a reconstructive movement which must be continued until American therapeutics had been placed upon a more scientific basis. The work of bringing about an improved knowledge of the tried remedies of the Pharmacopœia fell naturally within the scope of the activity of the American Therapeutic Society. The aim should be, especially by those in high places, to return to the more simple and more reliable therapeutic agents of bygone days.

At the evening session there was a joint meeting of the American Therapeutic Society and the Philadelphia Branch of the American Pharmaceutical Association.

The Autoprotective Resources of the Body; a New Foundation for Scientific Therapeutics.—Dr. Charles De M. Sajous of Philadelphia delivered this address.

The U. S. Pharmacopœia, a Therapeutic Standard.—Prof. Joseph P. Remington, Phar.D., of Philadelphia, gave a sketch of the history of the national Pharmacopœia, and said that, until the issue of 1900, it had never been a compulsory standard. The passage of the Food and Drugs Act, June 30, 1906, however, made it the legal standard for the United States. One of the most beneficial results of the act was the establishment of definite scientific names for drugs and medicines, the law requiring a compliance with the standards of strength and purity of the Pharma-

copœia. The essence of the Food and Drugs Act was that "the label must tell the truth." Another feature of the act was that it punished false or exaggerated statements in regard to medicines by providing a penalty for misbranding. The great need in therapeutics and in Pharmacopœial revision to-day was more exact knowledge for fixing the therapeutic efficiency of drugs, the action of which did not depend upon the presence of alkaloids or their principles.

Friday, May 8—Second Day.

Treatment of Tuberculosis.—Dr. Lawrence J. Flick of Philadelphia said that restoration of the individual to a normal physiological functional capacity and stimulation of his intrinsic disease-resisting qualities constituted in a broad sense the modern treatment of tuberculosis. Everyone had some power of resistance to bacillus implantation, and some tendency to recover after implantation had taken place; both of these matters varying in different individuals, different families, and different races. As a rule, the tubercle bacillus was not very virulent, and there was reason to believe that without mixed infection tuberculosis would never destroy life in the human subject. It was this mixed infection which manifested itself by symptoms which attracted the attention of the patient or those associated with him, and which had given us the clinical picture of consumption. Tuberculosis was essentially a local disease, and consequently an ever-recurring one, which in this way invaded all the tissues of the body; hence the prevention of implantation, or autoinfection, as it was sometimes called, was absolutely necessary for the successful treatment of the disease. It was therefore requisite to teach the patient methods of disposing of his broken-down tissue in such a way that tubercle bacilli could not get back into the system, either through food or air. The diet should be regulated with the one idea in mind of getting the best amount of nutrition with the smallest amount of consumption of energy in producing it. The consensus of opinion seemed to be that milk and eggs should always be important factors in the diet. The subject of forced feeding, however, was much misunderstood, and harm had been done by overfeeding. When milk and eggs were used largely, solid food should be proportionately cut down, and a good plan was to give each day one meal of solid food and besides this three quarts of milk and six raw eggs. At the solid meal meat, fresh vegetables, and fresh fruit should be used. If the patient was suffering from mixed infection, he should be put at absolute rest until this infection had been overcome. When activity of the process had ceased, occupation might be taken up, but it should be followed in moderation. A person who had tuberculosis should recognize his limitations and always keep himself within the limits of fatigue. For recovery, a patient should live in a house which was well ventilated, well drained, dry, and free from dust. He should be taught to sleep in the open air, if possible, and if not in the open air, at least in a room with all the windows open. The drug which was of most value in the treatment was iodine. This was administered to greatest advantage by the skin, and Dr. Flick's own practice was to have the body well rubbed twice a day with a saturated solution of europhen in olive oil, with a little oil of gaultheria and oil of anise. Nitroglycerin was of service when the heart was overacting, and was indicated when there was an accentuated second sound, as was found after recent pulmonary hemorrhage. It was also useful in preventing hemorrhage. Magnesium sulphate was valuable when the kidneys were beginning to show signs of overwork and in cases of intestinal tuberculosis. Digitalis might be given when the heart was weak. Creosote was perhaps of most service in advanced cases. It was best given in hot water, and in this way as much as 60 minims could be taken three times a day. Pepsin and pancreatin were of value in most cases as adjuncts in forced feeding. Tuberculin could be safely used in small doses in cases in which there was no mixed infection. Large doses should never be given except by experienced men. In conclusion, the necessity of looking carefully after the teeth, pharynx, and tonsils was referred to.

Choice of Occupation for Tuberculous Convalescents.—Dr. Albert E. Roussel of Philadelphia said that the knowledge that tuberculosis is infectious had been acquired by the lay public, to its own great advantage, but also the great disadvantage of the tuburculous subject who must needs earn his own living or become a charge on the community. The odium of the disease was sufficient to have a person turned away from light, profitable employment when his condition was known. Work, however, was a therapeutic agent and, used within its physiological limits, it could not be otherwise than beneficial. The speaker concluded that since tuburculous individuals were an expense to themselves, and eventually to the community, we were compelled to find some way by which they could be self-supporting. The regions so highly vaunted as health climates were in no industrial way prepared to support a consumptive, and the conclusion was forced upon us that the treatment should be conducted as near home as possible. The discharged consumptive was not able to cope with the competition incident to obtaining light, profitable employment in any of the industries, apart from his physical condition or the odium that would render him *persona non grata*. His opportunities, therefore, lay along the lines of his own ingenuity affording employment for himself. It might seem *a priori* an easy matter to obtain employment at home in work like sewing baseballs, making picture frames, clothing work, etc., but there were a hundred applicants for every such opportunity, the pay was small, and, in order to make any kind of showing, the work assumed a very harmful aspect. Farming was a kind of work available for everyone. The work of the vacant lots associations and sanatorium farm colonies proved conclusively that in this direction only could the consumptive find economic relief. No one had suggested it, but experience had taught the speaker that the rôle of street car conductor or that of itinerant merchant, peddler, book agent, insurance agent, etc., if too much walking were not involved, could be assumed by such patients with safety and profit. The keynote of the whole subject was outdoor employment.

The other papers read in the symposium were the following: "The Treatment of Tuberculosis in Private Practice," by Dr. M. Howard Fussell, Philadelphia; "Tuberculosis of the Ear," by Dr. W. Sohier Bryant, New York; "Some Dietetic and Therapeutic Points in the Home Treatment of Tuberculosis," by Dr. Howard S. Anders, Philadelphia; "Tuberculosis Among the Insane," by Dr. Frank Woodbury, Philadelphia; "Treatment of Tuberculosis in Children," by Dr. William C. Hollopeter, Philadelphia.

Dr. James Anders of Philadelphia said he had recently reached the conclusion of Dr. Flick that the knowledge of an expert is necessary to insure successful treatment of this disease. Some of the most remarkable cures, or arrests of the disease, which he had witnessed had been the result of home treatment in expert hands, and it was only when all other things were equal that the results of the climatic or combined climatic and sanatorium treatment surpassed those of the home treatment.

Some Commonly Overlooked Causes for Stomach and Bowel Disturbances.—Dr. Robert T. Morris of New York said that the appendix vermiformis was a degenerating organ which disappeared in two ways: first, by acute infection (explosive appendicitis), and second, by fibroid degeneration. While the cases of explosive appendicitis were recognized by all, those of fibroid degeneration of the organ were commonly overlooked. In the acute infection the stomach and bowel disturbances set up at once attracted attention, but the adhesions remained and the subsequent results of the inflammation often escaped no-

tice. Fibroid degeneration of the appendix was the common single cause of chronic intestinal dyspepsia. The speaker went on to describe this condition and its diagnosis in the same manner as in his presidential address before the Medical Association of the Greater City of New York in February. (See MEDICAL RECORD, March 28, 1908, page 541.) A less frequent unsuspected cause of chronic indigestion was eyestrain, and he had sometimes had sent to him cases to be operated on for gallstones, appendicitis, and other conditions which were readily corrected by the adjustment of proper glasses. Another cause was bile-duct adhesions, a subject upon which he had made a previous communication to the Society. Still another was loose kidney. Here it required much discrimination to decide which cases were suitable for operation and which were not.

Dr. EGBERT H. GRANDIN of New York said he was in thorough accord with Dr. Morris in his statements regarding the appendix. As to the influence of the displaced kidney, he was very skeptical. He had seen hundreds of kidneys which moved a few centimeters, but he had never yet been satisfied that he was justified in operating on them. If he could play ball with the kidney he believed in operation.

Thymic Opotherapy.—Dr. REYNOLD WEBB WILCOX of New York said his purpose in this paper was to present a record of the results of thymic opotherapy in a field in which the literature was exceedingly meagre. The thymus gland, particularly in infancy, had a remarkably full blood supply, and it contained a large amount of nuclein. Consequently, it was rich in phosphorus, which existed in the form of nucleinic acid. The purpose of the thymus might be fairly described as directed toward the attainment of adult growth by the individual, and the significance of this statement was illustrated in a remarkable case, of which he proceeded to give a full report. On February 15, 1905, the patient, a boy of 14, was referred to him by Dr. I. L. Hamant of Norfolk, Conn., under whose care he had been since December 28, 1904. The history was that he had not increased in weight or stature for three years, during which time he had been treated by several competent physicians. He had had no illness beyond an occasional sick headache, but he did not have quite the amount of endurance usual in a boy of his age and apparent health. He had a good memory and a bright, active mind, but physically he was undersized and deficient in strength and, although moderately well nourished, was slightly anemic. His weight was 81 pounds and his height 4 feet 10 inches. The circumstances seemed to afford ground for the hypothesis that the thymus gland had become prematurely atrophied, and Dr. Wilcox suggested that the administration of thymus extract might possibly be therapeutically useful. This was given in doses of 2 grains night and morning, and the results obtained were very satisfactory, for by February, 1908, his height had increased to 5 feet 7¼ inches and his weight to 124 pounds. Thus during the three years in which this treatment had been employed (following a period of three years in which there had been no growth) there had been a gain of 9¼ inches in height and 43 pounds in weight; and it was also noteworthy that during a suspension of the treatment for seven weeks in 1906 and for five weeks in 1907 there was absolutely no gain in height.

Therapeutic Measures of Value in Convalescence from Abdominal and Pelvic Operations.—Dr. EGBERT H. GRANDIN of New York read this paper. The vomiting following operations, he said, was one of the means nature employed for getting the excess of ether out of the system. He allowed his patient as much water as desired, and if it was not retained the stomach was thereby washed out, so that frequently it was unnecessary to resort to lavage. He forbade the use of ice and the various drugs recommended as antiemetics, as they had all failed him. If nausea and vomiting continued for twenty-four hours, lavage was indicated. As soon as these symptoms were in abeyance he allowed broths or kumyss, but never milk, on account of the danger of tympanites from intestinal fermentation. The best remedy against shock was a full dose of morphine, given hypodermically, and this drug was very useful in differentiating nervous shock from that due to hemorrhage; for if the symptoms did not yield to the morphine, internal hemorrhage could usually be inferred. This was the only condition in which he employed opium or any of its derivatives, with the exception of codeine, which, in 2 grain suppositories, he had found very efficient in relieving pain. Thirst was alleviated by the instillation into the bowel of sterile salt solution at a temperature of 110°. Suppression or insufficiency of urine was best met by the continuous irrigation of the bowel with hot salt solution. When the pulse and temperature indicated the presence of inflammation, the application of the ice bag or coil was used in association with frequent alcohol sponging. If the skin were very dry and the kidneys not working properly, the old formula, aconite, ammonium acetate, and spirit of nitrous ether, was of great value. When the presence of infection was shown by a pulse rapid in proportion to the temperature, he gave alcohol freely and endeavored to support the system in other ways, as by enteroclysis or hypodermoclysis. The caffeine salts, given hypodermically, were useful stimulants, and if the heart flagged, digitalis (preferably in infusion) or sparteine was employed. When the tension pulse was noted, nitroglycerin, in the form of the official solution, was given hypodermically in full doses, and with the full, bounding pulse he resorted to venesection. Only occasionally did he employ strychnine, and it seemed to him that in the main it had been abused. For such drugs as were indicated he selected the subcutaneous or the rectal route, as the stomach was required for nourishment. Having referred to the general care of the bowels, he said that in a case of obstinate or torpid intestinal tract, ileus having been differentiated, a pint of ordinary coal oil, thrown high up, frequently acted like magic. In beginning tympanites, which he considered due to spasm, hyoscine hydrobromide was his sheet anchor. Hyoscine was of service also in allaying cerebral excitement. When congestion was present, and iced cloths did not suffice, he gave sodium bromide. Hydrated chloral was the most reliable hypnotic. After operations it was of advantage to have the patient change his position frequently, provided this was not contraindicated by the pulse. It was now more than ten years since he had tolerated the so-called abdominal supporter, as the bandage weakened the muscles, which needed action in order to become strong.

Gout a Disease of Metabolism; Its Treatment.—Dr. OLIVER T. OSBORNE, of New Haven, reviewed the physiology of the organs of digestion, our knowledge of the digestive end-products, and some of the causes and results of imperfect metabolism. He thought that without stopping to consider the various theories which had been advanced as to its etiology, gout might be defined as a non-infectious, aseptic disease, due to a disturbance of the transformation of the protein food molecule, more especially the purin molecule, into the excretion end-product. There was nothing in this assumption to diminish the importance of the predisposing causes of the affliction. As to diagnosis, it did not seem to be necessary to have gouty joints, chalky nodes, gouty kidneys, concretions, or even shooting pains, in order to make the diagnosis of a probable gouty condition, or that disturbances were present which might lead to future gout or were gouty now. An increased arterial tension, a little extra amount of urine, slightly increased frequency of micturition, reported gastro-intestinal upsets, skin irritations, nerve pains, many headaches, especially occipital, irritability, nervous attacks, and many slight indispositions, which were often too trivial to mention, but were the difference between well and ill, could be set down as gouty, no organic disease having been

found. As there was no one cause of gout, so there was no one way to treat it. To manage it properly we must (1) carefully study the function of each organ; (2) know the kinds and amounts of food ingested, and how well it is excreted, especially how the nitrogen in the urine is excreted; (3) arrange the food and liquids ingested to meet the defects discovered in the functioning of the organs and in the deficiencies in the excretions; (4) treat or modify all complications present. In exacerbations of gout, with more or less pain, we had yet to find a treatment more efficient than a calomel purge, saline laxatives, salicylic acid and some form of colchicum.

Uses of Chromium Sulphate in Medicine.—Dr. Louis Kolipinski of Washington, D. C., had presented a previous communication on this subject at the meeting of the Society in June, 1902. Further experience with the drug, he said, had confirmed him in his opinion as to its usefulness. The most striking results which he claimed for it were in the treatment of tabes. Among other conditions in which he said he had found it of great service were preputial herpes, enlarged prostate, and uterine fibroids.

The Value of Morphine Derivatives in Ocular Therapeutics.—Dr. L. Webster Fox of Philadelphia said that of the newer salts of morphine, ethyl-morphine hydrochloride (dionin) was the only one which he had found of value in ophthalmic practice. The conditions in which it had proved of service were acute iritis and irido-cyclitis, where, combined with atropine, it assisted in breaking synechiæ and relieving pain.

A Simplified Method of Estimating the Opsonic Index.—Dr. H. W. Crane of Kalamazoo, Mich., read this paper, and in connection with it he demonstrated a new thermostat and a pipette rotated by clock work.

The Status of Opsonic Therapy.—Dr. Nathaniel Gildersleeve of Philadelphia spoke particularly of the extreme care required in injecting vaccines and carrying out vaccine therapy.

Dr. A. P. Hitchens of Philadelphia said that although we heard a great deal of criticism concerning Prof. Wright's method, he did not believe any other one yet suggested was equal in value to that in use in St. Mary's Hospital. He had had no experience with Dr. Crane's method, however, and if the instrument shown by him gave as good results as Wright's, and in addition really saved time, the newer method ought certainly to be adopted. He agreed with Dr. Gildersleeve that no procedure in the whole value of therapeutics required more ingenuity or painstaking effort than vaccine therapy, for to practise this was to go into nearly every method of treatment. These were of value in assisting the opsonins, even after vaccination, if the proper bacterium had been found and the focus of infection determined.

Dr. Jay F. Schamberg of Philadelphia spoke of the practical application of the vaccines in diseases of the skin. Gratifying results had been obtained by him in a number of refractory cases of furunculosis and carbunculosis, and he believed that this method constituted the best means of treatment at our disposal.

Dr. W. O. Robertson of Philadelphia said that last year he had had the opportunity of employing the bacterial vaccines (both autogenous and heterologous strains), in typhoid fever cases in his hospital service. While in every instance the index was a constant guide to the clinical condition, at no time could it be seen that any phenomena, either temperature or any other, were produced by these bacterial suspensions.

The Rational Treatment of Visceroptosis.—Dr. J. Madison Taylor of Philadelphia stated in this paper that the testimony was convincing that the causes of misplacements of the organs lay far back in constitutional weaknesses, general or local; hence the treatment must be directed to a radical reinvigoration of the body, as well as such parts as were affected. Contributory causes were secondary, though not unimportant. Surgical operation might ameliorate the local conditions, but much more remained to be done when the best possible in this way had been accomplished. It was frequently necessary to begin with a period of absolute or partial rest treatment, and dietetics and attention to the digestive organs were important. Replacement of the affected organs required much persistent attention, and this was possible only by the physician himself, however much secondary aid was had of masseurs, etc. Massage, general or abdominal, was capable of large harm as well as good, and demanded personal attention and supervision. Posture, or educative attitudes, was frequently necessary. Development of the abdominal supports was a matter which demanded early and long-continued attention, as success or failure depended on whether this was accomplished or not. The only artificial support for the viscera which gave satisfaction was the belt devised by Dr. Morris Longstreth, which exerted support upward to the torso, without making undue pressure on the soft structures of the lumbar region or encircling the abdomen. Finally, the essential measure recommended was manual treatment of the visceromotor centers in the paravertebral region, by means of which the nutrition of the relaxed structures and the whole organs might be markedly improved.

The Abuse of Arsenic in the Treatment of Diseases of the Skin.—Dr. Jay F. Schamberg of Philadelphia read this paper. Among the deleterious results referred to were general pigmentation and cancer of the skin. In view of such conditions being caused at times, arsenic, the speaker said, should not be employed except for a good reason. Moreover, its use should not be kept up for too long a period, and, in order to avoid this, patients should be prevented from having prescriptions containing the drug renewed.

Chronic Neuralgia; Its Cause and Cure.—Dr. Robert Reyburn of Washington, D. C., said the one great cause was increased blood-pressure. Among the remedies which he had found most efficient were quinine and ergot in full doses. In some instances drastic purgatives and the removal of blood by leeches had proved of great assistance.

Saturday, May 9—Third Day.

Digitalis and Its Congeners, with Special Reference to the Harmful Effects of Digitalis.—Dr. Wm. Egbert Robertson of Philadelphia in this paper entered a plea for the less indiscriminate use of digitalis, and spoke of the desirability of substituting squill for it in a considerable proportion of cases. In squill, he said, he had found a safer drug, without the disadvantages of digitalis, and one which was at the same time more prompt and powerful.

Symposium on Roentgen Ray Therapy.—The Treatment of Skin Diseases.—Dr. Russell H. Boggs of Pittsburg, Pa., read the first paper in the symposium. The rational indication for the Roentgen rays in dermatology, he said, depended upon the effects of these upon living tissue, and inasmuch as very wide variations could be produced by varying the quality and quantity of radiation, the rays should be employed with care. In each case a sufficient effect for the purpose in view should be caused, without going beyond the bounds of safety. The following were some of the changes which took place in living tissue when radiated: (1) Temporary or permanent atrophy of the appendages of the skin. This explained why the rays were indicated where it was necessary to remove the hair, either permanently, as in hypertrichosis, or temporarily, as in sycosis, favus, tinea tonsurans, etc. (2) Destructive action upon organisms in living tissue, as in lupus vulgaris, etc. (3) Increase in metabolism accounted for some of the results in chronic indurated eczema, lichen planus, psoriasis. (4) When the rays were used intensely diseased cells were destroyed long before healthy ones, and cellular tissues were most influenced by the *x*-ray. This explained the results of radiation in epithe-

lioma, sarcoma, tuberculosis of the skin, myeloides, etc. (5) The anodyne effect was shown in the treatment of painful malignant diseases, neuralgias, and itching dermatoses, such as pruritis, eczema and prurigo. (6) The action of the rays on keloid inhibited the degenerative cell development, stimulated normal processes, and prompted absorption.

The Roentgen Treatment of Tuberculous Glands.—Dr. George C. Johnston of Pittsburg said that of late years tuberculous adenitis had become a surgical disease, and while operation often succeeded, it often failed also, and the majority of patients coming to the roentgenologist had previously had the benefit of surgical interference. It was a mistake to speak of these cases as recurrences, as was often done, since an extirpated gland never recurred. They were reinfections; the portal of infection remaining open, the lymphatics patulous, reinfection was a natural sequence. He did not wish to be understood as condemning the surgical treatment of tuberculous adenitis. In the proper class of cases the ideal treatment was extirpation; but extensive dissection of the neck in the futile attempt to remove all glandular structures he did not believe advisable. The so-called Roentgen treatment had little or no bactericidal action; its effect in this disease was not therefore due to the latter. The result of its continued application was a definite histological change, so that the glands, markedly diminished in size, became transformed into sterilized, innocuous fibromata, while the lymphatic trunks were reduced to mere cords. Such a glandular chain was not liable to infection, tuberculous or other. With this agent it was possible and proper to treat areas of far greater extent than could possibly be explored surgically, while observation of the effect produced in distant organs, as an immediate result of the radiation treatment of infected areas, justified the surmise that the formation and generation of a compound or compounds allied in effect to the antibodies were caused by it. The class of cases peculiarly suitable for this method of treatment was that so frequently observed among poor patients, where a large number of glands had broken down and suppurated, discharging for months or years through sinuses. In no case had the treatment failed to reduce the size of the glands or stop discharge from sinuses.

The Roentgen Treatment of Sarcoma.—Dr. George E. Pfahler of Philadelphia said that the value of this treatment must be gauged by comparison with the results obtained by other means, and since most of the cases treated by Roentgen rays were considered hopeless, the method stood alone and above every other. The results were finally measured by the percentage of recoveries, by the permanency, and by the degree of associated risk and discomfort during the process of treatment. There was practically no risk or discomfort under skilful management, and therefore the permanency became the main point of investigation. Of twenty-two cases reported in detail by the speaker at the meeting of the American Roentgen Ray Society, Oct. 1-5, 1907, fifteen had recovered or were recovering under treatment. Of the twelve cases which had recovered at that time, ten had remained well. The present condition of each of the patients included in that report was given. To this list he now added six new cases, in which the results, while gratifying, were on the whole less satisfactory than in the previous group. Having given the details of these cases, Dr. Pfahler went on to say that too few cases had been treated to make statistics of any real value, but when these cases were carefully studied, and it was realized that nearly all were inoperable or recurrent after operation, and that of the twenty-two reported in 1907, fifteen had recovered, we must conclude that the results were more satisfactory than those from any other method. The cases were also too few to form a basis for prognosis, but, from his observations, he would expect at least 25 per cent. to recover; and if treated early at least 50 per cent. should recover.

Dr. W. Wayne Babcock of Philadelphia said that as regards the operative treatment of these tumors the operation was a trauma, and traumatism was apparently the most important cause in their etiology. As the result of the operation there was a lighting up at the seat of trouble, so that after operation sarcomas did not recur so often in different parts of the body (excepting metastases in the lungs) as in the scar, no matter where the scar might be situated. The *x*-ray had the effect of preventing recurrence, closing up lymph spaces, destroying lymphatic tissue, and producing a wall of fibroid tissue around the seat of the growth. It also had a marked distinctive action on the cells of sarcoma itself.

Post-operative Treatment of Malignant Disease.—Dr. Ennion G. Williams of Richmond, Va., said that on account of the number of recurrences after removal by the knife, particularly of mammary cancer, it was fair to assume that some malignant cells remained after the operation. Here the Roentgen rays were of great service, and if there should still be recurrences, the treatment should be repeated until all vestiges of the disease had been destroyed. The many cases of complete recovery under this treatment now on record furnished proof that all the malignant cells had been reached. If the distance of the cancerous growth from the surface was very great, or if bony structures like the sternum intervened, some of the cells would probably be left. There was, therefore, what might be termed a "successful zone" for Roentgenization, and this might vary according to circumstances. In using the rays after a surgical operation it was advisable to wait for about five days before beginning the treatment, in order to allow time for primary union in the wound.

Dr. William L. Rodman of Philadelphia said that he had seen the best results follow the use of the *x*-rays in superficial squamous epitheliomata and also very good results in sarcoma, but in a rather large experience in cases of carcinoma of the breast in which the *x*-rays had been employed, always after operation, it was his deliberate opinion that not a single one of them had been in the least benefited by this procedure. Radical operations at the present time should promise more than 50 per cent. of cures. Many were now getting such results, and until the same could be obtained from the *x*-rays, he would hold that it was entirely unjustifiable to use the rays prior to operation. Their employment should be wholly limited to post-operative cases.

Dr. Sajous thought that the treatment should not be limited simply to one procedure, either *x*-ray or surgery, but that these should be united when possible. Moreover, it was important to remember first and foremost the autoprotective resources of the body, the *vis medicatrix naturæ*. In some cases in which he had not been able to persuade the patient to resort to operation (which he believed afforded the greatest amount of protection), the internal secretions alone had proved of value, their use having been followed by the disappearance of glands in the axilla, etc. He did not present this as a treatment in itself, but he firmly believed that if in cases of sarcoma or carcinoma under treatment we used such measures as were employed in syphilis—say the administration of the iodides, mercury, small doses of thyroid extract, or adrenalin—we would have a potent aid. In post-operative treatment a similar plan would almost invariably prevent recurrence, and in any case of sarcoma he would urge that coincident with the *x*-ray treatment the patient he submitted to a course of internal treatment, for instance, small doses of thyroid extract with iron and strychnine, in order that the proteolytic substances of the blood might be increased, the toxic waste products which accumulated in the blood and endangered the renal tract be reduced, and the patient be protected against recurrence.

Palliative Treatment of Malignant Disease by Means of the Roentgen Rays.—Dr. Charles S. Leonard of Phil-

adelphia said the value and curative efficiency of early surgical removal of malignant disease could not be questioned when that removal was complete. The group of severe malignant cases in which the most favorable surgical results were shown was that of cancer of the breast, but while the most recent statistics showed that early operation gave 85 per cent. of cures here, the general statistics showed that in two-thirds of the cases of breast tumors operation could expect to be nothing but palliative and that 80 per cent. of these patients would die of the disease. An increase in the number of early operations, and a consequent decrease in the mortality from malignant disease, could best be secured by a careful discrimination in the cases selected for operation. The inability to cope with the disease in its later stages was manifest, and the combination of ante- and post-operative Roentgen treatment with radical operation and the results obtained from the Roentgen treatment of recurrent growths pointed to this combination as a method of decreasing the high mortality and increasing the extent of palliation. This treatment should not be confined to a few haphazard applications, but be given with a thorough understanding of the degree of lymphatic involvement, and regulated in length and severity by the evident malignancy and the extent of infection in the individual case. It should forestall rather than wait for recurrence. The palliation afforded by radiation was seen in the decrease or absence of pain, rendering opiates unnecessary. In addition, it localized the disease by destroying the lymphatics, healed superficial ulcerations, thus making life comfortable, and, where the lymphatic involvement was already too deep, permitted the patient to die in comfort from visceral metastases.

Dr. William B. Coley of New York said that as to the question of the value of the pre-operative or post-operative *x*-ray treatment in malignant disease, he considered the present data insufficient to permit of a final decision. In tumors in the early stages in which operation alone promised reasonable hope of success, he believed there were certain dangers connected with the pre-operative use of the *x*-ray. While the tumor itself showed diminution in size under it, there might be insidious glandular extension which lessened the chances of a final cure. Furthermore, after the tumor had decreased considerably, there was a probability that when the operation was done smaller incisions would be made and insufficient tissue removed. On the other hand, there were cases where operation and *x*-ray were both used as palliative measures in which pre-operative *x*-ray treatment might be of decided advantage. There was much more to be said in favor of the post-operative treatment, and at present the weight of opinion seemed to be decidedly in favor of the value of this treatment. In spite of this, however, he did not believe that there had been a sufficient number of cases carefully treated and reported, covering a period of three years after operation, to permit of any conclusions of value. He did not wish to be understood as speaking against the use of the *x*-ray as a post-operative measure, but he desired to emphasize the fact that its value as such a measure, up to the present time, rested upon theoretical grounds rather than practically demonstrated experience.

The Treatment of Leukemia by the Roentgen Rays.—Dr. Henry K. Pancoast of Philadelphia treated of a new and more rational method of employing the *x*-ray in leukemia, devised by Dr. Stengel and himself. The essential feature of this method, which was suggested by Dr. Stengel in December, 1906, and since then had been constantly employed, was the direction of the applications to the bone marrow of practically the entire skeleton as the primary object in the treatment, and the relegation of splenic and glandular exposures to a position of minor or secondary importance. He mentioned four points in support of the claim of the method to superiority over the older one: (1) It implied a much more direct attack against the cause of the disease. (2) Clinical experience showed that the secondary manifestations, such as the splenic and lymphatic enlargements, responded even more satisfactorily to this method than to the older one. (The technique included, however, an appropriate amount of direct exposure to these structures.) (3) The dangers particularly associated with the *x*-ray treatment of leukemia were, in a large measure, avoided. (4) Several other important but less significant advantages had been noted clinically. Regarding the prognosis, it was too early, he said, to prophesy as to ultimate results under this plan of treatment, but as the matter now stood, we were in a much better position to settle within a reasonable time the question whether a permanent cure could ever be attained directly from *x*-ray treatment, because we were bringing our forces to bear more directly upon the cause of the disease. At all events, the expectation of life was undoubtedly longer under this new method.

Committee on Therapeutic Research.—The Council announced that in accordance with the suggestion of Prof. Remington they recommended the appointment of a committee to be called the Committee on Therapeutic Research, and the Society ratified the action of the Council. This committee, which was to be a permanent one and to consist exclusively of members of the American Therapeutic Society, was constituted as follows: T. E. Satterthwaite of New York, Chairman; H. C. Wood, Jr., of Philadelphia, Secretary; F. H. Gerrish of Portland, Me., J. V. Shoemaker of Philadelphia, O. T. Osborne of New Haven, Conn. The number of its members may be increased to fifteen if this should at any time be recommended by the Council, the additional members to be appointed by the Chairman of the Council. It was specified that the work of the committee shall be limited exclusively to the investigation of the therapeutic value and uses of pharmacopeial drugs.

Officers.—The following officers of the Society were elected: *President,* Frederic H. Gerrish of Portland, Me.; *First Vice-President,* Alexander D. Blackader of Montreal, Canada; *Second Vice-President,* Howard Van Rensselaer of Albany, N. Y.; *Third Vice-President,* Robert T. Morris of New York; *Secretary,* Noble P. Barnes of Washington, D. C.; *Treasurer,* A. Ernest Gallant of New York; *Chairman of the Council,* Reynolds Webb Wilcox of New York; *Vice-Chairman,* Edward D. Fisher of New York; *Committee on Admissions,* Thomas E. Satterthwaite of New York; Oliver T. Osborne of New Haven, Conn., and D. Olin Leech of Washington, D. C. At this meeting the membership of the Society was filled to the limit prescribed by the Constitution—one hundred.

The next meeting is to be held in New Haven, Conn., May 6, 7 and 8, 1909.

SIXTH INTERNATIONAL CONGRESS ON TUBERCULOSIS.

Held in Washington, D. C., September 21 to October 12, 1908.

(Special Report to the Medical Record.)

SECTION ON STATE AND MUNICIPAL CONTROL.

Wednesday, September 30.

The Administrative Control of Tuberculosis in New York City.—Dr. Herman M. Biggs of New York stated that antituberculous work had been instituted in New York in 1894. At this time the Board of Health classed pulmonary tuberculosis as a communicable disease and required all hospitals and public institutions to report cases under their charge. At the same time private physicians were requested to do so, and in order to aid the physicians in reaching an early and definite diagnosis, the Board of Health established a diagnosis laboratory, where suspected sputum was examined for physicians free of charge. The only stipulation was that the physician should furnish the

name and address of the patient. In this way many cases came to the knowledge of the authorities that otherwise would not have done so. In 1897 the Board of Health was able to adopt a regulation requiring physicians to report their tuberculosis cases to the Board of Health. The basis of the work done in New York City was compulsory notification and registration of all cases of tuberculosis. The reported cases fell into two groups, those reported by private physicians as under their care and those reported as not under such supervision. The Board of Health did not interfere if the consumptive was under the care of a private physician, but if this was not the case all objection to the visitation and supervision of the Health Department was removed. It was in these cases that the health authorities did the most effective work. This work consisted in visitation of the consumptive in his home by trained nurses or by physicians. If country air would benefit him the Department of Health offered to take him to its country sanatorium at Otisville, or referred him to the State Sanatorium at Raybrook. If the patient could not leave the city but was able to be about he could receive free medical care at one of the many tuberculosis dispensaries. If his home surroundings were fairly decent he could receive medical attention from the Board of Health if he was unable to be about. If he needed hospital care he was sent to a hospital, and if his habits and surroundings were such that he was a menace to those about him he might be forcibly removed to the special tuberculosis hospital of the Board of Health on North Brother's Island. Millions of circulars in a score of languages had been supplied and distributed by the Board of Health. Stereopticon lectures, exhibitions, "Don't spit" notices, etc., had all had their place in the campaign, which had been by no means an easy one, but the result had been that the death rate from tuberculosis had dropped from 4.42 per thousand in 1886 to 2.41 per thousand in 1907.

Notification in Human Tuberculosis.—Dr. Hamel, Member Royal Bureau of Health, Berlin, read this paper, in which he argued strongly in favor of compulsory notification. When, however, compulsory notification was found to be impracticable, voluntary notification should be introduced instead, possibly with the payment of a bonus for every case reported, for government workman's insurance could be utilized for locating cases of tuberculosis.

Dr. Robert Koch of Germany said that Dr. Biggs' paper represented very impressive features, and he expressed unbounded admiration at the work that New York City had done. This work was especially surprising, in view of the unfortunate conditions of living and the problems that immigration presented. He thought their system exemplary, first, because of their system of compulsory notification, and, second, because they had succeeded in getting the right to remove patients who were a menace to the community. They had not been so fortunate in Germany. There they could only seek out patients and endeavor to make them harmless so far as was possible.

Dr. Arthur Newsholme, of London, England, said that in his opinion the campaign against tuberculosis in New York City was the embodiment of the most perfect piece of work yet done in this crusade. There had been no other work that equaled it. He had seen the work in operation and could only express his unbounded admiration. He wondered at the ease with which legislation had been secured. In England public opinion would not tolerate the removal of a patient from his home. The sanatoria here were so attractive that he did not wonder so much that this step was possible. Compulsory notification and education were only valuable in so far as they were utilized in a practical way for prevention. He was also impressed with the restraint with which the authorities used their power. Private physicians in England had not put into effect preventative measures to the extent that they were doing in this country. Authorities here had used their powers without arousing the antagonism of the family physician. The only thing he could recommend was a shorter course of treatment for a large number of cases rather than a long course of treatment for a small number of cases, because it was better to send out a number of uncured patients, knowing how to manage their own cases, and no longer a menace to the community, than entirely to cure a few while a large number were left to spread the disease. This was the only improvement he could offer to New York methods.

Dr. Harbitz of Sweden said that in Sweden compulsory notification was in operation, and the Board of Health had the privilege of recommending the removal of the patient. In certain cases for the prevention of infection the patient could be ordered to be removed to hospital or sanitarium. In these cases the expense devolved upon the community. The system was very much like that in New York, except that it embraced towns, municipalities, and rural districts.

Thursday, October 1.

The Need of Federal Health Departments.—Dr. J. W. Conaway, University of Missouri, presented a paper in which he described the danger that existed of infecting foods with the tubercle bacilli. He described the unsanitary conditions that were permitted in the packing houses of the West. He referred to the risks incurred by permitting consumptives to work in bakeries and other places where foods were produced and handled. He showed that the meat handled in the State of Missouri came from many other states, and that no state law could control it; it was imperative that the Federal Government should step in and use its authority. He called attention to the lack of sanitation in sleeping cars and day coaches on our railroads and said that state law could not control these. He thought one method of spreading the disease was that of sending consumptives in the later stages of the disease to supposedly better climates; these often died en route and were a dangerous element in spreading infection as they traveled about the country. The Federal Government could control this matter.

The Governmental Control of Tuberculosis Patients in Pennsylvania.—Dr. Samuel G. Dixon, Commissioner of Health of the Commonwealth of Pennsylvania, showed the advantages to be derived from governmental supervision of tuberculosis patients. It was necessary that the reporting of tuberculosis cases be compulsory, but it was not necessary to thrust the word "compulsory" before the public so as to arouse prejudice and antagonism. The family physician was the mediator in this matter and could make the patient feel that his case was a secret between himself and the Board of Health. Dr. Dixon described the dispensary system in operation throughout the State; there were at present 67 such dispensaries, and by the first of January there would be 40 more opened to the public. At these dispensaries the patients were given medical advice, even to the minutest detail. Trained nurses followed up the cases and investigated the home surroundings and saw that the advice was followed out in every particular. She continued the education of the patient begun by the physician and also instructed the family of the consumptive. A note book was furnished each patient, in which he kept an accurate record of his case, as regarded quality and quantity of food, number of hours of sleep and under what conditions, kind and amount of exercise, etc. The patients were divided into classes and were encouraged to emulate one another in the endeavor to show a good record. There were 723 health officers in the commonwealth who were working in this campaign against tuberculosis. As so much depended upon a regular routine of life in this disease, governmental control could be of immense assistance. It was the little things of life that told in this class of cases. A sanatorium should never be in or near a city, and sanatorium patients should be seen daily by the physician. He described the State institution at Mont Alto and said that the State would soon have a

hospital for incurables in operation. The State had already an organized piece of machinery in its bureau of statistics, health officers, nurses, etc., prepared to deal with infectious diseases, and it would be a great economic saving if the State would utilize this power which was already in its hands in the fight against tuberculosis.

The Official Care of the Tuberculous in Their Own Homes.—Dr. Pütter of Berlin presented this paper, which was read by Dr. Biggs of New York, and which described the dispensary care of tuberculosis in Berlin. There were 100 of these dispensaries in various German cities and four or five in Berlin. They did not furnish medical care, but were only for purposes of diagnosis; after the case was diagnosed the patient was sent to his family physician or to a sanatorium. The cost of these dispensaries was very little, the four in Berlin costing about $10,000 a year. Numerous other organizations were associated with these dispensaries, as some furnished food, others provided nurses and others money; among the latter was the Workingmen's Insurance Company. The expense of taking care of patients was divided between the government, the insurance company and the employer, whether an individual or a corporation.

Dr. S. A. Knopf of New York thought the German organization as complete as it could be. The prevention of pauperization was a good point. In speaking of the cases that were a menace to the community and that were forced by authority to be removed to institutions, he said that this class of patients had given them no trouble. The improved surroundings that they met were usually of great benefit to the patient and he soon adapted himself to improved conditions and was very grateful.

Dr. Otis of Boston thought there was practically very little difference in the way in which tuberculous patients were cared for in the different countries. The same results had been reached by slightly different means. He could not understand why the German dispensaries should examine well-to-do patients. He thought they should go to their physicians and pay for such an examination. The Associated Charities of Boston and other organizations did for their patients very much what the German organizations were doing. Continuous supervision was very necessary and a periodical report should be required as long as patients remained in their homes. The problem that remained unsolved was the provision of suitable occupation for this class.

Dr. Arnold C. Klebs of Chicago said that not only should every case be examined and kept under observation, but every member of the family as well; it was only in this way that we could get at the root of the matter. The children should be kept under observation and examined regularly over a long period, and in this way we would have a very effective method of controlling tuberculosis.

The Anti-Tuberculosis Campaign with Reference to the Proposed National Department of Health.—Dr. C. A. L. Reed of Cincinnati, O., stated that both political parties in the present campaign had planks in their platforms committing themselves to the establishment of a Bureau of National Health. Congress had committed itself to the consideration of this question at the coming session in December. His purpose on bringing the subject before this congress was to get it before the general public as forcibly as possible, in order that the necessity for the establishment of a National Health Bureau might be thoroughly understood and demanded by the people. It must be understood that the general efficiency, the productive energy of the population was the foundation of national prosperity. It was the human factor that counted, and this truth had been generally neglected. Human life had not been regarded as a unit of value translatable into dollars and cents. He showed by conservative estimates that the economic value of the lives lost and whose usefulness was impaired by tuberculosis would be sufficient, if transformed into dollars and cents, to maintain the army, navy, marine hospital service, coast defences and waterways of the United States. At present the duties that would properly belong to a National Bureau of Health were divided among the army, navy and marine hospital corps; the Secretary of the Treasury was the chief health officer of the nation, the Secretary of the Interior was sanitary administrator of the interior. There was thus no centralization, and, while many excellent results had been attained, there were some results of this loose administration that were disastrous. We needed coöperation between Federal and State authorities, not antagonism. There were many questions of sanitation that the States could not reach individually, as the sanitation of railway coaches and steamships. Taking the human life as capital and the earnings as interest, we would find the loss from mortality and morbidity, and the morbidity was perhaps five times as great as the mortality, the financial loss to the country was so great that when it was once brought to the attention of the public there should be no difficulty in securing this much needed legislation.

Dr. E. Liceaga of Mexico said that in Mexico the Service of Public Health was one of the national departments. Different States could not operate without a chief of public health. He described how they had been successful in combating the plague and yellow fever, and did not think this would have been possible without a national bureau. During the year 1907 they had had only seven cases of yellow fever and only three foci.

Dr. Montgomery said that Dr. Reed had omitted one very important point in his paper. It was imperative that the head of a National Health Bureau must be a medical man. Neither of the political parties had committed themselves to this stipulation. He then set forth the reasons why it was necessary to have a physician at the head of this department.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held April 13, 1908.

Dr. Leon Louria in the Chair.

The scientific session consisted of a symposium on gallstone disease.

Etiology.—Dr. Neil Macphatter of Manhattan read this paper. He said that the subject of gallstone disease had engaged the attention of physicians for a long time, and that the investigations of the past few years had thrown a flood of light upon it. From 12 to 20 per cent. of aged people had gallstones, in many cases of which the disease was not recognized during life. In some part of the world gallstone disease was quite uncommon. It was rarely found in India, Italy, or Egypt. The study of the composition of gallstones was intimately connected with that of the bile, where chief constituents were water, sodium glycocholate, and sodium taurocholate and cholesterin. The last was the most important constituent. A thorough knowledge of its chemistry and its distribution in the body was necessary in order that a clear conception might be gained of the mode of production of gallstones. It was erroneous to suppose that cholesterin was found only in the bile; it was found in nerve tissue, milk, crystalline lens, etc. Pathologically, it was found in pus. Ordinarily the cholesterin was present in the bile in a state of solution. When decomposition took place in the gall-bladder the quantity of cholesterin increased and changed from a state of solution to a crystalline form. In catarrh of the lining membrane of the gall-bladder, the cholesterin crystallized out. Whether cholesterin was a waste product or was a histogenetic substance was not yet known. Here were three theories that sought to account for its origin, namely: it was a product of the metabolism of the liver cells; it was extracted by the liver from the blood; it was formed by the mucous

membrane of the gall-bladder. The former two theories had been advanced by many authorities, but the number of these had been decreasing and the view was becoming more general that in all probability the cholesterin was the product of the mucous membrane of the biliary passages. When this substance was administered in solution to animals, there was observed no increase in its content in the bile. On the other hand, when there was a low inflammatory condition of the biliary passages, whether due to the typhoid or colon bacillus, or to passive congestion of the mucous membrane, as occurred in mitral stenosis or pregnancy, there was an increased secretion of cholesterin. It had not been proved that this substance was the product of a degenerative change in the mucous membrane. It was, however, probable that pathological changes in the latter disturbed the equilibrium between the bile acids and cholesterin, with the precipitation of the latter. There were two essential factors in the production of gallstones, namely: fundamental pathological processes, and some impediment to the outflow of bile. The concurrence of these two factors did not necessarily imply that gallstones would follow, but it was impossible for gallstones to begin without these. There were many local or constitutional conditions that impeded the free outflow of bile; they were: age, sex, pregnancy, the wearing of corsets, the accumulation of feces in the duodenum, insanity, typhoid fever, tumors of the head of the pancreas, and Bright's disease. As regards the etiological relationship of age, it was noted that children were practically free, young adults were rarely affected, while in the old, gallstones were relatively frequent. This frequency in the aged had been attributed to the fact that in them the bile was thick and concentrated. It was more probable, however, that in the old there was a muscular weakness of the wall of the gall-bladder, as well as degenerative changes in its mucous membrane, of a furry character. Gallstones were five times as frequent in women as in men. This was probably due to the constriction produced by dress, with the pushing of the liver upward and inward, and the resulting constant stagnation of bile. The frequency of gallstones in pregnant women was also noted, the occurrence being more frequent in the latter months of pregnancy; in this instance, the constriction of the abdomen with corsets was a powerful contributing cause. Other causes of gallstones commented upon were heart disease, cancer of the liver and gall-bladder, and insanity. The post-mortem examination of 1,300 lunatics showed the presence of gallstones in 20 per cent. It was a peculiar circumstance that in the insane the presence of gallstones rarely gave rise to colic. In many diseases there was an impeded outflow of bile, with a resulting low-grade inflammatory condition of the bile-passages, extending over a long period of time. In this manner the development of gallstones was frequently an insidious one.

The Symptomatology and Diagnosis.—Dr. Walter B. James of Manhattan read this paper. He said that the development of modern surgery has changed the attitude of the general practitioner toward abdominal diseases. In no other disease was surgery capable of affording more immediate relief to trouble that had formerly dragged along for years, than in gallstone disease. Exploratory laparatomy gave frequent opportunity for the study of anatomical conditions in the living. He who would know more about diagnosis had to haunt the operating room. Although gallstone disease was now more properly a surgical condition, most cases came to the family physician first. The recognition of diseases of the gall-bladder was one of the most frequent propositions that confronted the family physician. Their exact diagnosis was a heavy burden that bore upon the physician. Yet the diagnosis of gallstone attacks was simple; the symptoms were plain; the agonizing pain, radiating to the back, associated with jaundice, and possibly the subsequent appearance of gallstones in the stools. If the stone was impacted the symptoms were fever, jaundice, and chills, of an intermittent character. The speaker took up the consideration of the most common conditions in the upper abdomen with which gallstone disease could be confused. The upper right quadrant furnished the greatest number of pitfalls for the diagnostician. The presence in close proximity in this region of the gall-bladder, liver, kidney, the colon, and the head of the pancreas, explained the large proportion of abdominal puzzles. Cholecystitis could be present with calculi, and the latter could be present without cholecystitis. Clinically, there were two groups of cases that could be distinguished, namely, the mild and the severe. In the former the symyptoms were mild, while in the latter there was a secondary inflammatory process which was alarming. The symptoms of the mild cases were: dyspepsia, hypochondriasis, jaundice, postprandial pain, belching and pyrosis. These latter symptoms were identical with those of nervous dyspepsia, or came on three hours after eating and were relieved by food. Jaundice was not often present. In a great many cases it was possible to detect an enlarged gall-bladder, by means of careful examination. There were sometimes not only subjective but also objective manifestations of hypochlorhydria, which was probably secondary. Spontaneous pain was referred to the middle line or to the left of the middle line, like in nervous dyspepsia. One had to be ready to suspect gallstone disease in every case of dyspepsia with epigastric pain occurring particularly at night. Deep pressure in the region of the gall-bladder while the patient took a deep breath elicited pain and tenderness. In the Murphy method of examination, the patient with his back to the examiner and resting on his hands and knees, was examined from behind. The examiner placed his hand on the free border of the ribs and pressed with his palm upward toward the diaphragm. In this manner he could feel the enlarged gall-bladder. The physician was to regard with suspicion every case of catarrhal jaundice, particularly in any patient above 30. The milder cases were not the proper ones for surgical treatment. Rational treatment of these could be carried out by attacking the dyspepsia. The severer forms of gallstone disease were the ones about which the physician had to be anxious, particularly on account of the differential diagnosis from other surgical conditions. Diaphragmatic pleurisy was frequently confused with gallstone disease. When present on the right side it gave pain, tenderness, and muscular rigidity in the upper right quadrant of the abdomen. Such muscular rigidity was very common in diaphragmatic pleurisy. If cough, or rapid respiration developed, then the diagnosis pointed to the lower condition. Unfortunately, a certain number of cases of pneumonia developed, in which the sole symptoms were referred to the abdomen. A number of cases of supposed gallstone disease had been operated upon, that turned out to be cases of pneumonia. A useful point in differential diagnosis was this: in diaphragmatic pleurisy, by limiting the action of the diaphragm by encircling the ribs with the hands, the pain was relieved. On the other hand, in gallstone disease the lower costal tenderness was not relieved by this procedure. Gallstone disease was frequently overlooked on account of the failure to recognize two facts. First, jaundice was not constant. When the calculus remained in the gall-bladder or in the cystic duct, there was no jaundice; this occurred only when the stone got into the common duct and remained there. Yet, in 20 per cent. of cases of calculus in the common duct jaundice was absent owing to the fact that the observation was made at the time that the stone had already escaped into the intestine. Kelly had noted that in 34 per cent. of the cases of gallstone disease there was no jaundice at any time, while in 65 per cent. there was no jaundice at the time of operation. Another error was to expect to find distension of the gall-bladder at the time of operation. On the other hand, the round protuberance mistaken for an enlarged gall-bladder frequently turned out to be a protuberance of the liver or to be due to muscular spasm.

Subphrenic abscess resulting from appendicitis or from any other old focus of inflammation on the right side, gave pain that simulated the pain of gallstone disease. In the former the pain was more general and less spasmodic, while frequently a small area of dulness and bronchial breathing could be distinguished. Another condition that was confused with gallstone disease was the presence of septic infarcts of the kidney. These were more common than was supposed, occurring mostly on the right side. They were possibly caused by the colon bacillus. They gave rise to chills, malaise, and abdominal pain, to tenderness in the costovertebral angle and to the presence of a few red blood cells in the urine. Adhesions in the transverse colon frequently gave rise to pain and obstinate constipation, and were frequently confused with gallstone disease. The true condition could be recognized, however, by the absence of true gall-bladder tenderness, and the relief of the symptoms after the administration of a purgative. Cholecystitis, with or without stones, occurred in typhoid fever about the same time as the tendency to perforation. Differentiation was difficult. In cholecystitis the pain was less violent. When in serious doubt, exploratory laparotomy was advised. Patients with typhoid bore operation much better than was supposed. The cholecystitis of typhoid ran a good course. Gallstone disease was sometimes simulated by the perforation of organs in the neighborhood of the gall-bladder, for instance, the appendix. It was also simulated by acute diseases of the pancreas, as abscess, and pancreatitis. In the last the pain was referred more to the middle line, and a mass was felt deeply, while glucose was recovered from the urine, and fat from the stools. The practitioner was well equipped who was constantly on the lookout for the disease. The more elaborate modern methods of diagnosis were of little help. Radiography was of no value for gallstones gave no shadow. Exploratory puncture was not justifiable. The correct attitude of the physician toward gallstone disease was to be ready to suspect it and to be willing to diagnose it without jaundice or tumor, or the presence of calculi in the stools.

The Surgical Treatment.—Dr. Warren L. Duffield of Brooklyn read this paper.

State Medical Licensing Boards.

STATE MEDICAL BOARD EXAMINATION QUESTIONS.

Pennsylvania State Board of Medical Examiners.

June 23-26, 1908.

ANATOMY.

1. Describe the relations of the gall-bladder with its surrounding organs.
2. Describe the clavicle and its articulations.
3. Describe the heart, its cavities, and the vessels leading into and from it.
4. Describe the hip joint and name its ligaments.
5. Describe the pancreas and name the important structure that passes through its head.
6. Describe the position of the palmar arterial arches.
7. Describe the female mammary gland, with special reference to its lymphatics, and its relations with the surrounding structures.
8. What vessels furnish the nutritional, and what the functional, supply of blood to the lungs?
9. Name the external and internal rotators of the thigh.
10. Where are the motor centers of the cerebrum located, and how is their location delineated on the surface of the scalp?

PHYSIOLOGY.

1. Explain the endogenous (internal) and exogenous (external) sources of the purin bases and the production of uric acid.
2. Name and describe the causes producing the respective heart sounds.
3. Discuss the factors concerned in the venous circulation.
4. Describe the principal functions of the digestive juices.
5. Briefly describe visual accommodation, and mention the function of each involved factor.

MATERIA MEDICA.

1. Discuss the official iodine preparations with regard to their respective important medicinal properties, doses, and methods of employment.
2. Name the drugs that produce local anesthesia and describe the methods of using them.
3. Give the official names and the doses of the preparations of mercury which are prescribed for internal administration.
4. Name the drugs that are pharmaceutically incompatible with the following: (*a*) iron salts, (*b*) vegetable alkaloids, (*c*) gum resins.
5. Correctly write the following prescription without abbreviation (using official titles and either Metric system or U. S. measure and Troy weight):

Take of:—

Oil of Turpentine	120 minims
Powdered Gum Arabic	3 drams
Chloroform	16 minims
Syrup of Tolu	2 fluidounces
Peppermint Water a sufficient quantity to make	4 fluidounces

Directions—One fluidram sufficiently diluted with water every three hours.

CHEMISTRY.

1. Name and discuss the significance of five morbid products of the urine, and detail the tests for any two.
2. Give the chemical composition of two forms of urinary calculi and describe chemical tests for each form.
3. Name common and convenient antidotes for poisoning by the mineral acids, and tell what course should be pursued when the acid to be counteracted is unknown.
4. Describe two chemical tests to be used in water supposed to be contaminated with sewage.
5. State what diagnostic reaction takes place when diabetic urine is added to a heated alkaline solution of potassiocupric tartrate.

PATHOLOGY.

1. Define infarcts, and state where they most frequently occur.
2. Explain the production of the respective cardiac valvular murmurs, their conduction, and where most distinctly heard.
3. Describe the changes that occur in the crystalline lens in cataract.
4. Define and explain the causes of dry and senile gangrene.
5. Discuss the direct and indirect effects of the gonococcus upon the human body, and outline the technic for staining and recognizing its presence in the secretions.

DIAGNOSIS.

1. Differentiate acute pharyngitis and diphtheria.
2. Differentiate renal colic, hepatic colic, and appendicitis.
3. Differentiate tabes dorsalis and ataxic paraplegia.
4. Diagnosticate cerebrospinal meningitis.
5. Diagnosticate interstitial keratitis.

PRACTICE OF MEDICINE AND THERAPEUTICS.

1. Describe the course of a typical case of scarlet fever.
2. What are the symptoms of diabetes mellitus?
3. What are the symptoms of abscess of the liver?
4. What are the symptoms of tuberculous peritonitis?
5. What are the symptoms and signs present in pleurisy with purulent effusion (empyema)?
6. Outline a treatment for a case of acute follicular tonsillitis.
7. Outline a treatment for tapeworm.
8. What are the symptoms of poisoning by belladonna and how would you treat it?
9. How would you treat a case of cholera morbus.
10. What are the indications and contraindications in the use of arsenic?

SURGERY.

1. Describe the surgical and adjuvant treatment of septic peritonitis.
2. Give the symptoms of pyosalpinx and describe an operation for the same.
3. Describe the manipulations for the reduction of a posterior luxation of the hip joint.
4. Give a classification of burns, and the treatment for one of the third degree.
5. Define and outline the treatment for a penetrating wound of the urinary bladder.
6. Describe the symptoms of pyothorax (empyema) and an operation for its relief.
7. What are the general principles governing the treatment of fractures at or near joints?

8. Give the symptoms and treatment of dislocation of the semilunar cartilages of the knee joint.
9. Give the causes, symptoms, and treatment of varicocele.
10. Describe methods of control of severe epistaxis.

OBSTETRICS.

1. What maternal conditions would warrant the destruction of fetal life?
2. Differentiate normal pregnancy, tumors within the abdominal cavity, and ectopic gestation.
3. During the process of an apparently normal labor, what conditions may arise requiring either version or delivery by the forceps?
4. What may be the causes of uterine hemorrhages during pregnancy, and what would be your treatment?
5. For repeated spontaneous abortion, what is the course of treatment?
6. Should you find albumin and tube casts, or sugar, in the urine of a pregnant woman, what morbid conditions would be indicated, and what would be your treatment?
7. How would you manage a face presentation, with the chin in the hollow of the sacrum?
8. When the action of the uterus is insufficient, what measures and remedies may be used to bring about normal contractions?
9. Name the conditions requiring immediate delivery, and describe the methods of procedure.
10. What are the causes of ophthalmia neonatorum, and what means should be employed to prevent it? How should it be treated?

HYGIENE.

1. What measures should be enforced to prevent the spread of diseases through the schools?
2. What régime should be enforced in the sick-room of a tuberculous patient?
3. Why should we avoid using a general drinking and communion cup?
4. What methods are necessary in cities to reduce infant mortality resulting from digestive diseases?
5. Explain why the principles of "preventive medicine" can be more successfully and efficiently applied in the properly appointed home, with ample accommodations, than in a public or municipal institution?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA STATE BOARD OF MEDICAL EXAMINERS.

June 23-26, 1908.

ANATOMY.

1. The *gall bladder* is in relation *above* with the liver; *below*, with the first part of the duodenum, the hepatic flexure of the colon, the beginning of the transverse colon, and the pylorus; the fundus approaches the anterior abdominal wall behind the ninth costal cartilage and near the outer border of the right rectus abdominis muscle.

6. The position of the *superficial palmar arch* is represented by a line going across the palm of the hand from a point where the web of the thumb joins the palm.

The position of the *deep palmar arch* is represented by a line roughly parallel with the above, but one-half inch nearer to the wrist.

9. The *external rotators of the thigh* are: Obturator externus, Obturator internus, Gemellus superior, Gemellus inferior, Gluteus maximus, Gluteus médius and minimus (posterior fibers), Pyriformis, Quadratus femoris, Adductor longus, Adductor magnus, Adductor brevis, Pectineus, Ilio-psoas, Sartorius.

The *internal rotators of the thigh* are: Tensor vaginæ femoris, Gluteus médius and minimus (anterior fibers).

10. The motor centers of the cerebrum are located in the ascending frontal and ascending parietal convolutions, and the cortex adjacent thereto; they lie on each side of the fissure of Rolando. The leg center occupies the upper third of this part on the cortex, the arm center the middle third, and the face center the lower third. On the median surface, the centers for the head, trunk, and lower extremities are situated in this same order from before backwards.

To *locate the fissure of Rolando on the scalp:* Draw a straight line over the top of the scalp from the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the *fissure of Rolando.*

PHYSIOLOGY.

1. Uric acid belongs chemically to the group of substances called "purins," uric acid being trioxypurin. The uric acid which is derived from the purin bodies contained in the food is called "exogenous" uric acid; while that which comes from the breaking down of the tissues of the body which contain amiuo purins and oxypurins or nucleins is called "endogenous" uric acid.

2. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

3. The factors concerned in the venous circulation are: (1) The action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) some slight action of the valves in the veins.

4.

DIGESTIVE JUICES.	ACTIVE PRINCIPLE.	ACTION.
Saliva.....	Ptyalin.	Changes starches into dextrin and sugar.
Gastric juice.....	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice...	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal juice....	Invertin.	Converts maltose into glucose.

The bile is also a digestive juice, and its functions are as follows: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis; and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

5. *"Mechanism of Accommodation.*—The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the chorioid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines."—May's *Diseases of the Eye.*

MATERIA MEDICA.

2. The drugs that produce local anesthesia are: (1) Ether, (2) Rhigolene, (3) Ethyl chloride, (4) Cocaine, (5) Eucaine, (6) Holocaine, (7) Stovain, (8) Schleich's solution. Nos. 1, 2, and 3 are used as a spray; Nos. 4, 5, 6, and 7 are used hypodermically, or by being applied to a mucous surface; Schleich's solution is used by infiltration.

3. The official names and doses of the preparations of mercury which are prescribed for internal administration are: (1) Hydrargyri choloridum corrosivum, gr. 1/20; (2) hydraragyri iodidum rubrum, gr. 1/20; massa hydrargyri, gr. iv; (4) hydrargyri chloridum mite, gr. ij; (5) hydrargyrum cum creta, gr. iv; (6) hydrargyri iodidum flavum, gr. 1/5; (7) hydrargyri subsulphas flavus, gr. 1/4 to 1/2.

4. The INCOMPATIBLES of (*a*) *the iron salts* are: Vegetable astringents, alkalies, acids, phenol; (*b*) of *the vegetable alkaloids:* alkaline hydrates, tannic acid, picric acid,

salicylates, bromides, iodides, chlorides, bromine, iodine; (*c*) *of the gum resins:* oxidizing agents, phenol, menthol.

5. Recipe:

Olei terebinthinæ	ʒij
Pulveris acaciæ	ʒiij
Chloroformi	♏xvj
Syrupi tolutani	ʒij
Aquæ menthæ piperitæ quantum sufficiat ad	ʒiv

Misce.

Signa: One teaspoonful in half a glass of water, every three hours.

CHEMISTRY.

1. Five morbid products in the urine: Albumin, glucose, acetone, pus, and excess of indican.

Albumin is found in the urine: "(1) In fevers, as typhoid and pneumonia; (2) in valvular heart lesions, degeneration of the heart muscle, diseases of the coronary arteries, impeded pulmonary circulation, in pregnancy by pressure upon the renal veins, in intestinal catarrh, and in Asiatic cholera; (3) in purpura, scurvy, leukemia, pernicious anemia, jaundice, diabetes, and syphilis; (4) after taking Pb, Hg, I, P, As, Sb, chloroform, cantharides, oxalic, carbolic, salicylic or the mineral acids, turpentine, and nitrates; (5) in large amounts in acute nephritis and chronic parenchymatous nephritis; in small amount in chronic interstitial nephritis and amyloid kidney."

Glucose is found in urine as *"transitory glycosuria,"* "(1) in certain hepatic derangements, congestion, cirrhosis, and amyloid degeneration; (2) in many diseases of the central nervous system, with tumors or hemorrhages at the base of the brain, in meningitis, concussion, fracture of cervical vertebræ, railway injuries, in epileptic and apoplectic seizures, and also in certain diseases of the peripheral nervous system, as in sciatica and in tetanus; (3) in acute febrile diseases, pneumonia, typhoid, acute articular rheumatism, scarlatina, etc., particularly during convalescence; (4) under the influence of many poisons, such as curare, chloral, carbon monoxide, morphine, arsenic, and the anesthetics. As *'permanent glycosuria'* (1) in lesions of the brain involving the floor of the fourth ventricle; and (2) in diabetes mellitus."

Acetone is found in the urine "in febrile diseases when the febrile condition is prolonged, in certain mental diseases, such as general paresis, melancholia and epilepsy, after chloroform narcosis, in puerperal eclampsia, and in diabetes."

Pus is found in the urine in suppuration of any part of the urinary tract, and in case of rupture of an abscess into that tract.

Excess of indican is found in the urine "in hypochlorhydria; in hyperchlorhydria of gastric ulcer; in conditions in which there is diminished peristalsis of the small intestines, as in ileus and peritonitis, not in simple constipation; also in conditions in which putrefactive changes occur in the body elsewhere than in the intestine, as in empyema, putrid bronchitis, gangrene of the lungs, etc."

Test for Albumin.—The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for indican in the urine: The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.—From Witthaus' *Essentials of Chemistry.*

2. Two forms of urinary calculi: (1) Uric acid calculi, and (2) ammonium urate calculi.

Chemical tests: Saw the calculus in two, take some of the sawdust and heat it on a platinum foil. If it is entirely volatile, take a fresh portion of the dust, moisten with nitric acid, evaporate to dryness at a low heat, add some ammonium hydroxide solution; a red color will be produced. Treat a portion of the dust with solution of potassium hydroxide, but without heating; if an ammoniacal odor is observed, the calculus is *ammonium urate;* if no such odor is observed, the calculus is *uric acid.*

3. In cases of poisoning by the mineral acids magnesia in water, or a strong solution of soap should be administered. The same course of treatment should be pursued even if the acid is not known.

5. When diabetic urine is added to a heated alkaline solution of potassiocupric tartrate, a yellow or red precipitate is formed.

PATHOLOGY.

1. *Infarcts* are areas of tissue in which, owing to the plugging up of an end artery or terminal artery, nutrition is prevented.

Infarcts most frequently occur in the kidneys, spleen, lungs, base of brain, retina, and heart.

5. The gonococcus, on being implanted on the mucous membrane of the urethra, may produce: Gonorrhea, urethritis, prostatitis, orchitis, epididymitis, vulvitis, vaginitis, endometritis, salpingitis, by direct extension; conjunctivitis may result if the discharge is carried to the eye; by metastasis there may result: Gonorrheal arthritis, tenosynovitis, involvement of the pleura, pericardium, endocardium, or myocardium; also involvement of the lymphatic glands, *e.g.*, bubo.

To demonstrate the *gonococcus:* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly-made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

DIAGNOSIS.

1. In *acute pharyngitis* there is little or no systemic disturbance; the patient complains of pain and sore throat; the pharynx is red and dry; and there are no Klebs Loeffler bacilli present.

In *diphtheria* there is severe constitutional disturbance; an exudate is present, which is removable only with difficulty, and recurs after removal, and contains the Klebs Loeffler bacilli.

2. In *renal colic:* The pain is in the region of the affected kidney, it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In *hepatic colic:* The pain is in the region of the liver, it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

In *appendicitis:* The pain is at first diffuse, but later becomes localized over the appendix in the right iliac fossa; nausea, vomiting, and constipation may be present; tenderness over the appendix, and rigidity of the right rectus abdominis muscle are present; there is generally moderate fever.

3. In *tabes dorsalis:* There are lightning pains, loss of knee jerk, the presence of the Argyll-Robertson pupil.

In *ataxia paraplegia:* There are very rarely lightning pains, the knee jerk is exaggerated, ankle clonus is present, there is no Argyll-Robertson pupil.

PRACTICE OF MEDICINE AND THERAPEUTICS.

8. *Symptoms of poisoning by belladonna:* "In the first stage, that of delirium, there are dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely-dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration."

Treatment: Lavage of the stomach; morphine may be given cautiously during the period of violent excitement. Maintain respiration; strong coffee by the mouth or rectum is beneficial. Pilocarpine may be given, in not too large doses, to stimulate the secretion of saliva."—From Witthaus' *Essentials of Chemistry.*

SURGERY.

3. In posterior luxation of the hip joint the patient should be placed on a mattress on the floor, and then be anesthetised. The leg is then to be flexed on the thigh, and the thigh flexed on the abdomen; adduction is to be increased so that the knee is beyond the middle line of the body; then abduct, freely circumduct outward, and finally extend the limb so that it is parallel with the other.

OBSTETRICS.

10. Ophthalmia neonatorum is an infectious, purulent inflammation of the conjunctiva in the new-born.

It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

The treatment is: (1) *Prophylactic:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth. (2) *Remedial:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a two per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Jan. 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 1
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Jan. 5

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular state.

Mississippi.—At the recent examination there were one hundred and three applicants; but only thirty-three were successful. One of these is said to have been marked 100 in practically all the subjects. This is probably the highest grade that has ever been made by an applicant.

Connecticut.—At the July examination there were forty-seven candidates present; thirty-seven of these were successful.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending October 31, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	431	134
Diphtheria	321	21
Measles	145	3
Scarlet Fever	162	6
Smallpox	—	—
Varicella	81	
Typhoid Fever	85	19
Whooping Cough	26	4
Cerebrospinal Meningitis	9	5
Malarial Fever	—	—
Totals	1260	192

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending October 30, 1908:

OBSERVATIONS WITH THE ROGERS-TORREY ANTIGONOCOCCIC SERUM.*

BY GEORGE KNOWLES SWINBURNE, M.D.,

NEW YORK.

SINCE my paper on the Antigonococcus Serum in Epididymitis, read before this society in June, 1906, I have used the serum almost without interruption on a large variety of cases. Up to September, 1907, I used the serum furnished by Dr. Torrey of the Loomis Laboratory. After that date Dr. Torrey placed his method in the hands of the firm Parke, Davis & Co., who have furnished it to the profession for experimental purposes.

The cases treated since October, 1907, have had the serum furnished by that firm. There were in all during that period 69 cases—41 were dispensary cases and 28 were cases in private practice. The cases were as follows: Chronic relapsing epididymitis, 14; acute epididymitis, early stages, 27; muscular rheumatism, without joint involvement, 14; muscular rheumatism, with one or more joints involved, 10; purely joint cases, 5; chronic gonorrhea of kidney, 2; involvement of tube and ovary, 1; persistent presence of gonococcus in urethral discharge, 2; acute prostatitis, 1; acute vesiculitis, 1; threatening epididymitis, 1; rheumatism and epididymitis, 1.

In almost all the cases of relapsing epididymitis, ten of which were dispensary cases, there was marked improvement. The striking relief noted was in the diminution or quick cessation of the pain. These cases are more or less unsatisfactory, because they have been difficult to follow. Some go back to work too soon and only return because of further relapse, and as they have a variety of conditions in the anterior or posterior urethra, all of which require more or less prolonged treatment. in most of them the serum alone is not sufficient to prevent a relapse—still in all of them there was marked relief after the second injection.

One of these cases has proven very interesting: A. M., 28 years old, married, has had relapsing epididymitis for two years. In November, 1906, treatment was first begun. The right epididymitis had then existed for eight months without cessation; he had been in the hospital twice during that time and was treated at the dispensary in the ordinary way for two weeks without any change. The swelling was large, exquisitely tender, and he had a great deal of spontaneous pain. He received at that time about eight injections of the serum furnished by the Loomis Laboratory, covering a period of three weeks. After the first injection there was almost no pain, at the end of three weeks the swelling had completely subsided and the epididymis was perfectly normal. He then disappeared and returned the following February, when, without fresh infection, the right epididymis was again swollen and painful and again subsided under three or four injections of the serum. He again disappeared, returning in the early summer of 1907, having had a suppurating epididymitis on the left side. At the time he returned to us there was a sinus from the swollen epididymis leading to the surface. The discharge from the sinus was examined for tubercle bacilli, but they were not found, nor were gonococci. This was finally healed, leaving an atrophied left testicle. The right testis at that time appeared normal. He returned October 29, again with right epididymitis. On October 29 and 30, and November 2 he received the serum. He was relieved and remained away till December 17, when he again returned, having as before the right epididymis involved at this time. I examined his posterior urethra with the urethroscope and found a markedly hyperemic veru montanum, which was treated twice in addition to the serum. After relief of the pain he again disappeared, returning again January 14, 1908; received the serum a few days, was relieved, and disappeared. He repeated this same thing again in February and again in March, since which time I have not seen him. Each time that he returned he begged for the serum because of the relief it gave him, but as soon as the pain was gone he would go back to work, so that he received no systematic treatment.

The four patients in private practice were all cured. They received four or five injections of the serum, and then their other conditions were treated after the epididymitis was relieved, and there was no recurrence in these cases.

In the cases of acute epididymitis, 27 in all, the majority were relieved of pain within 48 hours, and almost all went on to uninterrupted recovery. In addition to these cases the following is the history of a case in the practice of Dr. W. S. Gottheil, treated with this serum, Dr. Gottheil writing me that he was much pleased with the result.

Walter B., aged 20, student, gonorrhea started November 24, 1907. February 16, 1908, epididymis began to swell. February 17, 1908, temperature 101°, very severe pain, swelling increasing. Injection of contents of one bulb; no reaction. February 18, 1908, temperature 100.5°, pain unchanged; evening temperature 102.5,° pain worse. February 19, 1908, passed bad night. Morning temperature 101°, swelling and pain unchanged. Injection of contents of one bulb. Evening temperature 100°, more comfortable. February 20, 1908, temperature 99.5°, affected testicle and epididymis less tender. February 21, 1908, temperature normal, no pain, swelling rapidly disappearing. Testicle dressed. February 24, 1909, swelling gone, condition normal, patient out of bed. February 23, 1908, seventh day after first injection, and fifth day after second injection, simultaneous

*Read before the American Association of Genito-urinary Surgeons, Hot Springs, Va., May 2, 1908.

local dermal reaction, as a localized urticaria around the sites of the injections. No treatment, remained 48 hours, disappeared gradually.

I should like to read here the histories of two cases which I treated in August, 1906, with the serum of Dr. Torrey, because I have never seen them equaled.

J. W. M., 22 years old, under treatment for two months with a primary attack of gonorrhea; telephoned me at 4 o'clock in the afternoon that he had severe pain in the testicle, that he was in the country and could not get to me before 10 o'clock at night as he had a long car ride in order to reach town. When he got to me the pain was intense, the epididymis was much enlarged but soft, and exquisitely tender. I dressed the testicle and gave him an injection of serum and sent him home to bed. The following afternoon, when he came to the office, there had been no pain since the previous night, the swelling had subsided, there was almost no tenderness, and the outline of the epididymis could be made out a little larger than normal. He received a second injection of serum. Two days later, when seen again, there was absolutely no trace of any inflammation. A third injection was given. The injections into the arms, however, were followed in a few days by a very marked reaction; both arms were swollen from the wrist to the shoulder and were painful on movement, and the glands in both axillæ were enlarged and painful. This subsided in two days without special treatment other than hot baths.

The other case, B. R., 25, a policeman, was under treatment for chronic prostatitis following a primary gonorrhea of two years before; was doing well and apparently going on to recovery, when he came one morning after an all-night tour having forgotten to wear his suspensory. The right epididymis was enormously swollen and painful. This was dressed and he received the serum then, and again in 48 hours, at which time there was no trace of the trouble and no pain. Three days later, however, after another all-night tour, when he had a long chase after a criminal whom he arrested after a fight, the epididymis was again swollen as large as before, but absolutely painless, and again subsided in a few days after the use of the serum, and then the treatment of his previous condition was resumed.

There were 4 cases of muscular rheumatism in connection with chronic gonorrheal disease treated with the serum, 2 were relieved, 2 received no apparent benefit.

There were 10 cases in which there was muscular rheumatism with apparent involvement of one or more joints. These were not pure joint lesions, but seemed to be involvements of the smaller joints, especially the feet, or pain about the joints rather than pain due to effusion into the joints, together with some evidence of gonorrhea, usually of a very chronic character. One of these cases was not relieved at all; the majority yielded promptly, while 2 of them, cases of long standing, seemed to fluctuate: better one day and full of hope, then worse another. One, in private practice, had a chronic urethral discharge containing gonococci, pain in the feet, calves of the legs, and back. This patient received four injections of the serum, one every other day, and for a few hours would experience relief from pain, and then it would return. After the fourth injection he disappeared. The other patient, M., 27 years old, has had rheumatism in back, knees, and feet. The knees are painful, but there is no effusion. Has had four attacks of rheumatism in the last four years, this last being the worst attack. Had, on coming to the dispensary, March 27, 1908, a tight stricture, in the anterior urethra and chronic posterior urethritis. Has had ten injections of the serum. At first there was slight improvement in the pain, the stricture has been dilated up to 26 F. from 19 F. In his case there will be but little improvement, until the urethral lesions have been completely healed.

The cases of pure joint lesions, one in the wrist, two in the knee, and two in the feet, all responded promptly to the serum. They all followed a primary attack.

The wrist case, M. A., 36 years old, came to the dispensary September 23. First attack of gonorrhea began fourteen weeks ago, was followed a week later with pain and swelling in right wrist. For six weeks was in the City Hospital, but left because an operation was ordered. Had severe and constant pain in right wrist. Marked swelling and fluctuation, fingers stiff due to adhesion of tendons. On September 23, October 6 and 8 received the Torrey serum. All pain was gone from wrist after the second injection. I could get no more serum till October 16. The pain had returned somewhat, but was not so severe. The amount of effusion was nearly as great as in the beginning. October 16 and 18 received serum, pain all gone. Serum again November 3, when note made—wrist reduced to normal. After this he received an injection of serum at irregular intervals, when he came, because of slight return of pain. The swelling and effusion did not again return, and he gradually regained the use of the hand.

The two cases of knee-joint were almost exactly similar: one came on during a primary attack of gonorrhea, the other two months after all symptoms had subsided. In each case, one of 18 days', the other of 10 days' duration, there was an immense amount of effusion, with a very painful joint—in each case within a week, the serum being given every other day, the effusion nearly disappeared, but after that remained slight in amount, the patients returning to work, and only returning for serum when there was a slight amount of pain.

In the two remaining cases the tarsus was involved. One, A. A., 35 years old, laborer, had first attack of gonorrhea four months before; had an attack of epididymitis in December, came in March. Several days before coming the dorsum of the foot was swollen, red, and painful; he was seen by an ambulance surgeon who incised the swelling; no pus appeared; there was at first some relief of pain followed by a return after the wound had healed. He received a single injection of serum, after which the pain was relieved and he returned to work.

In the two cases of gonorrheal kidney, gonococci had been found present in the urine from each kidney; both these cases were of several years' standing. After treatment in each case, gonococci could no longer be found in either kidney, but in each case the urine remained cloudy and one patient had at times a tinge of blood in the urine. Neither man had any pain. The serum was given several times in each case, but no change could be noted, the urine in each case remaining cloudy as before, and there was no reaction from the serum of any kind.

The case of involvement of tube and ovary is related here to call attention to the possible value of the serum in these cases, when they are acute, rather than for any result which I got in this case. The patient, Mrs. M., 28 years old, married seven years. Shortly after marriage was infected by her husband; shortly after this had severe pain in region of left ovary, and went to a hospital, where she was told

she must have an operation. This she refused and returned home. She remained in bed a while, gradually got better, and the following year had a healthy child, which is now 6 years old. Several months ago pain returned in the site of the left ovary, not so severe as it was seven years ago. Was again told she must have an operation. Her husband brought her to me March 26. There was pain on palpation over the left side of abdomen and palpation by the vagina gave more pain on the left side than on the right. I gave her serum March 26 and 28, when she disappeared. When she came, March 28, she said she was very much better.*

There were cases of persistent presence of gonococci in the urethral discharge. The first patient had had gonococci in a very slight urethral discharge. He had been under treatment a long time, and I believed that the focus of infection was in the prostate, having demonstrated gonococci in material expressed from this gland. The patient received two injections of serum one week apart, as he came only once a week to the office. The serum caused him so much discomfort and pain in the arm following its injection that he asked me to discontinue it. It is rather curious but though the patient receives massage and irrigation with a 1:1000 silbamine only once in two weeks, no gonococci have been found since February 23, the day he received his second injection. He still receives treatment every second week.

I am well aware that the serum is supposed to have no power over the gonococcus, but a similar case of a year ago is worth reporting in this connection. A patient who had been treated by Dr. Ackerman, one of my assistants, for six months by massage and irrigation, was sent to me for an opinion. This was in November, 1906. He had had his first and only attack of gonorrhea five years before, had been almost continually under treatment, but for several years had been practically in the same condition, though he had improved considerably during the past six months; but now his condition was again at a standstill. No gonococci were found in the slight discharge stripped from the anterior urethra, but the bladder urine contained these microorganisms, and as the prostate was still soft and material could be expressed, I advised the continuance of present treatment for another month, when he was to call again for an examination. At his second visit a month later his condition was practically unchanged. I then advised cessation of all local treatment and a trial of the antigonococcus serum. In the next six weeks he received about fourteen injections. At that time there was complete cessation of all symptoms. The prostate was normal, there was no urethral discharge, there were no gonococci in the urine, the patient felt well and better able to do his work. A beer test produced no change, and though he was followed by Dr. Ackerman for several months he had never had any return of trouble.

The second case on which the present serum was used, was peculiar, and I have placed it under the heading, persistent presence of gonococci, although it does not strictly belong here. But I think it worthy of an extended history.

Dr. W., 33 years old, from a neighboring city, came to me four years ago with a chronic gonorrhea which he had had for several years. He had a gonococcus-bearing discharge, profuse in character, a very large prostate, soft and full of material. After this had been cleared up, I found he had a badly strictured condition of the urethra, and after I had dilated him from 12 F. to 23 F., he discontinued coming.

A year later he came with an apparent fresh infection which was quickly subdued; the strictures were unchanged since last treatment, that is, had not progressed. He brought with him a brother physician from his town to see how I treated him, as he was to continue the treatment by dilatation. This proved unsatisfactory and he stopped all treatment. The following year he again appeared with an apparently fresh attack which was again quickly subdued, but he still neglected the stricture which was about as before. In February of this year he appeared again with a profuse gonorrheal discharge, which for two months he had been treating himself and was getting worse all the time. The day he came, the discharge was profuse, the posterior urethra was involved, and he seemed to be thoroughly infected. He was obliged to keep at work and could only come to me once a week. On the following visit one week later he had a beginning epididymitis, the discharge was still profuse, and the urine had the thick cloudy appearance which I have come to look upon as a precursor of epididymitis.

I injected the contents of one vial into his arm and dressed the testicle with guaiacol ointment. On his appearance the following week there was no discharge, the urethra was dry, the urine was perfectly clear. He stated that twenty-four hours after receiving the injection he began to feel better all over, the pain had left the testicle, the discharge abated, and there was no urethral discomfort. He received the serum twice more at weekly intervals. There has been no return of any of his symptoms, nor can the gonococcus be demonstrated.

I have reported these three cases at length, because, as a rule, in the large number of cases in which I have used the serum, the gonococcus has persisted after relief of the rheumatism or the epididymitis.

One case of acute prostatitis appeared, in which the serum was used once a day for three days with relief of the pain and throbbing.

One case of acute vesiculitis. This patient had been discharged by his physician as cured, though he complained of deep-seated pain which grew steadily worse, and I was called to see him at his home. He could not sleep, had been in bed all day with great pain. I found the left vesicle hot, swollen, and exquisitely painful. Within an hour after receiving the serum there was sufficient relief from pain for him to sleep. He received three treatments in all, was allowed to get up and go out. He attempted to go to work and a few days later developed an epididymitis on the corresponding side.

The case of threatening epididymitis was a case of gonorrhea at the dispensary, whose urine presented the thick cloudy condition which I mentioned above as a precursor of epididymitis. He received three vials at these visits. The urine remained thus cloudy for two months in spite of local treatment, but epididymitis did not develop. I cannot say that the serum prevented it.

With the cases here presented, however, as well as with cases treated the previous year and a half with the serum furnished by Dr. Torrey, I have come to rely upon it as a valuable aid in the treatment of these cases.

64 East Fifty-sixth Street.

*Since this paper was read, I saw this patient in the dispensary in latter part May, where she brought her child for vaccination. She stated that she had had much less pain than before she received the serum, but was not well; still she had had no treatment since that time.

ROENTGEN RAY FLASHES OR INTERMITTENT *X*-RAYS.

By FINLEY R. COOK, M.D.,
NEW YORK.

THE unique results following the introduction of Roentgen ray energy as a therapeutic agent led to its universal adoption by physicians, many of whom had no conception of the nature of this energy. When disastrous results became common among patients and operators alike, and particularly when these led to fatalities, a general fear was engendered which retarded the growth of *x*-ray therapy. Although considerable advancement has been made, as regards dosage, too little consideration has been given to physiological and therapeutic properties. All efforts made in the latter direction will tend to settle many of the *x*-ray mysteries, explain the radically different results obtained, dissipate the present public fear of *x*-ray treatment, and place Roentgen-ray therapy on a more scientific basis.

Radiant energy, just as chemical, mechanical, electrical, and heat energy, has four distinct therapeutic properties—sedative, stimulant, irritant, and escharotic. While most mistakes can be summed up in one word, overdosage, recent experimentation shows that this was the natural and unavoidable consequence of following the universal custom of administering *x*-rays continuously. Although the primary action of a continuous exposure is that of a stimulant, in the absence of both subjective and objective perceptibility, it stealthily passes to that of an irritant and finally to that of an escharotic. Even in the hands of cautious and skilful operators regenerative influences are shortlived, and when unskilfully handled the treatment generally results in degenerative tissue changes.

The endeavor to separate the purely stimulating from the irritative action led to the perfection of the *x*-ray flash which subsequent experience has shown not only to be regenerative, but which develops this potency to a hitherto unknown degree of efficiency.

Every agent for stimulation is employed intermittently, but if given continuously with the same intensity beyond a certain period, it becomes irritating and destructive. It is also a general law of stimulation that the power can be increased in proportion to the decrease in the time of action. Just as one would naturally surmise, this has been found to be equally true with regard to *x*-ray energy. By making and breaking the primary current, thereby securing flashes, it is possible to shorten the distance of the tube, greatly increase the amperage, eliminate the danger of the accumulative effect, secure greater penetration, and at the same time obtain a far greater degree of stimulation than has hitherto been possible with the continuous rays.

The degenerative action of the continuous and the regenerative action of the intermittent rays were first demonstrated in the eye. If a cataract approaching maturity were exposed to the continuous rays an ephemeral stimulation and improvement in vision was sooner or later followed by ripening through hyperstimulation or irritation. This discovery led to the development of a technique for maturing a cataract for extraction.

With flashes, however, although using much greater amperage, irritation and ripening were avoided in such cases, and in incipient cataract not only a purely stimulating and regenerating action was invariably obtained with more or less improvement in vision, but this effect could be maintained throughout the entire course of treatment.

Degenerative Actions of the Continuous Rays.—Continuous ray degenerations are both local and general. They vary from the hyperemia so commonly seen on the hand of *x*-ray operators to that of the deeply seated necrosis or *x*-ray burn. The former undoubtedly results from a paralysis of the vasoconstrictors inducing a chronic hyperemia which leads to a hyperoxidation degeneration of the skin and its glandular appendages. The skin becomes dry and wrinkled, the latter from oxidation and absorption of subcutaneous fat. Superficial irritation in such an area leads to papilomatous growths, while deep seated irritation or loss of continuity in the skin leads to fibrous growths. These phenomena may throw some light on the etiology of benign tumors, epiblastic and mesoblastic, the factors here being irritation and passive hyperemia. Subsequent exposures are apt to set up an obliterating endarteritis with degeneration of trophic nerves and the process ends in general atrophy.

The next stage is ulceration from the slightest trauma and repeated irritation favors malignant degeneration. Important deductions might be made from a careful study of these pathological changes, bearing upon the cancer problem, especially so, inasmuch as it is the first and only instance in the history of medicine where a definite agency has been found that has unquestionably produced cancer. Such evidence seems to point to the persistent irritation of degenerate cells, as one important factor.

The most common form of degenerative action is that which results from a prolonged course of treatment. Repeated bombardments with an accumulative action induce a chronic productive inflammation not unlike that resulting from alcohol, syphilis, and lead. Normal tissues degenerate to fibrous tissues characterized by a deficiency in glands, nerves, and blood and lymphatic vessels. Hence we may conclude that fibrous degeneration results from the persistent irritation of normal cells.

X-ray burns vary from a coagulation necrosis of the superficial epithelium, commonly called a dermatitis, to that of the deep seated ulcer. The peculiar pathological and clinical features of the deep *x*-ray necrosis are explained by virtue of its different modus operandi from all other forms of energy. The field of action is not only extensive, with greater penetrability, but the latter varies in different points of the field. Corresponding to these variations in the *x*-ray field we can recognize in the tissues three distinct zones of action, which also represent the three distinct pathological changes induced by *x*-rays; a central zone of absolute necrosis, and intermediary one of fibrosis, and a peripheral one of passive hyperemia.

Before healing is accomplished the area of necrosis must extend beyond and include the zone characterized by an obliterating endarteritis. These necroses are therefore always painful and progressive within certain limitations and the rapidity of progression is the most distinguishing feature when they undergo malignant degeneration.

The accumulative and degenerative action of the continuous rays is also observed in the blood-forming organs. While the primary action is one of regeneration with an increase of the red and white blood cells, especially the latter, degeneration is finally evidenced by a decrease. This has been most strikingly demonstrated in the prolonged exposures to which animals have been submitted, and notably so in one case, in which the autopsy revealed the total destruction of the white cells and a diminution and disintegration of the red cells.

Highly specialized cells are most susceptible to

this action, which accounts for the well known action of the *x*-ray in producing sterility. In the hair follicles the primary regenerative action is shown by a new and more vigorous growth which causes temporary baldness in displacing the old growth. Degenerative action is shown by the permanent baldness which follows prolonged and powerful exposures. In the organs of special sense, blindness and deafness have resulted after a prolonged treatment for recurrent cancer in close proximity to the eye and ear.

Clinically, the variable results obtained by *x*-ray therapists in treating various disorders demonstrate the same peculiar accumulative property of the continuous rays. In tuberculous adenitis glands that do not yield after a certain period become more resistent and are more apt to break down, as the treatment is continued. This is undoubtedly due to a degeneration of blood and lymphatic vessels and an impairment of the primary leucocytosis.

In the treatment of deep cancer the rule has been at first an improvement in these cases and finally a marked increase in the rapidity of growth. The former is undoubtedly due to a general cellular regenerative action and leucocytosis, the latter to a local degenerative action in the normal cells surrounding the growth and irritation of the cancer cells from the failure of the operator to discriminate between the radically different impressions which must be made upon the malignant and the environing normal, or at least, non-malignant, cells.

The same therapeutic transition is likewise accountable for the difference of opinion with regard to the efficacy of *x*-rays in leukemia, pseudoleukemia, and pernicious anemia. The best results have been obtained by small dosage frequently repeated. With average dosage the rule has been marked improvement for a time, followed by a more rapid decline. With maximum dosage a few cases of rapid fatality have been reported.

In chronic Bright's disease the same experience has been repeated. There have been some favorable and a few disastrous results. The dictum, "beware of *x*-rays in chronic diffuse nephritis," is readily seen to be based on simple scientific principles, when we consider that the accumulative action always induces the same pathological changes that exist in a chronic interstitial nephritis, and hence must only aggravate these cases.

Regenerative Action of X-Ray Flashes—The regenerative action of flashes is both local and general and is accomplished principally through their action upon the blood vessels. They dilate arteries, lower blood pressure, and induce an active and natural hyperemia. They stimulate cellular metabolism without exhaustion and each subsequent stimulation is followed by an improvement in cellular vitality, a stepping up process as it were, made manifest in a regeneration of tissue. This phenomenon has been accomplished in bone, nerve, muscle, glandular, vascular and epithelial structures. In the eye it can be obtained in the cornea, iris, crystalline lens, choroid, retina, and optic nerve.

As an active hyperemia is always in evidence when the natural forces are engaged in defensive or regenerative work, the frequent association of an abnormal pulse-tension ratio with either a local ischemia or passive hyperemia, in localized degenerations, indicates an inability on Nature's part to establish an active hyperemia through some loss of equilibrium in the forces that control the circulation. The local hyperemia of powerful *x*-ray flashes is too constant and too manifest to be open to doubt, and explains the local regenerative action of the rays in diseases of chronic degeneration.

To appreciate their action upon the general circulation, their vasodilating power on the whole arterial system, and hence their influence on general metabolism, we have to observe their influence on the heart and systolic blood pressure or pulse tension ratio.

With a high tube focused over the chest and abdomen, the pulse rate has been lowered ten beats per minute, and the blood pressure ten manometers with one instantaneous flash. With sixty such flashes, a fall of sixty manometers, and thirty-five in the pulse rate has been accomplished in a minute and twenty seconds. The subject is too vast for consideration at present, but we might add that the effects upon the general system are most remarkable and in selected cases seem equivalent to a saline infusion. These observations undoubtedly give an important clue to the physiological and therapeutic rôle which *x*-rays play in their general regenerative influence in chronic and local degenerative diseases, especially as such that have been favorably influenced by Roentgenization are almost invariably associated with a disturbance of general metabolism.

Therapeutic Application of Intermittent Rays.—*X*-ray flashes have been used in both acute and chronic infections. Tension is lowered, the circulation is improved, leucocytosis is induced, and a more rapid recovery has been effected.

In fatty degenerations and infiltrations a regenerative action is obtained. In these conditions *x*-rays stand out in contrast with the action of heat. With the former there is little or no loss in body weight, showing that coincidently with the ovidation of fat there is a development of normal tissue. In one instance where immense fatty deposits in the calf and around the knee-joint were exposed to *x*-ray flashes, a diminution in circumference of three inches was effected in ten treatments, with a development of the muscles of the lower extremeties. In cystic degeneration the regenerative *x*-ray action has been demonstrated. In one case the result was most unique. A mass the size of an English walnut, situated in the breast, having been observed for two years, disappeared entirely after one treatment.

In the degeneration leading to fibrosis, this regenerative action has been observed in many and varied conditions. The rapidity with which recent scar tissue becomes permeated with new blood vessels is at times almost incredible. Breaking down and displacement of the fibrous elements with normal epithelium ensues after complete vascularization. In corneal opacities the latter does not obtain, but absorption takes place through an indirect regenerative influence on the corneal cells and a hyperemia of the normal blood-vessels that supply nutriment to those tissues. In varicose veins the hard and thickened walls have become soft and elastic and thrombi removed through absorption. Regeneration is most likely effected through a hyperemia of the vasa vasorum.

In arteriosclerosis the same regenerative influence in fibrosis has been amply established.

This is shown by both local and systemic changes in senile degeneration. Numerous cases of senility have been treated by the *x*-ray flashes. The local morbid processes in these cases have been an epithelioma, rodent ulcer, chronic eczema, senile cataract, and impairment of vision through senile changes in the various tissues of the eye. They are almost invariably associated with mental worry, irritation of local cells, and a high arterial tension.

In some instances, in which the local condition has ceased to be progressive, the blood pressure is either normal or below normal, the latter showing a natural reaction. With the high tension the heart's action is either rapid or slow, sometimes intermittent, but invariably exaggerated. With the low tension, either fast or very slow, but always sluggish. Local improvement is always accompanied by more or less general rejuvenation and a radical change in the pulse tension ratio. Further proof of the regeneration of *x*-ray flashes is seen in their influence in degenerations induced by the accumulative action of the continuous rays. Favorable results are being obtained in *x*-ray hyperemia, necrosis, fibrosis, and atrophy. In one instance some vision was restored where total blindness had resulted from overdosage during the treatment of a malignant growth in close proximity to the eye, and in another hearing was restored where it had been lost in a similar manner. In both cases there was an extensive facial necrosis with ulceration that had existed for a period of more than four years. While regeneration was tedious, it began immediately after the first treatment. In one the pulse was 120 and the systolic blood pressure 175 manometers before treatment: after 200 flashes which a fluoroscope detected at a distance of 60 feet the pulse dropped to 76 and blood pressure to 125 manometers. The head and face were flushed with arterial blood which began to issue from the necrotic area. A regenerative process began at once, and many new blood vessels, both arteries and veins, appeared and extended throughout this area. Sensation which had been absent for four years was in time restored, showing a regeneration in nerve tissue. The gradual exfoliation of necrotic cells through an aperture in the cornea pointed to a new growth of cells within the eyeball, and eventually perception of light, and even the motions of the eyeball, were restored. Inasmuch as many *x*-ray operators are suffering from the accumulative action of the rays while no form of treatment has hitherto been found to afford relief, it would seem that in these cases much might be expected in the skilful administration of *x*-ray flashes.

In the treatment of chronic skin diseases intermittent rays possess every advantage over the continuous rays. Not only is the danger of degeneration entirely eliminated, but results are more readily obtained. In tuberculous glands this technique gives better satisfaction. A medium to hard tube is employed, amperage 10 to 25, distance of tube from 12 inches to contact, and the number of flashes is gradually run up from 200 to 1,000 or more. After an active hyperemia has been induced, which may persist for several days, treatment should be suspended until the hyperemia subsides. Following this line of treatment the glands do not break down or become unyielding by virtue of the fact that there is no impairment or destruction of normal tissues.

In raying the deep seated organs, the intermittent method of administration is the only one that permits of prolonged and powerful treatments without damaging the skin and superficial tissues. This method can also be utilized in fluoroscopic examinations. Many physicians have abandoned this useful means of diagnostic precision in fracture work, on account of the danger to both patient and examiner. Intermitting the rays during such examinations not only eliminates all danger, but serves to maintain a more uniform degree of vacuum, prolongs the life of the tube, and strengthens the vision of the operators by virtue of the tonic action of the flashes on the retina and optic nerve. The discovery by the writer of the regenerative influence of *x*-ray flashes in degenerative conditions of the eye has led to its employment in more than a hundred cases which are now being prepared for publication. These cases include atrophy of optic nerve, detachment of the retina, chronic glaucoma, cataract, keratitis, leucoma adherens, staphyloma, chronic iritis, iridochoroiditis, and impairment of vision not associated with any specific local disease.

In a number of cases where the blindness was of such a degree as to necessitate the use of a guide, sufficient restoration of sight has been given to enable the patients to be independent and to read ordinary print. Perception of light has been obtained where it had been lost for twenty years. In one case where vision was only perception of light for a period of eight years, it was restored to that of reading large print in one treatment. In one case where vision was zero, and had probably been so for twelve years, ability to count fingers and read large type at close range was obtained after two weeks' treatment. In several cases where vision was only perception of light for less than two years' duration, ability to read large type was obtained.

Failures have occurred in extreme cases of more than one year's standing, but we have rarely failed to obtain some improvement in fairly severe cases of comparatively short standing, and moderate but always grateful results in moderate cases of long standing.

Mechanism of Flashes.—Roentgen-ray flashes are made by a special apparatus. It consists of a small motor, a condenser, and a moving shaft. It can be regulated to give from sixty to six hundred flashes per minute. Treatment is measured either by the number of flashes, which is preferable in eye treating, or by the measure of time, having estimated the number of flashes per minute. The record also includes the amperage and distance of tube. The quality of rays remains decidedly more uniform with the intermittent rays and there is an economy in tubes, coils, and current.

Conclusions.—1. A simple and prolonged stimulation can be obtained only by an intermittent bombardment of tissue cells.

2. An intermittent bombardment not only eliminates the dangers arising from *x*-ray treatment, but enables us to increase the amperage, and hence to obtain a far greater degree of stimulation.

3. With flashes we do not use any protective measures, and inasmuch as the general action is just as important as the local, if not more so, the whole body is included in the *x*-ray field, the rays of maximum intensity being focused on the local area under treatment. For the same reason we use a tube approaching hardness.

4. The effort to secure pure stimulation by the customary continuous method was against the established principles of stimulation and must be attended with danger, as experience has amply shown.

5. In all conditions where *x*-rays have been useful it has been due to their general as well as their local action.

6. The general action is shown by the inevitable improvement in general metabolism with a local regenerative action in an area of localized degeneration.

7. The most striking proof of the systemic action is obtained through sphygmomanometric observations.

8. Sedation is obtained by a mild and continuous bombardment. This suggests low amperage with tube at a distance measured by feet rather than by inches. Tension is lowered and tendency to sleep

induced. This is an *x*-ray bath. The whole body is included in the *x*-ray field.

9. Escharization is obtained by a powerful and continuous bombardment. Maximum amperage, minimum distance, maximum time of exposure. All normal tissues should be thoroughly protected with heavy sheets of lead with an opening exactly corresponding to the parts to be destroyed.

10. Irritation is obtained by a moderate and continuous bombardment, prolonging the time of exposure or by repeated exposures. It comes through over-stimulation, which is the primary action. Like all irritants, it tends to induce a fibrosis, obliterating endarteritis, and culminates in atrophy. It should never be used on normal tissues, and when used on local morbid cells the surrounding normal cells should be carefully protected by sheets of lead foil.

In a general way we may state that it is our conviction that the evolution of Roentgen-ray flashes not only eliminate the danger of *x*-ray treatment, but that this method will extend the field of its influence, that its use in the eye will prove to be its most valuable therapeutic application, and there is a strong probability that if employed skilfully in the early and acute stages of many heretofore incurable diseases of the eye, it may prove to be a valuable preventive of blindness.

120 East Thirty-fourth Street.

SOME NOTES ON THE MEDICAL TREATMENT OF INFLAMMATIONS OF THE BILIARY TRACT.*

By WM. N. BERKELEY, A.B., M.D.,

NEW YORK.

The writer of this paper was one who, in his medical school days, listened with the ready conviction of youth to the confident claims of his surgical teachers that cholecystitis and chronic cholangitis, with and without stones, are surgical diseases. It has been only through a rather shocking series of experiences in recent years that his faith has been shaken and he has felt serious temptation to go over to the unbelievers.

There is a little touch of grim humor in the recent statement of a well-known Philadelphia surgeon, as follows: "The actual work at the operating table has been the prime factor in elucidating the very obscure facts in connection with the etiology, pathology, and diagnosis of cholelithiasis, assisted though it has been by many brilliant researches, and careful post-mortem pathology."

With admirable reserve the author has failed to add that the careful post-mortems have been largely on surgical cases of fatal termination. After having done about a baker's dozen of such autopsies myself in the last four years, all from the hands of reputable surgeons of large experience, I have been induced in the cases coming clinically into my own hands to consider far more seriously and anxiously than formerly the alternative methods of treatment. And I have been so surprised and pleased at the results that it seems worth while to talk about them, albeit much of the ground has been already acrimoniously disputed.

To introduce the subject of treatment a few brief notes on the causation of inflammations of the bile tract cannot well be omitted.

Upon the bacteriology it is not my purpose specially to dwell. Exhaustive and competent studies have referred most of the cases of cholecystitis and cholangitis to the typhoid germ, to *B. coli,* or to the common pus organisms. The same germs are very frequently present in the bile of normal gall-bladders. When we recall the speed with which pyelitis may complicate inflammations of the urinary bladder, or the ease with which the influenza germ creeps from the pharynx into the middle ear and the accessory sinuses of the nose, it seems reasonable enough to suppose that bacteria in the biliary tract work in from the gut.

In order to start up an inflammation we should expect, as elsewhere, an increase in the virulence of the infective germ—as doubtless happens in catarrhs directly transmitted from the duodenum—or a solution of continuity of the biliary mucosa resulting from mechanical injury.

Such damage results occasionally from rupture of an echinococcus cyst into the ducts, one or more daughter cysts causing a blockade of the bile. Two such cases have come under my notice in the last two years. Very rarely one or more roundworms may crawl into the choledochus communis, causing a dangerous condition not recognized usually until the autopsy is performed. Other intestinal parasites have been also found, but generally these are mere clinical curiosities. Far and away the most common source of trouble is gallstones. In order to understand more of gallstones, and to refresh our memories, I quote for convenience of reference a recent analysis (Halliburton) of the constituents of normal bile: A fat-splitting ferment; sodium glycocholate; sodium taurocholate; biliverdin; bilirubin; a mucinoid substance, and small amounts of fats, soaps, cholesterin, lecithin, urea, chloride of sodium, and phosphates of calcium and iron. Its reaction is faintly alkaline or neutral.

Regarding our knowledge of the bile itself we have made few advances upon the classic work of Frerichs in the sixties of the last century. The newest text-books of physiology are still quoting Frerichs's chemical analyses. One important statement of older writers has been modified, namely, that normal bile kills germs. It seems quite certain, in the light of recent work, that the bile is only feebly, if at all antiseptic.

Gallstones consist mainly, it is said, of cholesterin, which is mixed with varying quantities of epithelial detritus, inspissated mucus, phosphates of calcium and iron, and bilirubin. Cholesterin is a curious substance of which little is known, not even its exact chemical relations, nor whether it is a secretion or an excretion. It is commonly supposed to be a monatomic alcohol of the terpene series. It is soluble in ether, chloroform, dilute acids and alkalies, bile, and various other reagents. It appears to be quite easily soluble in the intestinal juices, as is evidenced by the eroded and seamed appearance of gallstones passed per rectum.

It has been known for many years that stones, even up to the number of many hundreds, may exist in the gall-bladder through long periods of time without symptoms. Several series of autopsies have been reported in which 5, 10, 15 and even 25 per cent. of all the gall-bladders examined contained stones. They may antedate or follow catarrh of the tract.

Exactly why they appear is little better understood to-day than it was by our professional grandfathers, and that, too, in spite of a vast deal of intelligent and scientific labor. A recent paper of Kramer's is illustrative (*Journal of Experimental Medicine,* 1907, IX., 309). Kramer was able, by growing typhoid and colon bacilli in bile and alkaline peptone, to produce in about four weeks a closely packed, semi-solid mass in the bottom of

*Read before the New York Medical Union.

his tubes corresponding in chemical analysis to the make-up of gallstones. He thinks he has thereby shown that certain bacteria play an important part. A brief notice of similar literature would require many pages. So far, however, no conclusions of more than provisional value have been arrived at.

A familiar clinical fact is that stones are more frequent in women than in men.

Another fact of importance, now well attested by statistics from both continents, is that 95 per cent. of all cases of cholelithiasis occur after the thirtieth year, and 20 to 25 per cent. after the fiftieth year. This I mention with some emphasis here because it has important relations to treatment.

Volumes could be filled with the futile and unscientific speculations as to the formation of stones, which have appeared from time to time from the pens of medical men who were never in a chemical or pathological laboratory in their lives. Some have laid their appearance to beer drinking, some to drinking too little water; some to eating too much fat; some to an excess of carbohydrate or proteid. I have no heart myself to add another guess. I shall only call attention to the simple fact, true of all solids in fluid solution, that the probability of precipitation increases with the concentration of the solution and the sluggishness of its movement. That is, simply, that the thinner the bile and the faster it flows, the fewer the stones and the smaller their size. This fact, we may note incidentally, seems enough to explain the prevalence of gallstones in women. Their habits are sedentary, their tissues often relaxed after child-bearing, and their anemia being on the average greater than that of men, tends to reduce the muscular tone of the gall-bladder.

As a preliminary argument for medical treatment we may fairly, and without prejudice, enumerate a few of the surgical difficulties encountered in operations on the bile-tract.

First of all, the anatomical structure of the parts makes interference with the biliary tract *vi et armis* one of the most ticklish tasks in abdominal surgery. Many surgeons are lacking in the manual dexterity required to do this work in even a passable way. Furthermore, one can have no previous notion, in any individual case, even if nothing more critical than a cholecystotomy is projected, whether the gall-bladder hangs below the lower edge of the liver, or is retracted far behind it. In the latter case it is proposed to make a path for the escaping bile by stitching up a canal in the adjacent peritoneal tissues to reach as far as the opening in the belly-wall. All I know of these is what was left of them at the autopsy after general peritonitis had set in. Again, old and dense adhesions often bar the way to the ducts in the very cases where a supposed stone is most loudly calling for removal.

The new connective tissue around the ducts, furthermore, is often so thick that it simulates stone when no stone is present.

Again, even after a stone has been removed, stitching up the ducts at the bottom of a surgical opening six inches deep and dark as Erebus, is no easy undertaking. The portal vein, lying just behind and to the left of the choledochus, is apt to be caught in the stitches, even if they can be inserted.

Still another troublesome and sometimes disastrous fact is the frequent coincidence of general jaundice, which increases the hemorrhage, retards the healing, and at times precipitates a fatal result.

We must not forget, also, that the shock incident to surgical operations on the gall-bladder is unusually profound. In patients over fifty it is by no means inapt in itself to be fatal. My last three autopsies were all on such cases. But it is precisely in such cases that the operation has oftenest to be performed.

If it be said that suppurative processes in the bile tract never recover without operation, I rejoin that while this is the usually accepted statement, yet there is no hard-and-fast line in this region, between the so-called catarrhal and the true suppurative inflammations, and all cases ought to be first given a chance for palliative measures to be put into rational operation before the surgeon is called.

Lastly a permanent biliary fistula may result.

With these difficulties (of all of which I have personal knowledge) staring us in the face, it becomes a matter for serious thought whether medical measures may not, in all but the plainest suppurative cases, have some greater value than we are in the habit of allowing.

I shall first mention some therapeutic practices "more honored in the breach than in the observance," and afterwards sketch the mode of medical treatment that seems best to meet the indications.

First of all let me say that there is no solid nor fluid medicament so far known which will have any perceptible effect in dissolving stones already present in the gall-bladder. The old French method of giving ether and turpentine on the supposition that they are eliminated in the bile, and will gradually wash away gallstones, is neither warranted by experiment nor justified by clinical results.

The olive-oil treatment owes its celebrity solely to the lumps of oil-soap (sodium oleate) made by the reaction of oleic acid with the alkaline juices of the gut, and slightly simulating gallstones. Analysis of these concretions will show to anyone's satisfaction that they contain few or none of the constituents of true gallstones.

A particularly dangerous practice is massage of the liver and of the region of the gall-bladder.

The medical treatment obtaining the most general indorsement of conservative practitioners may be considered under the heads of drugs and mineral waters, diet, and exercise.

I need not stop to say again that no drugs so far known have the least demonstrable solvent effect upon gallstones, any more than upon stones in the kidney and urinary bladder. We may, however, select among a large number of medicines which have more or less effect in increasing the fluidity of the bile, and apparently stimulating its secretion.

Any of the saline purgatives will act in this way to some extent. Sodium phosphate in dilute aqueous solution before breakfast has long been approved. The alkaline mineral waters have this additional advantage, that they are in extremely dilute solution, and the patient in taking his medicine is compelled to take a large amount of water at the same time. Glycocholate and taurocholate of sodium have been experimentally and clinically proved to be direct and very valuable cholagogues. Their nauseous taste, long a serious objection, has been latterly removed by dexterous admixtures in several of the new proprietary preparations, and they may be given as required.

Inasmuch as glycocholates and taurocholates are both split in the alkaline intestinal juices into cholalic acid ($C_{24}H_{40}O_5$) and a by-product, it has been also proposed to give cholalic acid directly, and the results so far with my own patients have been better than with anything similar that I have personally tried.

It is claimed for all these drugs only that they

put into healthy condition an inflamed biliary mucosa, enabling the gall-bladder to take care of the stones it already contains, facilitating the discharge of those already actually lodged in the ducts, and preventing the formation of new stones.

All these remedies, furthermore, reduce intestinal putrefaction, move the bowels more freely, promote digestion, and by improving the patient's general condition, increase his resisting power all along the line.

Anti-fermentative drugs, like salol, are often helpful. I have one patient, a lady of fifty-eight years, who liked salol so well some years ago, when she was recovering from an attack of cholecystitis, that she has kept a box of 2-grain tablets by her bed at night ever since—for use when in discomfort from flatulence.

Patients will ultimately find out for themselves what laxative remedy suits them best. By some means or other it will be absolutely necessary to keep the bowels open. Copious enemata are good.

Regarding exercise and hygiene, it will, of course, be a matter of common sense that riding in rough vehicles over stony roads, horseback riding and tight lacing should be forbidden. If any lady can be found who is willing to support her skirts by shoulder straps, she should by all means be advised to do so. Regarding diet for such patients the received authorities differ, and differ so radically that one is soon led to suspect the truth, namely, that we do not know enough yet to lay down any rules of general applicability. Practically I have found that to most patients a mixed diet will be most suitable, and that they may be allowed within limits almost any article of food that agrees. During the existence of jaundice of course fats should be excluded.

Finally—and this is a matter of great importance—the quantity of food should be small at each feeding, and the intervals between meals short. The reason for this is simple: At every feeding the gall-bladder contracts, the papilla dilates, and bile is discharged into the gut. Frequent meals hence prevent a stagnation of bile and, *a fortiori*, a precipitation to make stones.

I would remark, finally, that the diet and hygiene of these cases are fully as important as medicine. Almost all recurrent attacks of cholecystitis are associated with a fresh attack of indigestion.

PROPHYLAXIS VS. TREATMENT, OR PREVENTION RATHER THAN CURE.

By SAMUEL WESLEY SMITH, M.D.,

NEW YORK.

The war of extermination now being waged against house flies and mosquitos by the Government and by various Boards of Health throughout the country promises at no distant date to considerably diminish the number of these intolerable pests and transmitters of disease. Simultaneously, the war against tuberculosis is being prosecuted with vigor, not only in the United States, but in all other civilized countries. Independent of the value of tuberculin, as a preventive or as a remedy for consumption, the means adopted to stamp out the disease are bearing salutary results, and at no distant date tuberculosis may be relegated to the limbo of ailments which have ceased to be a menace to humanity. It is the same all along the line; medical science in its persistent efforts to eradicate disease will doubtless leave to the physician of the near future, as his special, almost sole work, prevention rather than cure. Physicians recognize, as never before, such agencies as proper diet, pure air, environment, and absolute cleanliness as essentials in the cure of the sick; less reliance is being placed upon medication. Prophylaxis rather than treatment seems to be the salient feature of recent medical practice.

Hence the physician of the future may be glad to adopt the method of the Chinese physicians and be paid for preserving health and beautifying human life and not for curing disease.

Strange that in our medical practice we are now reverting to methods of treatment recommended in the Papyrus Ebers, written in Egypt in the year 3500 B.C. In that, the most ancient medical writing, special emphasis is placed upon cleanliness as a preservative of health, and in the case of sickness careful attendance, proper diet, and pure air are recommended. The Children of Israel, who were in medical practice the followers of the Egyptians, also recommended similar methods for the continuance of health and the removal of disease. Even a cursory reading of the Pentateuch will show that various laws were embodied in the religious code of the Israelites which had special reference to the preservation of health and the eradication of disease. In cases of plague and diseases of a peculiarly offensive nature, the wearing apparel and bed clothes of those afflicted were burned.

But the general practitioner, in that future of which medical optimists dream, will have his place and it will by no means be a narrower sphere of operations. From the dawn of life until its close, he will be the friend, the consoler, the preserver, and the confidant of the family. He will be no less competent to deal with troubles of the mind than with disorders of the body, and his aim will be to preserve the *mens sana in corpore sano*. He will prescribe the rules of health and correct living, and through his beneficent influence and abhorrence of the artificialities and habits which have debased human life, he may aid in restoring to man the physical perfection of the Apollo Belvidere and to woman the symmetry and beauty of the Venus de Milo.

Among the ancient Egyptians and the Children of Israel the priests attended to the physical ailments, as well as to the spiritual needs of the people. In the new era now dawning upon the medical profession, it is not unreasonable to suppose that the physician will perform somewhat similar duties. Brought into the most intimate relationship with patients and their families his voice would be potent on the side of good morals and correct living. Essential as these are to health of body and mind he could not be accused of going beyond his sphere in becoming a preacher of righteousness—a righteousness which not only exalts a nation, but which also sanctifies and purifies individuals, and keeps them wholesome and clean.

Needless to say there is a great deal to be done before the dawn of the auspicious day I have been anticipating. The public, however, are alive to the importance of adopting measures for preventing disease and conserving health. In the department "News of the Week," in the Medical Record of July 18, the health plank in the platform of one of the great political parties is quoted. This plank recommends the organization of all existing national public health agencies into a National Bureau of Public Health, with such powers as are properly within the jurisdiction of the Federal Government.

Several sources of danger apparently have been lost sight of in the precautionary measures adopted to prevent disease. Many of the vessels arriving in this port are in an unsanitary condition, and though

no specific disease may exist on them, disease germs may be conveyed from them by passengers and sailors. A thorough process of cleaning and fumigation would remove this danger.

It is notorious that sleeping cars and even other passenger cars are sources of danger, not only to those traveling on them, but to the public at large. Though generally well ventilated in summer, they are at all seasons improperly cleaned, especially the sleeping cars, and are never so cleaned as to remove, or render innocuous, all disease germs which may be lurking in plush covered seats, carpets, and hangings, awaiting a proper medium for their development in the human system.

Sleeping cars upon arriving at the terminus of a journey should be fumigated or cleaned with the suction pneumatic cleaner, and not by the compressed air blow pipe, as is now in general use. In fact all cars on passenger trains at the end of each and every single trip ought to be subjected to the same purifying process. The Board of Health of New York City, I think, has an opportunity in this direction. It should compel railroad companies either to fumigate their sleeping cars upon arrival in the city, or to have them cleaned by suction pneumatic cleaners such as are now in use by some of our best equipped hospitals. If the Board exercised its authority in this respect, instead of ordering the indiscriminate slaughter of dogs during the summer months only, it would confer a greater boon upon the public, for the fact is that cold weather does not make a dog immune from hydrophobia any more than it makes a man immune from typhoid fever; besides there are so few who die from dog bites as compared with the number who die each year from infectious diseases. In this connection, I desire to direct special attention to the suction cleaners, as a preventive of disease. While they do not, of course, destroy any disease germs, they largely remove them from carpets, rugs or hangings, and capture the germ-laden dust which can easily be taken care of. Small suction cleaners, as easily handled as the ordinary carpet cleaner, or the whiskbroom and dustpan of the sleeping car, are now on the market, and they can be used in private houses and public places with excellent effect. The ordinary carpet cleaners have the fatal defect of removing only the heavier surface of bacteria-laden dust, while others dangerous to human life are left undisturbed or are sent adrift by the whiskbroom or rug-beater in the air to be inhaled by any person who may be there at the time.

I have been led to make the foregoing reflections by a case which attracted my attention not long since, when I had occasion to spend a part of two days and one night in a sleeping car returning from a Western city to New York. It so happened that a lone traveler like myself occupied in the sleeper a section opposite mine. I became interested in the man; his emaciated appearance and the drawn look of the face with the tell-tale rose-colored spot on the cheeks, the clubbing of the fingers, attacks of spasmodic coughing, followed by shortness of breath, and the sputum of a greenish-gray which he expectorated on the spittoon, attracted my attention and enlisted my sympathy. I did not need a bacteriological examination of the sputum to enable me to diagnose the case as one of pulmonary tuberculosis.

I casually made the inquiry as to his destination. He informed me that, by the advice of his physician, he was going to the North Woods to get rid of malaria and intermittent fever. "You poor man," I said; "if the change of climate and environment rids you of your malaria and fever, remain in the woods all winter and next summer and next winter too."

It is to be regretted that in this enlightened day such mistakes in diagnosis are made—yet they are.

On the morning of the second day when the sleeper had been turned into a day coach I saw the porter of the sleeper with his whiskbroom and feather duster vigorously dusting seats, carpets, and the wearing apparel of the passengers, *not* forgetting a frantic effort at dusting the top of the spittoon. Had the sputum deposited by my consumptive friend become sufficiently dried so as to be a part of the million particles of dust that had settled on it, and were its tubercle bacilli being dissipated with the cloud of dust through the car? We cannot deny the possibility or even the probability of this being so.

Again, a case of scarlet fever in my own practice leads me to believe that more care and supervision by the various Boards of Health throughout the country ought to be inaugurated.

Some time ago I was called to see a child who had recently arrived from a Western town. The little girl of five years had occupied a stateroom in a sleeping car with its mother for a day and a night. It was on the morning of the fifth day in the city that I was called to the bedside of the little patient. I found a temperature of 104°, reddened throat, and the strawberry tongue. My diagnosis was, probably, scarlet fever, which subsequently proved to be correct. At the time of my first visit the mother was very loath to accept my diagnosis. She informed me that there was no sickness of any kind at her Western home and that the child had not been out of the house for two or three days preparatory to leaving for New York; nor had any children visited the home of the patient during this time. There was certainly no scarlet fever in the house where my patient was nor had she been out of the house during the first two or three days following her arrival here. Hence I was led to the conclusion that in all probability the disease was contracted in the sleeping car. We cannot consider such a case in any way unique.

Remedial measures to become effective must be comprehensive and universal. When the medical profession, keenly alive to its responsibilites, is aided by Government and State officials and an intelligent public in the war against all kinds of pathogenic bacteria as well as *Bacillus tuberculosis*, we may reasonably hope for the disappearance of at least all preventable ailments that for ages have afflicted the human race.

7 West Twenty-sixth Street.

THE SURGICAL SITUATION.

By LUCY WAITE, B.A., M.D.,

CHICAGO.

HEAD SURGEON MARY THOMPSON HOSPITAL.

Twelve years ago a clarion voice rang throughout the professional world calling a halt on reckless surgery. In his address before the American Medical Association at Atlanta our lamented surgeon Nicholas Senn accused the profession of being dominated by a *furor operativus*, and warned the overbold surgeons that they were laying up wrath against a day of wrath. If his charges were true at that time with how much more force do they apply today?

The *furor operativus* seems to have only gathered momentum during these years until today it has burst upon the surgical world in all its fury, bearing down before it all other branches of the medi-

cal profession, anatomy, physiology and pathology, medicine curative and prophylactic all must make way for the knife which like an all conquering and all powerful giant stalks through the medical ranks leaving, alas too often, devastation and ruin in its path.

We are rapidly becoming a nation of scars. Is this a necessary condition? If so, let us satisfy ourselves that it is, resign ourselves to our scars and forever after hold our peace. If it is not necessary let us rise up in our might, for when aroused we are a mighty people, and turn back the sharp edge of the surgeon's knife. Let us insist that the surgeon shall stop cutting long enough to take a deep breath and hold converse with the pathologist, the neurologist and the physiologist, yea, even the anatomist, and the men of medicine might give him a few clarifying points.

The time has come when a reformed movement is bound to be inaugurated. If it does not come from within it will come from without. If we do not reform ourselves we will be reformed, *nolens volens*. The laity are not all fools and the surgical situation is no longer a professional secret. Putting aside all question of ethics, of our duty as a profession toward a confiding laity; the law of self-preservation forces us to take up this question in earnest. That portion of the laity which has not already gone over to Christian Science, Osteopathy and psychotherapy is casting a critical eye upon the medical profession, and if I mistake not the signs of the times will require a speedy accounting.

Let us, therefore, bravely face the situation; let us probe the ugly wound to its very depths; let us fearlessly apply the cautery while it yet remains in our own hands, and while we can make a thorough aseptic operation.

What are the abuses in the surgical camp to-day, and how can they be remedied? In the first place there is no doubt that the profession is in the throes of a "furor operativus." The great professor must have his large clinics; the amateur must get his experience, so that he may some day fill the great professor's chair; every surgeon must invent at least one new operation or modify an old one, and these must be justified to the profession by a glittering array of statistics; post-graduate schools must have clinical material to make mushroom surgeons who return to their small towns and start a hospital which must be supported from the appendices of the entire surrounding country; and alas, everybody must have money for necessary and unnecessary expenses.

I do not mean to accuse surgeons as a rule of operating for a fee. But that there are a few who will do so knowingly is a lamentable fact. But the surgical conscience has become so warped that we don't know it ourselves when we are operating for a fee. When a surgeon says to himself—"This patient is determined to have an operation; if I don't do it Dr. A, or B, or C will, a wealthy man like Smith can't expect to carry his appendix around with him"—Is he operating for appendicitis or for the check which he knows Smith is anxious to hand over to some one? And would he operate if he thought there was any danger of his patient dying under the knife? Certainly not. But there is so little danger now in making an incision one and a half inches long and removing a normal appendix; and the patient can sit up the next day and be at his desk in a week! Nothing really has happened except the transfer of a few thousand dollars from the bank account of a man who didn't need it to the account of one who did. Where is the harm? It would indeed be difficult to say if we were speaking of dry goods or green groceries, but is this surgery? Word comes from Lord Lister that at the age of eighty he is sitting with bowed head wondering if after all he has brought any real benefit to humanity in introducing antiseptic and aseptic surgery to the profession; that he views with alarm and consternation this wave of surgical furor which is sweeping over Christendom. And no wonder. It is safe to say that every year thousands of unnecessary operations are to be laid at the door of aseptic surgery. Would any surgeon have the temerity to remove a normal appendix or open the abdominal cavity to "hang up" a uterus if the mortality was 50 per cent? Certainly not, for with all our faults we are not butchers.

But why do I seek for words when it has been said for me so much better by the "Master Surgeon."* "To the immortal Lister," he said, "belongs the honor of having opened a systemmatic and successful crusade against the surgeon's most treacherous enemies—the pathogenic germs. * * * No wonder that a sense of security created by such wonderful changes made the surgeons bold. * * * The physician found himself suddenly out of his long, time-honored routine practice. * * * Much of this ill applied energy in the surgical world has resulted in detriment to patients and in retarding actual surgical progress. Operative surgery has been carried to extremes. * * * The bold surgery of to-day upon organs of the abdominal cavity is largely due to the comparative safety with which the peritoneal cavity can be invaded under proper aseptic precautions. This new field for the display of surgical talent and ingenuity has been diligently cultivated in a legitimate way by the honest, progressive surgeon, but it has also been made the playground of unscientific sensational surgery by men who are ignorant of the legitimate limits of the art of surgery. * * * The greatest onslaught of modern surgery has been upon the organs of generation, male and female. * * * When I arraign the gynecologist for innumerable and inexcusable transgressions of the rules which ought to govern and control the art of surgery, I do not include the scientific, honest, conscientious workers in that department of surgery, but my remarks will apply to the class of routine operators which has recently grown to alarming dimensions. Not only in this but in nearly every country which has been penetrated by the dim rays of so-called bold surgery. * * * The new generation of doctors finds no longer satisfaction in practising their profession in some rural district. They have their eyes on large cities and have heard of enticing fees paid to specialists for insignificant operations. Why buy a horse and saddlebags when a fortune awaits them in devoting themselves to a specialty. The recent graduate seeks a much employed gynecologist, follows his work for a month or two and returns a full fledged specialist. * * * Has humanity been the gainer since the gynecologists became surgeons? This is a timely and serious question. * * * It is difficult to say where this rage will end or what organ will be the next battleground for the aggressive gynecologist. The clitoris, the vagina, the cervix uteri, the ovaries, the Fallopian tubes, the uterus and its ligaments have successively passed through a trying ordeal of the *furor operativus*. What the next fad will be is impossible to foretell. * * * If gynecology is to live and become a real benefit to women it must become more conservative. * * *

*On some of the Limits of the Art of Surgery, By Nicholas Senn, M.D., address delivered before the American Medical Association at Atlanta 1896.

Let us have in the future more of the *nil nocere* in place of the *furor operativus*."

But the remedy? Aye, there's the rub. It is such a very elusive subject, this "furor operativus." Can it be checked? I fear not in a legislative way. The spirit of the times is opposed to any medical censorship nor is this practicable at least in any form that has as yet been suggested.

Since then it is a question between a more or less intelligent profession and a more or less intelligent laity (for the laity are by no means altogether blameless for the present conditions) how is the situation to be handled? By education perforce, and I very much fear that the curriculum must include not only anatomy, physiology, and pathology, but a system of ethics in which the golden rule shall be given a conspicuous place. The cultivation of the individual conscience would be no doubt the radical remedy; a conscience which would not allow us to perform an exploratory incision until we have exhausted every means to make a diagnosis without the knife; a conscience which would say, am I sure that this is a surgical case in the first instance, and secondly is the operation that I am contemplating conformatory to the laws of anatomy and physiology, and the one most likely to rid the patient of the pathological condition; a conscience which would hesitate before attempting to improve nature's arrangement of organs—or to deprive the human system ruthlessly of organs evidently created for a purpose; a conscience which would finally ask itself: "Am I certain that I am operating for a pathological condition in the patient and not in my own purse." "Would I that some surgeon (more or less skillful) should perform such an operation upon me or upon one who is dear to me as I am contemplating on my patient," is a very good question to ask ourselves before we give the routine order to prepare the patient for the operating table. If all surgeons were women, conscientious women I mean, I am thoroughly convinced that all manner of hysteropexies for so-called uterine displacements would rapidly disappear for want of statistics.

The "golden rule" was certainly promulgated for a purpose, and here is a beautiful opportunity to use it. The most skilled surgeon needs to ask himself these searching questions. Then what of the unskilled, the amateur surgeon who has succeeded in obtaining a hospital position, the recent graduate and the hospital interne?

Already there are voices crying in this surgical wilderness. Let those who have ears to hear—listen. Not long ago Dr. Henry T. Byford made the statement that no amateur should be allowed to do an independent laparatomy until he had done at least one hundred abdominal sections under the direction of a master. What a revolution this one reform would make in the surgical world! Dr. Morris Richardson during the last few years has written a series of articles condemning overbold and unscientific surgery which should rouse the profession to the necessity of reform. Dr. J. M. Baldy in his presidential address before the American Gynecological Society has outlined most needed reforms. In a recent number of the *Boston Medical and Surgical Journal* Dr. J. C. Monro has a stirring article on the "Surgical Rights of the Public."

There are, of course, many others thinking and writing on this subject. Then why can not some concerted action be taken by those who are aroused to the situation? At least some system should be devised by which the laity and the profession as well may know whether they are dealing with a surgeon or an unskilled, unscientific cutter. Surely it is not asking too much that a physician shall give some guarantee to the profession and to the public that he is also qualified to practise surgery. It is absurd that the same college degree which confers the title of M. D. should give the right to perform operations to a student who has never taken the knife in his hand. If there is any way in which the laity can protect themselves by law from the ignorant and unscrupulous in the medical ranks let it be thought out by those who have the confidence both of the profession and of the laity. If it can come only in the form of recommendations, we are waiting for them and some of us at least will accept them.

The time is ripe and we are looking to the conscientious skilled surgeons of our country to institute some movement toward rescuing our beloved profession from those who would make it only a stepping stone to a passing greatness or exploit it for their own selfish interests, that the noble art of surgery which yearly saves thousands of lives and restores a lost health to thousands more, may be raised to the lofty pedestal to which its legitimate achievements have richly entitled it.

SYNOVITIS OF THE KNEE-JOINT AS A LATE MANIFESTATION OF ACQUIRED SYPHILIS.

REPORT OF A CASE.

By ISAAC LEVIN, M.D.,

NEW YORK.

Richet[1], in 1853, was the first to express the opinion that a joint disease may be caused by the syphilitic virus directly, without the influence of another etiological factor. This opinion was not accepted immediately, and Ricord[2] and a number of others held that if an individual suffering from syphilis contracted a joint disease, it simply meant an incidental complication of the syphilis with another disease, possibly tuberculosis or rheumatism. But since then cases of purely syphilitic joint disease have multiplied to such a degree that no further doubt can be entertained as to the existence of this clinical condition.

The joints may be affected in one degree or another in every stage of both acquired and congenital syphilis, and usually each stage is characterized by different pathological conditions of the affected joint. Already in the period of secondary incubation the patient may suffer from pains in the joints, but this so-called "arthralgia" is not accompanied by any anatomical abnormality in the joint. The same arthralgia usually manifests itself at the beginning of the period of secondary symptoms during the time of fever and roseola, and it resembles them very closely, the rheumatic pains accompanying any other acute exanthema or muscular fatigue. The only peculiarity of this arthralgia that differentiates it from other conditions is that the pain increases greatly during the night.

Another form of a joint disease, which also appears early in the period of secondary symptoms of syphilis, is subacute synovitis. Here, besides the pain, there is some swelling and all the other symptoms of an acute inflammation. This condition resembles very closely both gonorrheal arthritis and polyarticular rheumatism. Fournier[3] calls the disease syphilitic pseudorheumatism. The disease usually appears simultaneously with secondary skin eruptions and disappears together with the latter. The condition that usually occurs in the later part

of the period of secondary symptoms of syphilis is chronic synovitis or hydrathosis. It appears most frequently during the third year after the initial lesion, takes a more chronic course than the subacute synovitis, but, like the latter, involves only the serous covering of the capsule, and, if treated, heals without leaving any trace of abnormality in the joint.

In great contrast to the forms just described, the joint lesions of the tertiary period of syphilis are very grave in character. They usually take the form of chronic arthritis secondary to formation of gummata either in the tissues surrounding the joint, so-called perisynovitis gummosa, or in the interior of the joint, the chondroarthritis gummosa. Both conditions lead to destruction of tissues and impairment of function. They resemble clinically tuberculosis of the joints, and were, therefore, described by Richet and subsequent French authors under the name of *tumeurs blanches syphilitiques*.

The clinical difference between acquired and congenital syphilis consists mainly in the absence in the latter of the primary lesion and the period of incubation, and besides the symptoms of the secondary and tertiary periods are not so clearly separated in the congenital as in the acquired syphilis. Otherwise the clinical manifestations that are met with in acquired syphilis occur also in congenital cases. All the forms of joint diseases described in cases of acquired syphilis can be seen in congenital cases. The only condition peculiar to congenital syphilis is the "deforming arthritis." This form, first described by Mericamp[4] in 1882, usually occurs in the later period of congenital syphilis. The disease manifests itself with enlargement of the epiphysis of the bones, absence of effusion in the joint cavity, and impediment of the function of the joint.

While it may seem from the foregoing description that we have to deal here with a clinically well defined disease, the differential diagnosis of which presents no difficulties, it is far from being so in practice. When the lesion of the joint is accompanied by other symptoms of the disease, then it is comparatively easy to reach a conclusion, but when the joint disease is the only manifestation of syphilis, the correct interpretation may be very hard indeed. As Morestin[5] puts it, in considering the cases of chronic synovitis in syphilis, "the cases are much more frequent than one would think, but, common as they are, they remain commonly unrecognized." It is of great importance, therefore, to bring forward and discuss clinically every additional case as it occurs. Besides this, the case that I shall report here has certain characteristics that distinguish it from the majority of the reported cases and gives it a peculiar interest from the standpoint of the conditions of syphilitic joint disease, and also of the general question of syphilis.

Mrs. W., aged 35, consulted me in May, 1908, for "rheumatism" in the left knee, from which she had suffered for six months. She had been unsuccessfully treated by large doses of salicylates and the usual antirheumatic remedies. On close questioning I could collect the following history. Parents, brothers, and sisters healthy—at least, there is no indication of tuberculosis or syphilis. Patient was not nursed by her mother, but by a wet-nurse, who, as she had heard, was at the time suffering from "scrofulosis." The patient herself never suffered, to her recollection, from anything resembling syphilis. She had been married for thirteen years, gave birth three times at term to stillborn children at intervals of about two years, and the fourth time, six years ago, gave birth to a living and perfectly healthy child. Her obstetricians explained the first three stillbirths by an abnormality in the pelvis. Her present illness, dating back six months, began suddenly with severe pain, swelling, and impairment of motion in the left knee-joint. The pain was most severe at night and did not yield to treatment. On examination I found several characteristic syphilitic scars on the skin of the chest and back. The patient could not give any account as to their origin. There were no enlarged lymph nodes nor thickenings of the bones; no abnormality in any of the organs of the chest, abdomen, or pelvis. The pelvic measurements were normal. The left knee-joint was enlarged, filled with fluid; the capsule felt somewhat thickened, and on the inner surface of the tibia there was a tender spot which did not feel softer, or in any way different to the touch, than any other part of the bone. The radiogram showed nothing abnormal either in the bones or capsule. I made a diagnosis of syphilitic hydrarthrosis, and ordered large doses of potassium iodide, with daily inunctions of mercurial ointment on the surface of the knee-joint, with two days' rest after each four inunctions. In ten days after the beginning of the treatment the pain ceased, and in four weeks the fluid was absorbed and the appearance and function of the joint were restored to normal.

This case presents several points of interest. The syphilis was acquired by the patient innocently in her infancy through her wet-nurse, and, though never treated, did not present any symptoms with the exception of the few skin lesions until she married, twenty-two years later. She apparently was then in the tertiary period, as her husband remains healthy, but she had three successive stillbirths, which was the first indication that she was not cured of her syphilis. Then, several years later, she got a lesion in the knee-joint. But here again the disease took an unusual course. As stated above, the joint lesions in the tertiary period of acquired syphilis are usually of a severe destructive character and based on formation of gummata, while in this case there was a simple chronic synovitis with severe nocturnal pain as the most prominent symptom. Such a mild form of the disease takes place, as a rule, in the earlier stages of the secondary period. A very plausible explanation of the condition would seem to be that the patient received an attenuated infection and, though untreated, the disease took all along a benign course.

For the practitioner there are two points in connection with the case that ought to be kept constantly in mind. In the first place, a patient, and particularly a woman, may carry an uncured syphilitic infection for years and show no indication of it. In the second place, a syphilitic joint disease does not show any pathognomonic clinical difference from a joint disease due to some other cause, and, unless the physician thinks of syphilis, the case may go on without the right treatment for months. Such a lack of treatment not only causes a great deal of unnecessary pain and discomfort to the patient, but, as Frauenthal[6] has shown, such a syphilitic arthritis, if untreated, may readily become infected with tuberculosis.

Joint disease in syphilis, both acquired and congenital, is a great deal more frequent than it is thought to be, and of all the joints the knee-joint is the most frequently affected.

How little the general surgeon is familiar with the subject can be seen from the statement of Hippel[7], who says that congenital syphilis of the knee-joints is hardly ever recognized by the surgeons, but usually by the ophthalmologists, because the disease

usually follows an attack of parenchymatous keratitis, which is considered by opthalmologists to be always of syphilitic origin.

When the joint disease is the only manifestation of syphilis and there are no other symptoms, the nocturnal exacerbation of the pain is in itself a sufficient indication of the true etiology. But even in the absence of this pain, in every case of chronic hydrarthrosis of unknown origin that does not respond to the usual treatment, syphilis ought to be considered. A couple of weeks of treatment with large doses of potassium iodide may cure the case completely.

THE ACTION AND DOSAGE OF PHENOLPHTHALEIN.

By WARREN PHILO ELMER, M.D.,
SAINT LOUIS, MO.,
ASSISTANT PROFESSOR OF MEDICINE, SAINT LOUIS UNIVERSITY.

Phenolphthaleix has been known as a purgative for about eight years,[1] but so little has been written concerning its physiological action and definite dose that it has not received the attention from the medical profession that it deserves.

In reviewing the literature the following problems present themselves: (1) What is the physiological action? (2) Has it toxic properties or is it broken down in the course of its passage through the body into substances which are toxic? (3) What limits, if any, must we place on the dose prescribed, and how is it best administered?

Valmosy[2] and Tunnicleffe[3] believe that phenolphthalein remains unchanged in the acid media of the stomach, but on reaching the intestine forms a sodium salt in the presence of the bile. This salt is said to increase the osmotic pressure in the intestine and thus to act as a hydragogue cathartic.

It is a well-known fact that phenolphthalein is much less active in dogs than in man, and Valmosy[2] explains this by saying that less of the sodium salt is formed in dogs.

With these statements in view, I performed the following experiments on dogs: Three dogs were selected, weighing 35, 25, and 7 pounds, respectively. The stools were carefully watched for ten days, the average number and consistency being noted. On the eleventh day phenolphthalein in aqueous suspension was administered by means of a stomach tube in doses of one grain per pound of body weight; *i.e.*, the 35-pound dog received 35 grains; the 25-pound dog received 25 grains, and the 7-pound dog received 7 grains. During the forty-eight hours following no change was noted either in the number or consistency of the stools, although phenolphthalein could be detected in the stools of all three dogs by the end of thirty-six hours.

On the fourteenth day 70, 50, and 14 grains, respectively, were administered in the manner described above, with the same negative result as regards the number and consistency of stools, although larger quantities of phenolphthalein could be detected.

On the seventeenth day doses of 95, 75, and 21 grains produced no noteworthy changes. On the twentieth day 140, 100, and 28 grains were given. Twelve hours later the 25-pound dog developed a moderate diarrhea (five stools in twenty-four hours), and examination of the urine showed traces of phenolphthalein. The consistency of the stools, while somewhat thin, was by no means watery.

The 35-pound dog showed no changes in the stools, but the urine gave a fairly marked reaction for phenolphthalein. The 7-pound dog showed no changes either in stools or urine.

On the twenty-third day, after a dose of 175 grains, the 35-pound dog developed a moderate diarrhea (seven stools in twenty-four hours). The reaction for phenolphthalein in the urine continued. The stools of this dog resembled those of the 25-pound dog, viz., thin but not especially watery. Phenolphthalein in large quantities and absolutely unchanged could be detected. The 7-pound dog at this time was given 40 grains without effect.

During this series of experiments the dogs were fed on boiled beef and bread, and allowed free access to water at all times. They were kept in roomy wire cages so placed that urine could be collected, and with a wire grating in the bottom, so that the stools were kept fairly well separated from each other. The general condition of all the dogs remained good; there was no loss of weight; in fact, the 7-pound dog at the end of twenty days had gained three-fourths of a pound. The appetite was unimpaired, and no evidence of any ill effects from the drug could be observed.

After a rest of ten days, a further set of experiments were undertaken, but in the meantime the 7-pound dog was accidentally killed, so that further experiments were performed on the 35-pound and the 25-pound dogs. The same quantities of phenolphthalein were again administered, this time suspended in 100 c.c. of N/40 sodium hydrate. After the first three doses the results were the same as in the previous experiments, except that the stools were streaked with the red sodium salt from twenty-four to thirty-six hours after each administration, and continued to be so colored for from twelve to twenty hours, showing that the sodium salt left the body unchanged.

After a dose of 95 grains the 35-pound dog showed traces of phenolphthalein in the urine. The urine of the 25-pound dog showed phenolphthalein after a dose of 70 grains. Both dogs continued to show small amounts as long as the experiments were continued, the urine never being free from it even at the urination previous to the following administration.

After 140 grains the 35-pound dog developed a moderate diarrhea, similar to that appearing after the administration of 175 grains of the watery suspension of the drug.

The 25-pound dog developed a similar diarrhea after 100 grains. The stools of both dogs were soft, but not watery, and contained considerable quantities of the unchanged phenolphthalein, together with the sodium salt.

After another ten days' rest, the 25-pound dog was given 70 grains suspended in 100 c.c of 0.3 per cent. hydrochloric acid, without result; 110 grains produced practically the same results as previous suspensions of a like amount.

I conclude from the above experiments that while there is slightly greater absorption of phenolphthalein when suspended in N/40 sodium hydrate, there is not sufficient difference to warrant a conclusion that sodium plays any part in the purgative action of

the drug. This conclusion is also strengthened by the results in the two cases of catarrhal jaundice reported below, where the bile was almost entirely absent from the stools. Suzzor[4] and Tunnicleffe[3] report similar observations in jaundiced patients.

As to whether the action of the drug is directly on the mucous membrane as an irritant *per se*, or indirectly as a hydragogue, I am not prepared to state; but, from the character of the stools, both in dogs and in man, I am inclined to believe that the action is that of a direct irritant, otherwise the stools should be more fluid.

In regard to the toxic properties of phenolphthalein, little can be found in the literature. Best reports a case of poisoning from a 15-grain dose, but I am unable to find the records of any other case of poisoning. My own experience with dogs, cited above, and the statement of Valmosy[2] that doses up to 1 grain per kilo of body weight can be given to animals without danger, would indicate that phenolphthalein is practically without toxicity for animals. In my experience four patients have taken 30 grains or more daily for at least two weeks, one taking from 30 to 60 grains daily for fourteen months without ill effect.

As to its fate within the body, according to Valmosy[2] 87.17 per cent. of all phenolphthalein taken by the mouth can be recovered from the stools. Allowing for the usual errors of such determinations, it would appear that practically all of the drug is excreted by the bowel unchanged. After very large doses small quantities appear in the urine.

If phenolphthalein were broken down, one would expect an increase of the aromatic sulphates in the urine; this, however, neither Valmosy[2] nor Tunnicleffe[3] was able to obtain. It should be borne in mind, however, that active purgation decreases the aromatic sulphates to some extent, so that these observations are not absolutely conclusive, but for practical purposes are sufficiently accurate. The statement of Suzor,[4] that 0.3 grains will cause the drug to appear in the urine is not confirmed by the majority of observers, and was not true in any of my cases. For this reason Tumminia's[6] claim that phenolphthalein may be used as an indicator, for the functioning power of the kidney is without foundation, at least, in the vast majority of cases.

My conclusions then in regard to the toxic properties of phenolphthalein are: It is not toxic in any dose that I have given it, and can certainly be given with safety up to twenty or thirty grains daily. It is not broken down within the body so far as can be determined. Best's case I am inclined to regard either as an idiosyncrasy, such as at times gives rise to statements of toxicity in regard to almost all drugs; or else the symptoms described were due to something else beside the phenolphthalein.

The more recent writers, as Tumminia, state that the dose of phenolphthalein varies greatly with different patients. To a certain extent this is true, but in 90 per cent. of patients the variation is not greater than with most drugs. A brief summary of one hundred and sixteen cases of various diseases, combined with constipation and treated with phenolphthalein at the St. Louis University Dispensary and in private practice, will best illustrate this uniformity.

In one hundred and twelve cases the dose varied from one to ten grains daily, the average being 3½ grains. The above cases included the following conditions:

Chronic constipation without other symptoms other than those referable to this condition, eighteen cases. Chronic constipation, accompanied by hemorrhoids, ten cases. Contrary to the experience of Buckley,[7] the hemorrhoids were not aggravated by phenolphthalein.

Catarrhal jaundice, two cases, in both of which were acholic stools. In neither case was more phenolphthalein required than in cases where the stools showed abundance of bile, although both patients were quite constipated. The remaining cases included: influenza, eleven cases; actute and chronic rheumatism, seventeen cases; neurasthenia, seven cases; hypochlorhydria, ten cases, and hyperchlorhydria, thirty-five cases. Of the four cases requiring large doses three were diagnosed spastic constipation; each patient took from thirty to forty grains for at least two weeks without satisfactory results, but without any symptoms of intoxication.

The fourth case was that of a man, 68 years old, with benign stenosis of the pylorus contracting the opening so that a bead three-eighths of an inch in diameter was the largest that passed through the stomach. This patient requires from forty to sixty grains of phenolphthalein daily, and has taken such doses for eighteen months. Of other cathartics tried, all require from five to eight times the usual dose, and most of them produce disagreeable symptoms, such as cramps and tenesmus.

I have secured better results from using phenolphthalein in powder than when compressed into tablets, or even when given in capsule. Usually I prescribe 2 drams of the powder, and direct the patient to take what will lie on a dime (about 3 grains) before going to bed. It is best taken by placing it on the tongue and taking a swallow of water. The powder is tasteless and odorless, and as a rule is not objectionable; the dosage is easily regulated by the patient.

General Conclusions.—Phenolphthalein probably belongs to the class of intestinal irritants, but its action seems to be accompanied by less discomfort than the majority of cathartics of this class.

It is nontoxic, at least in doses up to 25 or 30 grains. It is extremely stable, very little if any being broken down in passing through the body. A little is absorbed, but is excreted by the kidneys as such.

The average dose may be placed at from 1 to 5 grains, best given in the powdered form, either at night or in divided doses after meals. In cases of hyperacidity it can be advantageously combined with an antacid powder.

CLERICAL HEALING.

THE announcement made a few weeks ago by the rector of an Episcopal church in this city, that he was going to take up the practice of medicine as a part of his clerical work, calls renewed attention to this curious movement. While it was confined to the Emmanuel Church people in Boston it was generally regarded as a sort of Neo-Eddyism, one more of the many queer fads with which the citizens of that town are wont to amuse themselves, and little more was thought of it. Now, however, two at least of the Episcopal churches in New York are going to adopt the Emmanuel plan of treating disease, and doubtless some of the rectors of other churches in that denomination will be ready to join the ranks of irregular practitioners. It is time therefore to ask what the movement means, and why physicians, even trained neurologists, are to be found lending themselves to the movement and supporting it by voice and pen.

The first question raised by a perusal of the official book of the Emmanuel movement, is, why? Why clerical healing, and why the limitation of clerical healing to functional diseases? We do not find either question answered satisfactorily in this book and we do not see how they can be answered. If the physician is to entrust the care of his patients to the clergyman why not to the lawyer? The latter is as much the confidant of his clients as the minister of his parishioners, and could speak just as authoritatively to the subliminal self of the sick. But the physician ought to be able to speak with much greater effect. When he cannot, the explanation must be found in that curious state of mind which leads the ignorant to trust the confident amateur rather than the professional, to pin greater faith to quack remedies or grandmother's simples than to the prescription of the physician. The skilful physician despises no remedy which may benefit his patient, and if he believes a word from a sincere and tactful minister of the gospel will help, he is glad to send, and often does send, the sick man to the clergyman. As physicians we should regret indeed to lose the powerful therapeutic force that resides in religion, but it does not follow from this that we are ready to welcome the priest as a fellow practitioner of medicine, or even to acknowledge that he can exercise that function in the public and wholesale way of the Emmanuel rectors without the danger of doing far more harm than good.

Clergymen are no more than human, like all the rest of us, and once this movement is well launched it is safe to predict that medical men will have less and less to do with it—not, we fear, because they will become convinced of their folly in committing patients to the care of men ignorant of the rudiments of medical science, but because the clergymen will no longer care for their help. When men speak with the confidence, shown by the authors of "Religion and Medicine," of matters concerning which their words show them to have only uncertain knowledge, it is but a step to the rejection of all advice and suggestion from the physician. Pride, we are told, is one of the seven deadly sins, and there is no form of it more enthralling and ineradicable than the therapeutic pride of the unlearned.

At present the catchword of the Emmanuel movement is "functional disease." We are told repeatedly that the clerical healers will have nothing to do with any sufferer from organic disease, and they use their medically trained allies to separate the functional sheep from the organic goats, the latter being thrust back into the outer darkness of legitimate medical practice. But what do these people mean by "functional nervous disorders?" Do they really believe that there are two distinct kinds of disease—functional and organic? If they do not know, their medical advisers should tell them, that every day we are shifting so-called functional diseases into the class of organic diseases. Will these clerical healers abandon a functional disease to the medical healers when it is discovered to be dependent upon an organic lesion of brain, spinal cord, or sympathetic nervous system, or will they simply deny its organic basis and continue to treat it? And once they find themselves treating one disease called organic, why not others? why not all? Every physician knows that "cheerfulness, hope, courage, and religious faith and prayer," which constitute the pharmacopeia of the New York school of clerical healing, are just as necessary in the treatment of tuberculosis as in that of constipation, and indeed that they are often distinctly curative in various organic diseases. If the clergy have a divine commission to heal the sick they are recreant to their trust and cruel to the suffering to deprive any of the benefit of their healing words, and it will not be long before they recognize that fact and act accordingly. That the law forbids them to practise medicine is, of course, a detail of no importance.

THE NATURE OF GANGLIA AND THE STRUCTURE OF SYNOVIAL MEMBRANES.

LAYMAN as well as physicians are familiar with the so-called "weeping sinews," or ganglia, that often appear in the form of small oval or round elastic swellings on the dorsal surface of the wrist in piano players, needle workers, typewriters, etc. It would seem that so common an object would be well understood so far as its nature and development are concerned, but an article by Dr. W. C. Clarke in *Surgery, Gynecology and Obstetrics* for July, 1906, shows that this is far from being the case. Thus the common view is that ganglia are produced by the protrusion of the synovial membrane of joints

or tendon sheaths, and are distended by the fluid secreted by this membrane; some look upon them as fetal sequestrations of synovial membrane or recesses occluded in the development of the joint; others still claim that distention of regular or adventitious bursæ may be responsible for the swellings, while the most recent writers classify ganglia among cysts caused by the degeneration of connective tissue. The material examined by Clarke leads him to think that the distention of bursæ, because of some inflammatory condition, may be responsible for the appearance of some ganglia; most frequently, however, they are degeneration cysts, the finding of typical ganglia within the substance of tendons in cases described by Thorn, Franz, Borchardt, Hofman, and Clarke supporting the truth of this explanation.

Of wider interest are Clarke's investigations into the structure of synovial membrane, which were carried out in connection with the study of ganglia. Everyone remembers the textbook statement that these membranes are covered by a layer of endothelial cells, the secretion of which is the synovial fluid that lubricates the joint. According to Clarke, however, no such cells are found in the lining of joint cavities. Endothelium is a single complete layer of flat cells that covers a free surface, and is supported by tissue differing from it in structure. Histologically it is easily recognized in preparations of peritoneum, pleura, and blood-vessels by the beautiful mosaic of serrated or wavy lines which outline its cells, when impregnated by solutions of silver salts. The elements lining synovial membranes, on the other hand, are flattened or rounded connective tissue cells, but little differentiated from the deeper cells supporting them and having no such specific appearance when impregnated with silver salts. The endothelium of superficial vessels often precipitates these salts when the synovial membranes are exposed to their action, and it is this, as well as threads of coagulated synovia, that have probably misled earlier investigators of the structure of synovial membranes.

It is thus seen that the innocent "weeping sinews" which physicians treated, before the days of aseptic surgery, by slapping with a heavy book and by the application of pressure, are of much scientific interest so far as their structure and their relation to joints are concerned. Dr. Clarke's investigations suggest further questions for research and study. In the first place, it must be shown whether trauma, low-grade infection, or other causes are responsible for the degeneration of tissues which result in the formation of the cysts called ganglia. On the other hand, the new microchemical methods must be applied to the study of synovial cells and of the fluid lubricating the joints in order that more light may be thrown on the ultimate origin of the differentiated cell complexes in the animal organism.

DANGERS OF DIRECT TRACHEOSCOPY AND ESOPHAGOSCOPY.

It is now several years since Gustav Killian of Freiburg first made known his method of direct examination of the upper respiratory tract and published his description of the instruments and technique. The supposed difficulty of the procedure and the cost of the necessary outfit have precluded the use of this very excellent method save for those few investigators who have possessed all the facilities and requirements essential to carry it out successfully. There is no question that this is the method *par excellence*, for the diagnosis and treatment not only of respiratory conditions, but also of tumors, injuries, and diseases of the esophagus. It is now possible to introduce a light-carrying tube into the esophagus, or, in some cases, into the stomach, obtain a view of any growth present and remove a section for examination; and it is therefore not difficult to understand what a great good this maneuver is in skilled hands. Removal of foreign bodies and tumors from larynx, trachea, and bronchi is carried out much more easily than by the old indirect method, and with less injury to sound tissues.

A word needs to be said, however, against the careless or indiscriminate use of tubal exploration of these cavities. In the first place this operation should never be performed (unless the saving of a life in an emergency demands immediate and quick action) without preparing the patient as if for a major surgical operation. Introduction of unsterile tools by unsterile hands into a cavity which has not been made as aseptic as possible is a dangerous thing and is unfair to the patient. The procedure is not to be recommended for office routine nor for use in the unclean rooms of an out-patient clinic. Killian has collected reports of 164 cases of foreign bodies in the lower respiratory tract, in 159 of which the results were definitely known: two patients died of cocaine poisoning, two of stenosis, sixteen of pulmonary complications, five with the foreign body *in situ*, and eleven in spite of its successful removal. In America E. Fletcher Ingalls reports two fatal cases supposedly from irritation of the vagus nerve by instrumentation.

It is doubtful if cocaine anesthesia should ever be used in children for this purpose, since children do not withstand cocaine at all well, and the dosage must be necessarily of 10 to 20 per cent. strength and of uncertain amount. Adults, however, suffer very little inconvenience from its use, and from the operator's viewpoint, local anesthesia is less troublesome and the results are quite as good as under general narcosis.

In esophagoscopy there is also some danger of rupture of the walls, due either to normal thinness or to an ulcerative process brought about by aneurysm or malignant growth. Where such condition is suspected the tubes should be used with extreme caution, and the surgeon should surround himself with every facility for carrying out a major emergency operation.

The Stomach's Protection Against Self-digestion.

The old question of the immunity enjoyed by the stomach and other parts of the gastrointestinal tract against self-destruction by the active secretions produced in the process of digestion has acquired new interest since the various operations involving artificial connection of the small intestine with the stomach have been devised. The success of these operations proves that the intestinal mucous mem-

brane, when connected with the stomach, is protected somehow against its digestive power, so that permanent artificial communications between the stomach and the intestines can be established. More systematic study of this matter has been recently made by Katzenstein, who reports a number of animal experiments in the *Berliner klinische Wochenschrift* for September 28, 1908. He has found that closed loops of the jejunum introduced into the stomach are completely digested within that organ; one end of the spleen treated in the same manner was likewise digested; on the other hand, part of the duodenum, sewn into the stomach, remained intact, and the same effect followed the suturing of a part of the stomach itself into the cavity of the organ. The conclusion therefore must be reached that living tissue is digested by the stomach juices, even while retaining its connection with the rest of the organ to which it belongs; on the other hand, tissues which produce gastric juice or are constantly bathed by it are able to withstand the digestion within the stomach. Katzenstein's results throw new doubts upon the various theories offered in explanation of the absence of selfdigestion in the stomach, one of which ascribes the protective powers to the mucus of the organ, another to the lining epithelium, still another to various chemical and biochemical protective substances, while John Hunter claimed simply that all living tissue withstands digestion because of its very vitality. One greater interest, however, was the application of the observations made by Katzenstein to the therapy of gastric ulcer which affection partly depends upon the diminution in the self-protecting power of the gastric or duodenal wall. The author claims to have obtained very gratifying results with a new treatment of gastric ulcer founded upon the above results of his study of self-digestion. It is in one sense a specific treatment, depending upon the administration of antipepsin to the patients, and the description of the method, publication of which is promised by Dr. Katzenstein for the near future, will be looked for with interest.

Orrhotherapy in Chronic Nephritis.

Although no microorganisms have been found that could account for the origin and continuation of such chronic inflammatory conditions in the kidneys as are classed under the general name of Bright's disease, yet it had seemed reasonable to Casper and Engel to apply the recently developed orrhotherapeutic measures to the treatment of these conditions; the results which they report in the *Berliner klinische Wochenschrift* for October 12, 1908, seem encouraging, however empirical are the reasons for such novel treatment of nephritis. The serum used was prepared in the usual way by immunizing rabbits with the blood of the patients, and eleven nephritics were then treated by subcutaneous injections of such serum. The results showed first of all that the treatment was quite harmless; in one case albumin and casts permanently disappeared from the urine; in several other cases these elements were diminished in quantity, while in a few no changes were noted. The general condition of the patients seemed much improved by the treatment and one troublesome symptom, edema, was in all cases favorably affected. The *rationale* of this therapeutic experiment lies of course in the supposition that the ultimate cause of the kidney lesions is to be found in the blood of the patients. This view is supported by the fact that as a rule all elements of the organs are affected, however different may be the degree of the lesions in the various elements; that frequently other organs are simultaneously impaired in function or in anatomical structure as is exemplified in amyloid disease of the kidneys; and, finally, that acute infectious conditions are often responsible for the beginning of nephritis, the toxins derived from the infected foci irritating and injuring the kidneys when brought to them by the general circulation. The small number of cases observed by Casper and Engel are not enough, of course, to decide the value of the treatment proposed by them; chronic nephritis, however, is an incurable disease with the means at our disposal at present, and further reports of the results of orrhotherapeutic measures will be awaited with interest.

Multilocular Branchiogenous Cysts.

A certain confusion exists in the classification of congenital cystic tumors of the neck. E. Estor and G. Massabuau, writing in the *Revue de Chirurgie* for September, 1908, after a careful examination of all the cases of this kind that they could find described in literature, state that there are to be found on the side of the neck complex multilocular tumors which arise from the ectoderm, the eneoderm, or the mesoderm, or which contain tissues of all three layers mixed. These tissues form the lining of the cystic cavities or the intercystic stroma. Such tumors should be carefully separated from the polycystic parathyroid tumors. The origin of these tumors is not entirely explainable by the hypothesis of the development of neoplastic growths from remains of the embryonic tissues of the branchial clefts. We must enlarge our conception of their origin. They are embryonic cysts of a mixed type. Among them are tumors of all embryonal types from true teratomata to solid or cystic tumors of mixed type, and simple embryomata, or dermoid cysts. The origin of all these tumors is to be sought in a vice of embryonal evolution more or less early in the process of development. Up to the present time only sixteen undoubted cases of multilocular cysts have been reported.

News of the Week.

Public Health and Marine-Hospital Service.—The examination of candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service will be held on Monday, January 11, 1909, at 10 o'clock A.M., at No. 3 B street, S.E., Washington. Candidates must be between twenty-two and thirty years of age, and graduates of a reputable medical college. The examinations are physical, oral, written, and clinical. After four years' service, assistant surgeons are eligible for examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority and after due examination. Assistant surgeons receive $1,600, passed assistant surgeons, $2,000, and surgeons, $2,500 a year. For further information application should be made to the Surgeon General, Public Health and Marine-Hospital Service, Washington, D. C.

The Society for the Suppression of Unnecessary Noises is about to consider the possibility of eliminating the shouts of hawkers and peddlers, and Mrs. Rice, president, has suggested that different colored signs be displayed by persons wishing to purchase pushcart wares, just as merchants hang out signs for express drivers. Thus a green sign

would signify that the housekeeper desired to buy apples, a red sign that she wished potatoes. The plan seems esthetic as well as practicable.

Tuberculosis Exhibit.—An echo of the International Congress on Tuberculosis has reached New York, in the shape of the exhibit which will be displayed at the American Museum of Natural History, beginning on November 20. The exhibit was brought to New York recently in over a thousand packing cases, filling thirteen large freight cars. On the opening night, the committee in charge plans to have addresses by Governor Hughes, Mayor McClellan, and others. The exhibit will remain here for at least six weeks, and it is thought that while thousands viewed it in Washington, hundreds of thousands will view it here.

Tuberculosis in the Aleutian Islands.—Forty per cent. of the natives of the Aleutian Islands are said to be sufferers from tuberculosis, and the death rate is very high. It is suggested that the spread of the disease may be due to the ceremony of kissing the dead, which is a part of the religious ritual among the islanders.

Yellow Fever in Yucatan.—It is reported that a serious epidemic of yellow fever has broken out among the Yaqui Indians who were deported to Yucatan from Mexico, and that they are dying in large numbers. Many Spanish settlers in Yucatan are also said to have contracted the disease.

The Hewitt Lectures.—Dr. William J. Gies, Professor of Biological Chemistry in the College of Physicians and Surgeons will deliver this course of lectures at the Cooper Union on Monday evenings beginning on February 8, 1909. The subject will be the Chemistry of Nutrition, and Prof. Gies is arranging a series of experimental demonstrations to accompany the eight lectures. The course is given under the auspices of Columbia University.

Death Rate in New York.—For the week ending October 31, the death rate in New York was 13.75 against 16.49 for the same week of last year, the total number of deaths being 1,355 for 1907, and 1,166 for 1908.

Christian Scientists on Trial.—The New Jersey Supreme Court is at present hearing the appeal against a verdict of voluntary manslaughter in the case of the parents of a seven-year-old boy who died in May, 1907, without medical attendance. The counsel for the defendants contends that the trial judge erred in charging the jury that it was the duty of parents to furnish food, clothing, and medical attendance to their children, and quoted from Oliver Wendell Holmes, and others, to show that lack of medical attendance was in many cases of benefit. He argued that each person had the right to choose his religious belief, and that the boy's parents did their full duty in treating him according to such belief, and called upon the State to prove that there was nothing curative in Christian Science. The Prosecutor, in reply, said that as the child was incapable of judging the duty of providing medical attendance devolved upon his parents, that the religious belief of the parents was no defense of their action, and instanced the fact that the State recognized medicine by licensing its doctors. A charge of manslaughter has also been brought against the father of a twelve-year-old girl who died recently in Mt. Vernon. The coroner who investigated the case found that the child's death was caused by acute toxemia, the result of the negligence of her parents in failing to provide proper medical attendance.

Restricting the Height of Buildings in Denver.—The Medical Society of the City and County of Denver at a recent meeting approved the appointment of a committee of physicians to confer with the city officials and remonstrate against the proposed changing of the ordinance restricting the height of buildings to 125 feet. "Culture beds for germs" was the appellation given to the tall buildings, and it was contended that New York was polluted with tuberculosis because of its many-storied piles.

Dr. Frederic Brush of Boston has been appointed Superintendent of the New York Post-Graduate Medical School and Hospital. Before assuming the position, it is announced, he will devote some time to a study of post-graduate instruction and hospital administration in the various American medical centers.

Dr. Brown Pusey has been appointed head of the Department of Ophthalmology in the Northwestern University Medical School, Chicago, vice Dr. Casey A. Wood, resigned. Dr. Frank Allport has also resigned from the Faculty of this University.

The Harlem Eye and Ear Infirmary has just completed a new building, and funds to furnish it are being raised by the Ladies' Auxiliary, who held a fair for the purpose during the past week.

The Boston Insane Hospital will, on December 1, be taken over by the Massachusetts State Board of Insanity, the Board assuming control over the land and buildings constituting the hospital, now owned by the city. This is done under an act of the last legislature, which also provided for a considerable extension of the hospital and the work.

Fire in State Institution.—The State Custodial Asylum for Feeble Minded Women, at Rome, N. Y., was badly damaged by fire on November 1. Ward B of the group of buildings was totally destroyed—a loss of about $140,000. Forty of the inmates were paralytics and it was only with great difficulty that they were saved from the flames. That there was no loss of life was due to the efficient work of the fire fighters connected with the institution and of the Rome firemen who responded to the alarm.

The New Bellevue.—The first of the new buildings at Bellevue Hospital was opened in November. This has just been completed at a cost of something over a million dollars. The building is seven stories high, and contains two pavilions, known as A and B, of eight wards each, altogether accommodating about four hundred patients. The top floor will be devoted to wards for maternity cases, and the children's and medical wards will be housed on the lower floors. In the main building it will now be possible to have four wards for the tuberculosis patients, who have hitherto been housed in small wooden buildings along the river front. These will be abandoned, as will the building outside the hospital grounds which has been used for maternity cases.

Dr. Samuel T. Armstrong, who has been General Medical Superintendent of Bellevue and the Allied Hospitals, New York, since July, 1905, resigned on November 4.

Colleges Merge.—The Keokuk Medical College of Keokuk, Iowa, has recently been merged with the College of Medicine of Drake University at Des Moines, and a number of its students will continue their studies at the latter place. The Keokuk Medical College was organized in 1849, and in 1899 absorbed the College of Physicians and Surgeons; later on colleges of dentistry and pharmacy were added. The library, museum and laboratory equip-

ment will be transferred from Keokuk to Des Moines.

Chicago Urological Society.—At the annual meeting of this Society, held October 23, 1908, the following officers were elected: *President,* Dr. David Lieberthal; *Vice-President,* Dr. Robert Herbst; *Secretary-Treasurer,* Dr. V. D. Lespinasse; *Councilor,* Dr. William T. Belfield; *Alternate,* Dr. B. C. Corbus.

Association of Military Surgeons of Illinois.—At the annual meeting of this Association, held in October, the following officers were elected: *President,* Major Thomas C. McCord, assigned Fourth Infantry; *Vice-President,* Lieut.-Commander David W. Graham, Naval Reserve; *Secretary,* Major Charles Adams, Surgeon-General; *Assistant-Secretary,* Major S. C. Stanton, assigned First Infantry. The next meeting of the Association will be held at Dixon.

Western Illinois District Medical Society.—This Society held its annual meeting October 30, at Jacksonville. Dr. James W. Pettit, President of the Illinois State Medical Society, delivered an address, as did also Dr. Edmund W. Weis, of Ottawa. It was decided to hold the next meeting in Quincy. The election of officers resulted as follows: *President,* Dr. John W. Adams, Carrollton; *Vice-Presidents,* Drs. John H. Rice, Quincy, and David W. Reid, Jacksonville; *Secretary-Treasurer,* Dr. Wm. P. Duncan, Jacksonville; *Censors,* Drs. Robert J. Christie, Jr., Quincy, Frank P. Norbury, Jacksonville, and Levin H. A. Nickerson, Quincy.

The Pathological Society of Philadelphia, at its meeting on October 22, elected the following officers: *President,* Dr. Joseph McFarland; *Vice-Presidents,* Drs. Edsall, Reisman, Kelly, and Smith; *Secretary,* Dr. R. S. Lavenson; *Treasurer,* Dr. C. Y. White; *Recorder,* Dr. F. H. Klaer; *Curator,* E. H. Goodman.

The First District Branch of the Medical Society of the State of New York, at its second annual meeting in Poughkeepsie on October 21, elected the following officers: *President,* Dr. Charles E. Townsend of New York; *Vice-President,* Dr. Theodore D. Mills of Middletown; *Secretary,* Dr. C. E. Denison of New York; *Treasurer,* Dr. J. E. Sadlier of Poughkeepsie.

The Fifth District Branch of the Medical Society of the State of New York, at its annual meeting held in Utica on October 15, elected the following officers for the ensuing year: *President,* Dr. G. D. Gregor; *Vice-President,* Dr. F. E. Fox; *Secretary,* Dr. W. D. Garlock; *Treasurer,* Dr. F. Edward Jones.

The Sixth District Branch of the Medical Society of the State of New York, at its annual meeting in Binghamton, elected the following officers: *President,* Dr. S. A. Mereness; *Vice-President,* Dr. F. DeW. Reese; *Secretary-Treasurer,* Dr. H. W. Fudge.

Death of Centenarian.—Mrs. Julia O'Brien died on November 6, at the St. Francis Home in New York, at the age of 104 years. Born in County Tipperary, Ireland, she came to this country seventy-five years ago, and up to the time of her death took the keenest pleasure in smoking a corncob pipe, "to which habit she attributed her long life."

Obituary Notes.—Dr. Walter R. Gillette of New York died on November 7, at the Roosevelt Hospital, where he had recently undergone an operation for intestinal cancer. Dr. Gillette was born in Philadelphia in 1841, and was graduated from Hamilton University in 1861, and from the College of Physicians and Surgeons, New York, in 1863. For two years following he served in the United States Army as assistant surgeon, and for thirteen years thereafter was surgeon of the New York Postoffice. For fifteen years he was a member of the Faculty of the University Medical College. He was also a member of the New York Academy of Medicine and of the County Society, and consulting physician to Bellevue, St. Francis', and the Manhattan State Hospitals.

Dr. Walter J. Corcoran of Brooklyn, N. Y., died at his home on November 5, aged 51 years. Dr. Corcoran was graduated from the College of Physicians and Surgeons of New York in 1882, and has since practised in Brooklyn. He was a member of the Brooklyn Pathological, Surgical, and Gynecological Societies, and visiting gynecologist to St. Mary's Hospital and St. Mary's Female Hospital.

Dr. Francis F. Parker of Chicopee, Mass., died at his home on October 29, after several years of ill health. Dr. Parker was born in 1841, and was graduated from Tufts College in 1865, and from the Harvard Medical School in 1869. He had practised in Chicopee continuously for thirty-eight years.

Dr. David J. Doherty of Chicago, Ill., died on October 27, at the hospital of St. Bernard de Dieu, aged 58 years. Dr. Doherty was graduated from the medical department of the University of Minnesota in 1887, and from the University of Freiburg in 1888, and for several years had made a study of the language and customs of the Filipinos, having become interested during a trip to the islands.

Dr. Thomas Gregory Walsh of Milwaukee, Wis., died at his home of kidney trouble, on October 25, aged 47 years. Dr. Walsh was graduated from the Rush Medical College, Chicago, in 1888, and after a year as interne at the Cook County Hospital, settled in Milwaukee. For twenty years he served as visiting physician to St. Vincent's Orphan Asylum, and was on the staff of St. Mary's Hospital up to the time of his death. He had recently attracted attention because of a successfully performed operation of skin grafting on a young woman whose scalp was torn off in an accident in a knitting mill where she was employed.

Dr. John H. Jackson of Fall River, Mass., died at his home on October 27, in the 71st year of his age. Dr. Jackson was a native of Maine, and was graduated from the Colby College in 1861, and from the medical department of Bowdoin College in 1868. He was a member of the American Medical Association, the Massachusetts State Medical Society, and the Fall River Medical Society. In 1893 he was appointed registrar and professor of the theory and practice of medicine in the College of Physicians of Boston, and was for many years on the staff of the Union Hospital of Fall River.

Dr. William G. Buckley of Philadelphia, Pa., died on October 26, aged 74 years. Dr. Buckley was graduated from the medical department of the University of Pennsylvania in the class of 1861, and served as surgeon in the 1st Pennsylvania Reserve Corps during the Civil War.

Dr. Engelbert Voerster of St. Louis, Mo., died at his home on October 26, after a short illness, aged 66 years. Dr. Voerster was graduated from the Washington University, St. Louis, in 1865, having interrupted his studies to join the Union army during the Civil War. He served as coroner of St. Louis County from 1870 to 1878.

Dr. Nathan C. Gunder, one of the oldest practitioners of Columbus, Ohio, died at his home of

arteriosclerosis, on October 22, aged 76 years. He was graduated from the Cincinnati College of Medicine and Surgery in 1860, and had been in active practice until two years ago.

Dr. Emil G. Rehfuss died at Philadelphia on October 30 at the age of 47 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1884 and became resident physician in the German Hospital.

Correspondence.

A QUERY.

To the Editor of the Medical Record:

Sir:—I take the liberty of asking you and the editor of the *New York Medical Journal* a question. As you, in your capacity of medical editors and teachers, naturally take a warm interest in the subjects of alcohol and of therapy, have you no room for discussions on the hygienic and medical uses of alcohol and on psychotherapy? Both are of vast and universal import. If you have room for them—provided they are more than mere momentary notions—can you and will you tell your colleagues and readers why some of our brethren swamp the daily newspapers with their knowledge, or their convictions, or opinions, or impressions? A. Jacobi, M.D.

New York, November 9, 1908.

THE ABUSE OF A CALLING.

To the Editor of the Medical Record:

Sir:—One of the greatest impediments to progress at all times has been the liability of the crowd to respond to appeals to its subjective weaknesses, with the result that it has blindly followed some leader or adopted some cult which has done the most in the way of emotional stimulation, and appealed but in a minimum degree to the proper exercise of judgment. In all ages we have been furnished with examples of this, and LeBon in his excellent work sketches the psychology of the crowd most admirably. The genesis of new religions, the influence of "Messiahs," and the history of "Cures" are full of picturesque examples of what may be done by a clever, or even a dull and persistent leader and a receptive mob. These popular movements are more or less short-lived, but the original frailty of human nature continues, ever ready to be played upon by the designing rogue or the unbalanced fanatic.

Just now we are upon the summit of a wave of this kind; the sensational newspapers are playing their part, the pseudoscientists and the medical amateur are in evidence, and the meddlesome divine is appealing to the unstable members of his flock, just as his predecessors have done for centuries.

"Regular medicine" is unpopular just now, and an ignorant Assembly legalizes one species of fraud after another, while our own profession, secure in its conscious sense of dignity, sits quietly without protest, hugging to its soul the flattering delusion that the public will some day see its error and the disloyal patient will return to the fold after he has had his experience. Unhappily he does nothing of the kind, for new frauds are as numerous as the leaves—or let us say, rather, the toadstools—in the forest of Vallambrosa, and all are inviting. In this connection it is to be regretted that much supineness exists, and that medical men can be found to encourage these abuses. One physician of good standing has added to the popular unrest by the peculiar stand he has taken in regard to an alleged cure that has been recommended for a hopeless organic disease, which, after all, is a very ancient and popular method with various "old" doctors whose names and pictures appear from day to day in the cheap newspapers, and who treat all disease through the male urethra.

Medical approval has also been given to what has been facetiously called "Christian Science with Worcester Sauce," an imitation of the methods of Mrs. Eddy and her followers, who are at least, to a degree, original and apparently prosperous, and not dependent upon the languishing of their own churches and the loss of interest of their parishioners. It would appear from an inspeciton of the "year book" of one Episcopal Church of this city that there has been a decided falling off in attendance and actual interest in church work; and the empty church of another clergyman has been filled only through a sensational play to the Socialists from the East Side, who themselves have finally become disgusted with well-dressed and clean people, and finding it was not "the real thing" have abandoned their opportunity. No wonder a new craze is demanded!

The suggestion has been made that a remedy for all this is that the public should be instructed. As a Utopian proposition, this is very attractive—as a practical one it can only be compared to the trouble that would arise if lawyers taught their clients law, which they were subsequently to utilize at their own discretion. Information as to the public health and what to do in emergencies is well enough, but "domestic medicine" certainly has its limitations, which nowadays seem broad enough, and we are always reminded that a little knowledge is a dangerous thing when we take into account the ease with which patients procure tabloids of many dangerous drugs with perfect impunity.

Instead of the present apathy of our profession, we should in some measure arouse ourselves to expose fraud more actively than we have hitherto done—if necessary, by tracts or other publications, and there should be a publicity committee of the County Medical Society for this purpose. Other medical bodies should *visé* every paper submitted for delivery; unlicensed practitioners should be more rigidly prosecuted than at present, and new and comprehensive laws should be enacted, including the prohibition of various forms of treatment, as well as the giving of drugs, by unqualified individuals. Persons who have been swindled or maltreated should be helped and encouraged to bring suit against those who have not kept faith with them. Physicians themselves should cultivate the lost art of prescribing, and never be tempted to cater to the fanciful idiosyncrasies of their patients at the cost of their own dignity and self-respect for fear that the latter would go elsewhere. Allan McLane Hamilton.

New York, November 9, 1908.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE HARVEIAN ORATION—ROYAL SOCIETY OF MEDICINE—GENERAL PARALYSIS IN CHILDHOOD—GASTROSTAXIS—TRAUMATIC RUPTURE OF INTESTINE—WOMEN ADMITTED TO COLLEGE OF SURGEONS—GUILD OF ST. LUKE—MEDICAL EXHIBITION—OBITUARY.

London, October 23, 1908.

The Harveian Oration at the Royal College of Physicians was delivered on Monday by Dr. J. A. Ormerod, who devoted it to the subject of heredity in disease. He began by referring to the wishes of Harvey, who in founding these orations desired them to be exhortations to search out the secrets of Nature by observation and experiment. Harvey meant to emphasize the importance of independent, individual research as opposed to blind and lazy submission to authority. He refused to let learning trammel investigation, and this frame of mind was most necessary in the study of medicine. In directing attention to heredity, especially in disease, Dr. Ormerod said that though a German physician had denied the existence of hereditary disease they need not argue the point, as they would all admit that heredity had a good deal to do with the production of disease. In Harvey's work, "De Generatione Animalium," he gave probably the best account that could be given at that time of the phenomena of development, and in that book he wrote: "Some diseases propagate their kind, but why speak of diseases when the moles, warts, and cicatrices of the progenitor are seen in the third and fourth generations?" As to whether acquired characters are transmissible or whether the forces which help to fashion us have similar effects on our unborn offspring: The unlearned man said yes, and so did the learned until some time ago. Darwin's theory of selection assumed this, but it was incompatible with Weissman's. His central idea was continuity of the germ plasm—a plasm not manufactured afresh within the individual of each generation, but continuously handed on from one generation to the next, only changing in this sense, that as each successive individual is made, a portion of the germ plasm is set aside within him, with which to carry on the work of propagation. Thus we are not links in the chain of life, but flowers or leaves springing from a common stem—the germ plasm. The relationship was not that of father and son, but of brothers, the real father of all being the family germ plasm, and the duty of each individual was to accommodate him in the house he had built, that is, one's body, until another house, viz., that individual's son's body, was ready to receive him. The

next question might be: Do the ills acquired by parents affect the well-being of their children? If they suffered the germ plasm would have to suffer. It was another question altogether whether when a parent acquired some particular disease, the same or a similar one would affect his offspring. Those who denied this said it would not be, because it contradicted the theory. Here was a legitimate field for observation. At first sight syphilis seemed a decided instance, but this was answered by ascribing it to infection. If a healthy man acquired phthisis or gout, would his children be consumptive or gouty? Dr. Ormerod did not profess to be able to reply to this question, but observed that many of those he addressed had experience which might supply some material towards the determination of these problems. He passed on to refer to the value of Galton's statistics, and then to the work of Mendel as to the hypoidization of plants, but what we wanted to know, he said, was whether Mendel's laws were applicable to man, or how far they were so. In some cases where observations had been made on special points, such as the color of the iris, hereditary diseases of the eye, and hereditary deformities of limbs, the Mendelian proportion worked out, and perhaps more than that could not be asserted. With plants and animals experiment was possible—but not with mankind; we could not select our parents. On the Mendelian principle consanguineous marriages were the means of bringing to life hidden characters, and these might be either good or bad. The orator also spoke of the manner in which heredity was seen in the nervous system, and mentioned the curious fact that a person might develop late in life a disease which had potentially existed from birth.

After the oration the Bissett Hawkins medal was presented to Sir Shirley Murphy. This medal is awarded triennially for distinguished service in sanitary science. Sir Shirley expressed appreciation of the honor, and held it to be a compliment to those who worked with him as well as himself.

The clinical section of the Royal Medical Society was among the early ones to meet, and some very interesting cases were exhibited and discussed. Dr. Poynton showed a girl of 11 and a boy of 8½ whom he considered to be subjects of general paralysis—a rare affection in childhood. In the first there were some signs of syphilis, but not in the other, which dated from two seizures at night, in which there was screaming and trembling. Sir T. Barlow thought that the first case syphilitic and the other infantile paralysis, though there was room for doubt. Such cases were seldom met with in asylums, and so general physicians more often saw them than alienists. Dr. Walter Carr thought the diagnosis of the second case was between general paralysis, disseminated sclerosis, and a tumor of the pons. He had seen tremors in such a tumor, but here the other symptoms did not support that diagnosis.

Dr. Stanley Green of Norwich showed a case which he called gastrostaxis, from its correspondence with the description of Dr. Hale White and no pathological lesion having been found at two operations. The patient, a young woman, was first seen in January, 1901, in collapse from hematemesis—had had pain after eating for three years and gastric ulcer which had perforated was suggested. Recovery was slow, and for twelve months she acted as a lady's companion, but hematemesis recurred, with melæna. Gastroenterotomy was done, and for six months there was no hemorrhage, but it then returned as bad as ever. The stomach and duodenum were therefore opened and explored, without any discovery. In 1907 gangrene of the fingers began, and some digits were successfully amputated. A younger sister had had hematemesis and lost a phalanx of one finger. Sir T. Barlow said surgeons recognized that the bleeding point could not always be found. The attention to this condition had been called by Dr. Donald Hood, and many years later by Dr. Hale White. Dr. White himself said he knew of no record of gangrene of the fingers in these cases, though he always thought the capillaries must be affected, and this case showed imperfect vascular supply to the hand.

A case was shown of a man with a foreign body in a bronchus, and who had cough, dyspnea, purulent expectoration, and hemoptysis; no tubercle bacilli. At this meeting also Brüning's recent modification of Killain's instrument for exploring the trachea, etc., fitted with a suction pump by which secretion and a foreign body might be withdrawn, was exhibited. Mr. Godlee asked how far down the air passage could a foreign body be removed. He mentioned a case in which a pin lying across the left bronchus had been extracted, and remarked that, unfortunately, the prognosis of these cases was unfavorable, on account of bronchiectasis soon setting in and the persistence of this dilatation. He also referred to some operations done by German surgeons under modified atmospheric pressure, by which manipulation of the lung could be carried out without producing pneumothorax.

In the surgical section Messrs. Berry and Giuseppi contributed a paper on traumatic rupture of the intestine without external wound. They related a case of recovery after operation, and then analyzed all the cases admitted into ten London hospitals during the last fifteen years. These numbered 132, and no less than ten had been under one of them and seven others came under his notice, the post mortem being in most cases performed by him. Only seventeen of the 132 recovered; eighty-four were operated on, and seventeen of them were the recoveries. In fifteen the rupture was not found, and in seven of these it was duodenal, and only one recovered. The authors discussed these and other points, and submitted as conclusions: (1) That rupture of the duodenum was by no means so rare as usually supposed; (2) that rupture was usually produced by direct crushing, not by bursting or traction; (3) that the early symptoms of primary complete rupture were few, but fairly characteristic; (4) most important were severe, continuous pain, rigidity of the abdominal muscles, and vomiting; (5) that secondary rupture was by no means uncommon (the symptom there might be delayed for hours or even days); (6) early operation was the only treatment; (7) if operation is delayed until the abdomen is distended or liver dullness absent, there is practically no chance of success; (8) after operation the patient should be set up in bed and treated with massive saline infusions *per rectum*.

The Royal College of Surgeons has decided to admit women to its diplomas. They will therefore now be eligible for the double qualification of the two colleges as soon as the arrangements are concluded.

The Guild of St. Luke had their annual service at St. Paul's on the 20th.

The fourth annual medical exhibition, organized by the "British and Colonial Druggists," was held last week, and was highly successful.

Dr. Jas. Grey Glover died on the 14th inst., aged 76. He took his M.D. at Edinburgh in 1854. He was one of four brothers, and all of them attained a high position in their different professions. Dr. Glover for many years held a high position in the North of London, and continued in general practice to the last. Of late he was in partnership with his son, who is following in his profession. Journalists as well as medical men regret the loss of Dr. Glover, who for some forty years was on the staff of the *Lancet*, and always upheld the best traditions of his profession and contributed to the high tone of medical journalism. He was one of the first elected representatives on the General Medical Council, was a visiting justice of Holloway prison, and one of the warmest supporters of the Hospital Saturday Fund, and served on its first council. To many Glover's death seemed sudden. He was attending to the practice while his son was on holiday, and taken ill on the Monday, he died on the Wednesday.

Dr. Cuthbert Collingwood, the eminent botanist who has died at the age of 82, was a member of our profession. He was educated at Oxford, Edinburgh, and Guy's Hospital, graduating at Oxford in 1840. He became a member of the College of Physicians in 1859, was then a lecturer on botany at the Liverpool Medical School until 1866, when he went to the Far East to study marine zoology. His "Rambles of a Naturalist on the Shores and Waters of the China Seas" grew out of this voyage. His other investigations were recorded in scientific journals.

Dr. John Taylor, who died on the 10th inst., had been blind for the last few years. He was 73 years of age, and greatly respected in Hampshire, where he had practised for some time. In early life he served in the army, was through the Crimean War, and subsequently the Indian Mutiny.

INTERNATIONAL CONGRESS OF UROLOGY.

(From Our Paris Correspondent.)

PARIS, October 15, 1908.

FOUNDED at Paris in 1907, the International Association of Urology has for its object the study of all questions that pertain to urology. It meets as a Congress every third year, in a city designated by the General Assembly, under the presidency of a member elected by the preceding Congress. The number of members of the association is limited, and only those can be members who are agreed upon by the international committee, having been proposed by the committee from their own country.

The first International Congress has just been held at Paris, from September 30 to October 3, 1908, under the presidency of Professor Albarran of Paris. The vice-presidents were Posner of Berlin and Watson of Boston. The inauguration of the Congress took place in the large amphitheater of the Paris Faculty of Medicine, under the presidency of the Minister of Public

Instruction, who welcomed the many foreign members of the Congress who had come from all parts of the world. Then Professor Guyon, in a few words, which were much applauded, showed the usefulness of Congresses, and especially of International Congresses. Israel of Berlin spoke in eulogy of Professor Guyon, who has, so to speak, created urology. All the urologists of the world are proud of proclaiming themselves his pupils.

Four questions were studied by this Congress: (1) "Pathogeny and Treatment of Anuria"; (2) "Vesical Retention Without Mechanical Obstacle"; (3) "Normal and Pathological Physiology of the Prostate"; (4) "Operative Indications in Tuberculous Kidney."

The first question, "Pathogeny and Treatment of Anuria," was presented by Kümmel of Hamburg, Watson of Boston and Achard of Paris. Kümmel distinguishes two kinds of anuria; the first, true anuria, in which the kidney produces no urine and the secretion of urine is entirely absent; the other, false anuria, in which the urine secreted by the kidney cannot reach the bladder on account of the obliteration of the ureters. The most frequent cause of ureteral obliteration is the presence of calculus, but it may result from the pressure of pelvic tumors, tumors of the ovaries, and especially cancer propagated from the uterus. True anuria, in which the renal function is entirely suppressed, may be produced by nephritis, whether this arises from chronic inflammatory phenomena, from toxic conditions, or infectious diseases. It may also be caused by tumors of both kidneys or by an affection of one kidney coexisting with a congenital absence of the other kidney. Lastly, reflex anuria, from lesions of a single kidney, is particularly interesting to study, as is hysterical anuria. The treatment of anuria will vary with the cause: if the ureter is obliterated we must remove the cause of the obstruction (calculus or tumor); in true anuria produced by nephritis, incision of the capsule or nephrectomy is indicated. In reflex anuria on account of disease of one kidney, the cause of the morbid condition of the kidney must be removed.

Watson of Boston had especially studied calculous anuria; he considered that the first kidney to be operated on when the two organs have a sufficient functional power should be the one least involved; in case of bilateral calculus the two kidneys should be opened at the same time whenever the operator doubts whether the first kidney opened will be sufficient to maintain life. Achard of Paris had studied the question of the pathogeny and treatment of anuria principally from the medical standpoint. Like Professor Kümmel, he distinguished two kinds of anuria: one consists in an arrest of secretion, the other of an obstacle to secretion. The type of excretory anuria is represented by calculous anuria, but it may also be produced by a tumor, such as uterine cancer. Secretory anuria has a more obscure pathogeny; sometimes it is possible to believe that obstruction by means of the epithelium of the convoluted tubules is the cause of the anuria, but in reality the mechanism of anuria is complex and several conditions may act separately or conjointly; in the anuric patient we often see coincident lesions of the kidney of a complex nature, epithelial, of the connective tissue, and vascular. The treatment of excretory anuria belongs to surgery, that of secretory anuria to medicine; stimulation of the secretory mechanism of the kidneys may be produced by renal diuretics and by subcutaneous injections, either of saline serum, or better still by intravenous injections of solutions of sugar; lastly, two operations may be done in these cases, nephrotomy and decapsulation of the kidneys.

After the reading of these papers and some interesting discussion Chauffard spoke, insisting especially on anuria produced by intoxications, and chiefly that by corrosive sublimate. This intoxication has been known to produce immediate anuria, ending in death. At the autopsy it has been found that the glomeruli were normal, the lesion being in the epithelium of the convoluted tubes which were completely necrosed. He believes that the alteration of the epithelium of the convoluted tubes is the principal cause of anuria of nephritic origin and medical anuria. Tessier of Lyons believes that anuria of medical origin finds its cause not so much in the kidneys as in the liver; it is the toxins not eliminated by the liver but acting on the kidneys which cause the alterations of the kidney epithelium and secondarily the anuria. Nicolich of Trieste and Albarran of Paris insisted on anuria of calculous origin. Jeanbrau of Montpellier demonstrated the good results of injections of sugar in two cases of anuria; the advantages of the solution of sugar are that they need much less work by the kidney to dispose of them than solutions of chlorides; second, they do not introduce any chlorides into the organism, thus being less toxic than salt solution; third, the sugar that they contain is partly burned up by the organism and eliminated as water and carbonic acid by the lungs. As to the doses, in urgent cases he advises the injection of 500 cubic centimeters of a 25 per cent. glucose solution into a vein. Pavone of Palermo recalled the usefulness of catheterism of the ureters in calculous anuria. He reported three cases in which this method of treatment gave him excellent results. Ponsson of Bordeaux insisted upon the value of nephrotomy in anuria and oliguria of medical and surgical affections of the kidneys. The principal advantages of these operations is to open a way for the escape of the fluid which engorges the renal canaliculi, and thus to prevent the alterations of the tubal epithelium. He believes that incision of the kidney offers a precious resource in the acute periods of nephritis caused by calculi with oliguria. Legueu of Paris insisted in calculous anuria on the alterations of the kidneys on the opposite side from the obstruction. He operates at once on the obstructed kidney, and the diagnosis of the side to be operated on is made by him an indication noted by him, which consists of the contraction and resistance of the abdominal parietes of that side.

The second subject of the day was "Vesicular Retention without Mechanical Obstruction." This question was treated by Frankl-Hochwart of Vienna and Albarran and Nogues of Paris. Frankl-Hochwart insisted on the rôle played by the nervous system in vesical retention without mechanical obstacles; among the nervous maladies are those of the spinal cord which often cause retention, and among them was especially noted tabes; of the neuroses hysteria often causes complete anuria from retention. Albarran and Nogues distinguished three different divisions in retention of urine; they studied, first, retention occurring with an insufficient obstacle such as occurs in the course of small hypertrophies of the prostate in prostatitis, and in stricture. They then considered retention without any obstacle and with lesions of the bladder. These are the so-called medical retentions which are due to an acute or chronic intoxication; they are met with in acute affections, such as typhoid, eruptive fevers and diphtheria. In such cases the authors insist on the rôle of spasm, which is simply due to the normal inhibition of the sphincter. Lastly, retention of urine with no obstacle, but with lesions of the bladder, are due sometimes to true degeneration, such as is seen in the aged; sometimes to inflammatory lesions. It is these that are seen in tuberculous cystitis. Finally, there are cases of chronic nature that have an etiology that is obscure, and which cannot be classified under any of these three heads, and which cannot be explained. There is still much to be studied with reference to cases of obscure etiology.

An interesting discussion now began, in which Hock of Prague and Edward Keyes participated. The latter author insisted on the importance of slight obstructions of the neck of the bladder; these cannot be diagnosed except by palpation of the lower part of the posterior urethra with the finger introduced into a perineal buttonhole; he also insisted on the benefit obtained by electrocauterization of the sphincter (Bottini) practised by the perineal route; he is reserved with reference to all operative procedures, which generally aggravate the condition. Fenwick of London and Rothschild and Frank of Berlin then mentioned cases of interest in this connection. Serralach of Barcelona believes that testicular secretion is of great importance, and may be employed with success in vesical retention without obstacle. He has observed in such cases that an injection of testicular juice has produced excellent results in stopping incontinence. The mode of action of testicular juice is due to the fact that it increases the nervous power. Bartrina of Barcelona attaches great importance to deformities produced by even slight hypertrophy of the prostate; this is also important in prostatitis without hypertrophy.

The third question was "The Normal and Pathological Physiology of the Prostate." The readers of papers were Posner of Berlin and Haberern of Budapest. Posner believes that the prostate has no single function, but serves several purposes; it contributes slightly to the closure of the bladder; it is above all the apparatus that serves at the moment of ejaculation; mingling with the spermatic fluid, the prostatic juice protects the vital force of the spermatozoa and prolongs it. The prostatic extract of one animal is poisonous to other animals; thus rabbits and guinea pigs are killed by even a small dose of the prostatic juice of the bull; however this may be, the importance of the prostate has not been completely elucidated and many obscure

points still exist. Haberern thinks that the most important function of the prostate is the secretion of a thin, milky, slightly alkaline fluid, having the characteristic odor of spermine. It acts upon the movements of the spermatozoa, perhaps by dilution, perhaps by a specific excitation, and its powers are most important at the moment of ejaculation. An important discussion followed, and among the views detailed must be mentioned those of Pardoe of London, who, following the evolution of the prostate in the animal series, presented many interesting facts on this subject. One series of experiments made by him showed that the prostatic juice is indispensable for the movements of the spermatozoa, so much so that when this juice does not exist the spermatozoa cannot produce fecundation. He has made observations on many patients on whom he has done transvesical prostatectomy, and in many cases he has found the presence of living spermatozoa.

The fourth question was "The Indications for Operation in Tuberculous Kidney." Among the readers of papers present the most remarkable work was that of Brongersma of Amsterdam. The author studied especially the way in which the tubercular infection reaches the kidney; he believes that if ascending infection is possible it is exceedingly rare; entrance of bacilli by way of the blood, regarded up to the present time as most frequent, and as proved to exist by miliary tuberculosis, does not appear to this author to play any considerable rôle. He believes that much more frequently renal tuberculosis is brought by the lymphatics, and this theory explains the unilaterality that is frequently observed in renal tuberculosis, as well as the consecutive propagation to the other kidney. With reference to spontaneous cure of renal tuberculosis, the author denies the possibility of it; by clinical observation, by autopsies, and by statistics it is proved that the normal kidney must be fatally infected as soon as the lesions of the diseased kidney are of considerable amount. The natural deduction from all these observations is that when there is a single tubercular kidney a nephrectomy should be done as soon as possible. The only possible contraindications will be bilaterality, advanced lesions of other organs and bad general condition of the patient.

A second paper was presented by Dr. Barthélémy Guisy of Athens. This author thinks that total nephrectomy is the only procedure that will bring about a cure of unilateral renal tuberculosis. Operation is contraindicated only when there are bilateral renal lesions; on the contrary, operation should be done early; it should be done equally in cases in which one kidney being tuberculous, the function of the other is not perfect; when there are pulmonary lesions, or lesions of the lower genitourinary region, nephrectomy is indicated when the general condition of the patient is not bad. The author does not advocate the resection of a large part of the ureter, since he thinks that the ureter will atrophy of itself and become a fibrous cord. Dr. Heresco of Bucharest also presented a paper. Like the other writers, he believes that renal tuberculosis is incurable by medical means, and since its course is progressive, there is only one operation that can be of value. This operation is nephrectomy, the results of which are much more certain when it is done early. the disease must be diagnosed at its beginning, and the watchword of the author is: Early diagnosis with early operation.

Finally, Dr. George Luys of Paris, admitting as an established dogma that unilateral renal tuberculosis demands immediate nephrectomy of the diseased kidney, thinks that the entire history of operative interventions may be summed up by early diagnosis and certainty that the tuberculosis involves only one kidney; to establish perfectly this diagnosis the clinical history and the ordinary methods of exploration are not sufficient. Precise diagnosis of unilaterality of renal tuberculosis can only be obtained by the study of the separate urines of the two kidneys, and the separation of the urines should be made either by endovesical separation of the urine with the separator of Luys, or by ureteral catheterism, but the two methods of investigation should never be placed in opposition with one another; on the contrary, they should be mutual aids to one another and each should be applied in its own way. In the immense majority of cases the separator is the instrument to which we should have recourse; it will show, thanks to the careful chemical analysis which should be made of the separate urines, which is the diseased side and which the sound side. It is only in the most doubtful cases that it will be necessary to confirm the work of the separator by ureteral catheterization of the diseased kidney. This will happen when the separator, having shown pus and Koch's bacilli in one side, there are combined with a possible lesion of the other kidney tuberculous nodules in the corresponding lobe of the prostate, or in the seminal vesicles. Under these conditions ureteral catheterization of the corresponding diseased kidney will show whether the pus comes from the kidney, or the prostate, or the vesicles, or whether an abscess has been produced by Pott's disease of the spine, which has opened into the bladder. In children the smallness of the passages to the bladder will not always allow of the employment of the separator reduced in size for use in children. When there is a secondary tuberculosis of the bladder and the organ is intolerant of manipulation, and will not admit any exploratory instrument, and it is absolutely necessary to know whether the renal tuberculosis is bilateral or not, only one method is possible, ureteral catheterization of the healthy side with the direct vision cystoscope designed by Luys. With this instrument used under chloroform it is generally possible to find the orifice of the ureter of the healthy side, and having done this, it is possible with a tampon soaked in silver nitrate to make the ureteral orifice itself antiseptic; thus a thoroughly sterilized sound will not come in contact with the portion of the vesical mucous membrane which surrounds the ureteral orifice, while this will be entirely aseptic; in this way there will not be any risk of infection of the kidney which is supposed to be healthy by the introduction into the ureter of the ureteral sound. Practised in this way ureteral catheterization will never be harmful, as would be the case when it is done with a cystoscope with prisms through a limpid liquid, or an obscure infected one.

The members of this first International Congress of Urology had come in great numbers to Paris. Receptions and entertainments were given in their honor. Besides receptions by the official Faculty, the members of the Congress were received by the Municipality of Paris at the Hôtel de Ville, and after the close of the sittings of the Congress all the members were received at a private audience at the Elysée by the President of the Republic. M. Fallières congratulated his guests on enriching the field of science by new studies for the good of the object of their first reunion at Paris.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 29, 1908.

Fractures of the Os Calcis.—A preliminary paper on this subject is presented by F. J. Cotton and L. T. Wilson, who emphasize the following points: Comminuted fractures of the os calcis are comparatively common and nearly all of them are of substantially the same type. Following the injury, there is apt to be permanent deformity or disability with reference to raising or shortening of the heel or its outward deviation, flattening of the arch, projection of fragments into the sole of the foot, loss of motion between the astragalus and the os calcis, and mechanical interference between the latter and the external malleolus. These results are often so pronounced as seriously to interfere with the patient's work or disable him entirely. The trouble arises, not from the fracture as such, but from the various displacements. Treatment heretofore has been practically mere negligence. In fresh cases certain measures are practicable. Difficulties in handling them arise from the hard task of correcting displacements and retention in position. The authors have employed an ordinary cast of plaster-of-Paris equipped with two felt pads, one over the tendo Achillis and os calcis, one over the dorsum of the foot. After the plaster is on, the foot is put up at about 15 to 20 degrees of plantar flexion, and during the setting of the plaster, downward traction is made with the hands on the dorsum of the foot and behind at either side of the tendo Achillis. Usually it seems wise to secure some inversion as well as very slight plantar flexion. The reaction following such reduction is surprisingly slight. The patient can be up on crutches (if the lesion is of one side only) within a week. In a week or ten days the primary callus seems adequate to hold the connection. At this time removal of the cast occasionally for massage and guarded active motion is wise. They have not allowed weight-bearing for a month, though delaying the beginning of use so long may be unnecessarily conservative. There seems little tendency to reproduction of deformity or stiffening. Return of full function is rather slow; probably three months will be a fair average of time. Provided such measures have not been carried out, and provided disability is present, palliation is possible by apparatus in some cases, while in others certain safe and simple operations will insure decided improvement of function. These operations are necessitated by loss of motion in the joints,

excessive bony thickening below the external malleolus, bony spurs in the sole, outward displacement of the heel, and extreme upward displacement of the heel. Forcible correction may be done under ether with early passive motion, bony thickening and spurs may be removed with a chisel, etc. The paper is presented as a plea for a more accurate study and a more active and real surgical treatment of the condition.

New York Medical Journal, October 31, 1908.

The Expectant Treatment of Pulmonary Tuberculosis.—A. B. Judson considers that the problem of pulmonary tuberculosis is paralleled by that of tuberculosis of the hip. The tissues affected in these respective maladies have peculiarities of anatomy and physiology which make it reasonable to believe that the treatment accorded to one may be applied, *mutatis mutandis,* to the other. The lung is a semidetached, almost pedunculated organ. The hip is an inherent part, interlocked with other parts of the body by far-reaching and rigid processes. The construction of the lung is simple, that of the hip complex and jointed. Lung tissue is soft and homogeneous, completing development with the cry of the new born, while the tissues of the hip range from hardest bone to impalpable synovial membrane, and reach development in late adolescence. The vascular network of the lung invites infection and encourages repair, while the hip, with its comparatively deficient circulation, reluctantly yields to disease and reacts so slowly that a typical case of hip disease covers several years. If the hip rises superior to tuberculous infection, what forbids the expectation of signal recovery in the lung, so separate from the rest of the body, so simple in construction, with rapidly developing, homogeneous, and plastic tissue, so infused with vascularity, and altogether so alert and responsive to the appeals of disease and recovery? And the factor of safety is to be considered. If both lungs were seriously impaired the case would be fatal, but when it is known that with only part of a lung life may be indefinitely prolonged who can put a limit to recovery in a favorable environment? The local treatment of pulmonary tuberculosis based on the teaching of orthopedic practice may be thus outlined: (1) The omission of whatever unduly excites respiration and circulation, (2) habitual reduction of the volume of respired air to a minimum, and (3) inhibition of coughing.

Family Tuberculosis.—A recapitulation of the facts given by W. C. White in regard to a certain family may be stated as follows: There developed in fifteen months eight cases of tuberculosis in a family of nine who had not lived together for ten years, who were scattered in six different homes in five different American and Canadian cities. The ages of the victims ranged from seventy-one to twenty years. There was no known source of infection; they had always lived under the best conditions. Four were diagnosticated by the presence of tubercle bacilli, one by tuberculin, and three by physical signs and symptoms. The writer made or confirmed the diagnosis in every case. In this group of patients most careful inquiry failed to reveal any source of infection of human origin. Far more likely is the other possibility that all were infected with approximately equal doses at approximately the same time from some source other than human. This allows the difference in the chemical resisting powers of the individuals caused by innate and extraneous factors, such as work and worry, to explain the paltry differences in the time of the appearance of the malady in each case. Such a view is strengthened by the bovine morphology of the infecting organism in those cases in which it was found, by the habit of the family in consuming large quantities of milk, and by the escape of the only one who used very little milk; which facts also go to prove that the source of infection was bovine. The writer also calls attention to the facts shown by charts based on the death rate from tuberculosis in various countries for the past fifty years. These demonstrate that in the first twenty-five years of the half century the decline in death rate from tuberculosis was quite as great and in some countries greater than in the last twenty-five, or, in other words, greater in the quarter century preceding the discovery of the tubercle bacillus than in the quarter of a century following this discovery.

Journal of the American Medical Association, October 31, 1908.

The Work Cure.—A. S. Thayer calls attention to the utility of stimulating the normal activities in abnormal conditions as a therapeutic measure, and points out that this is largely the secret of the success of modern psychotherapy, faith cures, etc. Among the first to discuss the value of occupation as a means of cure were the physicians in charge of the insane, and while work was first provided as a means of reducing expense, its other good effects could not fail to be observed. It has passed as a means of cure to the various sanatoria for nervous conditions and also to general hospitals, and he suggests that it might advantageously be introduced into tuberculosis sanatoria whose inmates are sometimes only too well satisfied with their life of fed and fatted monotony. This has been done at the asylum for consumptives at Frimley, near London, where, when conditions favor, the patient turns loose into his system a fresh dose of bacterial vaccines when indicated by the opsonic index, by regulated work. In treating most of our patients, Thayer says, the end toward which we strive is heightened resistance to disease, and he asks is there any single agent more effective for the development of antibodies than work?

Serum Treatment of Carcinoma.—S. Strauss relates his experience with the serum treatment of carcinoma. He discusses first the various theories of the origin and nature of the disease and formulates his own theory as follows: The cancer elements are found *in utero;* that is, there is an abnormal development of the embryonal cells, which group is the starting point of a carcinomatous growth. Intermingled with the healthy epithelial cells are these cancer units, and whenever the conditions for hemming them in or retarding their growth is overcome by exciting causes, such as improper living and eating, mental worry or grief, senility, etc., they multiply very rapidly, destroying and penetrating into the surrounding tissue, giving off a toxin which in time infects the entire system. Therefore, our endeavor should be to demonstrate a cancer specific reaction in the human body by means of a serum precipitant establishing its identity, irrespective of a microscopic examination. The serum which he uses he obtains directly from lower animals suffering from malignant growths, principally the horse; the diagnosis being substantiated microscopically. He describes his technique for obtaining and sterilizing the serum and states that shortly after injecting it the patient's face becomes flushed and there is an increase in the blood pressure. The serum, he states, seems to have a marked effect on the spinal centers, producing pain in the back, radiating down the legs. In some cases a chill appears within the first few hours. After from four to six hours there is an elevation of temperature, but not exceeding three degrees in any case observed. Strauss reports cases and summarizes his paper as follows: (1) Visceral carcinoma is incurable and fatal in nearly all cases. (2) Superficial or surface carcinoma is curable and amenable to treatment if attended to early. (3) Carcinoma is hereditary, the tendency to its formation being transmitted to successive generations, and it becomes evident whenever the natural restraining influences are removed. (4) Carcinoma is on the increase, the death rate being over seven thousand in New York State in 1907 (Gaylord). (5) The serum treatment should be used after every operative case to immunize the system and prevent recurrence. It raises the opsonic index and causes a leucocytosis. (6) The serum treatment should be used in inoperable cases, because it relieves the pain and ameliorates the symptoms without interference with the natural functions of the body.

Milk and Infections.—J. W. Trask remarks that when it is considered that available evidence seems to show that between 2 and 4 per cent. of typhoid convalescents become chronic bacilli carriers, the probability that some of them are employed at dairies in milking cows and handling milk is very great. The dangers of infected bottles in typhoid epidemics is also emphasized. Diphtheria outbreaks and their relations to milk distribution have been studied, and he points out the methods of observation by which outbreaks of these three diseases have been traced to special milk routes and stamped out before they had reached very formidable dimensions. The question of human tuberculosis from cattle is not altogether settled, but the facts seem to show that man is capable of infection with bovine bacilli and that a certain proportion of cases in the human species are of bovine origin. The prevalence of tuberculosis among cattle is estimated in many parts of the country as ranging from 15 to 40 per cent., and the possibility of milk infection, even though the udder is not diseased, is always to be considered. We may expect to find tubercle bacilli in market milk and milk products, and this has been frequently shown. Other diseases in the epidemiology of which milk plays an important part are dysentery, epidemic diarrhea, cholera, and milk sickness.

Typhoid Prevention.—W. F. Dutton says that from all that can be learned typhoid has existed in the Ohio Valley since the early settlement of the region, but accurate data do not go back of 1850. We know, however, that whole colonies were nearly depleted by epidemics at earlier periods. In Pittsburg, Dr. J. F. Edwards, superintendent of the bureau of health, has said that since 1878 50,000 people have been stricken with typhoid and 7,615 have died.

This does not account, however, for those living in the outlying towns from which the city draws largely its office and working population, which would nearly double the above figures. In 1907 there were 5,729 cases and 608 deaths, and in some years the death rate per 100,000 population has been as high as 140 or 150, the latter the highest figure for typhoid for any city of the world. Dutton points out that the filtration plants now in use or under construction are insufficient, to say nothing of the objectionable source—the taking of water from the river. Steubenville, Ohio, also gets its water directly from the Ohio and is never free from typhoid, many physicians having as many as twenty and thirty cases at a time. The health of the city of Wheeling for 1907 gives 39 deaths from typhoid, a decrease of 13 from the preceding year in a population of 40,000. In Cincinnati the people for the most part are drinking badly polluted water, but some improvement is shown within the last year. The death rate for 1905, 1906 and 1907 was 155, 39, and 157, respectively. Dutton gives his recommendations for improvements of the conditions, including sewage purification, cremation of garbage, regular inspection of water supplies, public education on the subject, etc., and says that in almost any place along the river it is not necessary to use the river water, as a pure supply can be obtained from other sources.

Fresh Air for Children.—A. McAllister holds that if fresh air treatment is demanded for the tuberculous adult it is threefold more imperatively needed for the child. It is indicated, moreover, in all children of delicate, frail, or puny growth; in fact, it should be general. In other words, there is a great need for a return to the old practice of "hardening children." He says that modern research has shown that the majority of cases of tuberculosis begin in the earliest years of life; when it appears in a youth it is probably from germs that have lain a long time dormant in the lymphatic system. The earlier the system can be stimulated to throw off the infection the better. Children are generally readily responsive to the treatment; what they need is that it be carried out under the intelligent supervision of the physician with the cordial cooperation of the parents.

The Lancet, October 24, 1908.

Hernia Through the Foramen of Winslow.—T. Carwardine reports the case of a man who was suddenly seized with severe colicy pains, which recurred at intervals for two days and were then followed by ink-like vomitus. Extremities were cold, pulse feeble, and temperature subnormal. The abdomen was distended but not tense, except in the epigastrium, where there were impairment of resonance and resistance corresponding with the position of the lesser peritoneal sac. Constipation had been absolute for twenty-four hours. The general condition at operation was very poor. On abdominal section the bowel, black and lusterless, was discovered on tearing through the gastrohepatic omentum. A portion of the bowel was reduced, but an uncertain vascular band seemed to prevent reduction of the remainder; and as the patient's condition was bad, drainage tubes were put into the involved gut, the patient dying three hours afterwards. The autopsy showed that about 2¼ feet of the lower end of the ileum were present in the lesser sac. The entering portion had passed over the ascending and right part of the transverse colon, and then into the lesser sac. From the point of entry the lower part of the ileum dragged on the ileocecal valve, the mesentery being twisted so as to form a distinct, sharp edge, simulating a band containing bloodvessels.

Acute Goiter.—S. J. Dickins reports the case of a girl of sixteen years who, when first seen, had a simple parenchymatous goiter which was causing some slight pressure symptoms. The latter were more in evidence the next day. On the following morning she suddenly suffocated and tracheotomy was advised, and finally agreed to by the parents, but in spite of the procedure the patient died. The obstruction seemed to be opposite and below the isthmus. The author calls attention to two points. First, did the iodide of potassium and the syrup of iodide of iron, which had been prescribed in moderate dosage on the first visit, cause contraction of the gland so as to increase the pressure upon the trachea and increase the irritation of the recurrent laryngeal nerve? He hardly thinks so, as he has successfully treated several other cases of simple goiter in the same manner. Secondly, the fact that the heart was still to be heard beating, although very slowly (the pulse at the wrist was imperceptible), led him to hope that there might have been some response after the tube was inserted and the lungs inflated and artificial respiration resorted to for some time. But the gradually progressing slowness of the pulse noted from the first appears to point to cardioinhibitory action being the real cause of death, which might have been relieved by division of the isthmus in time, and perhaps should have been done at once, after the tube had been introduced. Most unfortunately, the patient was practically moribund before permission to operate was obtained.

Some Points About Puncture of the Brain.—H. Tillmanns enumerates the diagnostic and therapeutic purposes of this procedure. After this he proceeds to the description of the techniques of puncture. The proper point must be localized by a study of the symptoms, and the area selected is to be prepared as for trephining. When the spot has been selected either a small incision is made down to the bone and the periosteum is pushed aside, or else section of the pericranium is avoided altogether. In the latter case a hand or electric brace, fitted with a round-headed Doyen or Sudeck drill, is pressed firmly on to the skin, which is pierced at the same time as the bone below. When drilling through the bone it is advisable to press more firmly at first than later in order to avoid injuring the dura mater after piercing the inner table. Injury of the dura mater is best avoided by first using a broad-pointed, oval-shaped Doyen drill to pierce the cranium, and then using a ball-pointed Doyen drill to pierce the inner table. With this drill an injury to the dura mater is impossible. Hemorrhage of the bone can be stopped by spreading on aseptic wax. When the cranium has been pierced a fine hollow needle fitted to a Pravaz syringe that closes well is inserted and suction is produced. This suction must be performed as delicately as possible, so as to avoid causing hemorrhage. The fluid matter which is abstracted should, if necessary, be examined at once microscopically and bacteriologically. Should the puncture produce no result, or should it be impossible to elucidate the case sufficiently through the small aperture in the bone, the opening can be enlarged as required either with a larger ballpointed Doyen drill or with a Dahlgren forceps in order, for instance, to judge the pulsation of the brain, intracranial pressure, etc. When a larger opening has been made the dura mater should be taken hold of with a small-pointed hook and cut crosswise with a very sharp, thin knife. The suspected hemorrhage, abscess, or cyst is then pierced with a fine hollow needle or a thicker one; grooved needles or a very fine, sharp knife can also be used. In cases of tumor this simple aseptic piercing of the cranium with a ball-pointed Doyen drill is also devoid of danger, and Neisser and Pollack have shown that with the above-mentioned simple puncture the presence of a tumor can be discovered—for instance, in the frontal lobe of the brain—where it had not been expected and where it would have been impossible to ascertain its existence in any other way. If necessary, the puncture can be repeated, as the operation is relatively simple. Neisser once punctured nine times in succession, and finally succeeded in locating the suspected tumor. In the cases of newly-born children and of hydrocephalus it is usually not necessary to pierce the bone. The cranium is opened at a suitable membraneous spot where there is neither a large blood-vessel nor a cerebral center—for instance, next to the sinus longitudinalis. The author gives the various rules for puncturing the ventricle and finally calls attention to the fact that it may be entered from behind, from the occipital lobe, if the cranium is opened 4 cm. over the external protuberance arch 3 cm. to the side of the central line of the skull, in which case the needle is inserted in a forward and slightly upward direction.

British Medical Journal, October 24, 1908.

Painless Labor in a Primipara.—The patient of H. J. Cates was a woman with normal pelvic measurements. One evening, about full term, she retired at half past ten, feeling perfectly well. At three the next morning she arose to pass a small quantity of urine, and although she felt a slight pain in the thigh, soon fell asleep. Four and a half hours later she woke and found the child born as far as the navel, and labor was soon finished. The child was a male weighing eight and a half pounds. The head showed well marked moulding characteristic of an occipito-anterior position, and there was a large caput succedaneum.

Breurs's Appliance for Use After Colotomy.—The apparatus here described and illustrated by J. Ingram was devised by a patient on whom he had operated. It consists of an oval silver box, the bottom of which is wanting. It is surrounded by a flange which is applied to the skin. This flange is about three-fourths of an inch in breadth, and is provided with studs on its outer surface, by means of which the appliance is fastened to a body belt. The outer part of the box is in the form of a lid, which can be removed and reapplied when it has been fixed in position. At the dependent part of the box it is prolonged in the form of a chute; this is completed by a similar prolongation from the cover. The box is quite small and the intestinal contents do not remain in it, but at once

pass out along the chute, where they are received in an india rubber bag which is fixed over at the end of the chute. The result is that all discharges collect in the bag without remaining in contact with the skin, which is thus preserved from irritation, and the comfort of the wearer greatly enhanced. In applying the apparatus the lid is removed, and the patient then stands in front of a mirror, so that he can see what he is doing; the opening of the box is then fitted so as to surround the colotomy opening or openings completely, the size being such that about a quarter of an inch is left between the mucous edge and the wall of the box. Before placing the box in position, the body belt is attached to it by means of the studs, this belt being a slightly modified abdominal binder with perineal strap. No great pressure is necessary to ensure the appliance remaining in position. The lid of the box is then placed in position and fixed with a screw, and the india rubber bag is applied over the chute and hangs down in front of the thigh, and the whole appliance, being quite small, is not in any way noticeable. The appliance is comfortable to wear, does not get displaced, no leakage occurs under the appliance, the patient gets rid of the offensive smell of the ordinary india rubber cap, and a more hygienic effect is obtained, as the instrument can be easily and thoroughly cleansed. Unless the bowels are loose, it is not necessary to wear the apparatus at night, its place being taken by a pad of wool and a bandage. In the morning the patient has his bath and then fixes on the apparatus, and unless the bowels are loose, the action occurs without any trouble, soon after the patient gets up. When the action of the bowels is finished the apparatus is detached and cleansed, and usually the patient goes through the day comfortably, without any further inconvenience. The inventor, who is a very busy man, and who travels much over the country, always carries two or three spare arrangements with him, along with a small looking glass, and if it should be necessary during the day to change the soiled apparatus, it is placed in a sponge bag and thoroughly cleansed when the patient gets home again.

Cats as Plague Preventers.—A. Buchanan has previously advocated the use of cats as preventives of plague by devouring the infecting animals, the rats. In India he has had the opportunity of comparing villages in which cats were kept with villages in which they were not. It seems that in India the caste ideas allow some persons to keep them but prohibit the privilege to others. Thus there were natural conditions in existence for experiment and control. It was found that the plague was much more common in those villages in which cats were few. The same conclusions were obtainable with reference to "inohulla" or groups of houses and to single houses. The author believes that, owing to the reluctance of many of the native population to submit to anti-plague vaccination, etc., the latter can never come into general use to the extent of eradicating the disease. His remedy, therefore, is to encourage the breeding of cats, not neglecting in the meantime whatever sanitary measures have proved themselves of service.

Berliner klinische Wochenschrift, October 19, 1908.

Transposition of the Viscera.—Smirnoff says that the first case of complete transposition of the viscera was described in 1643 by Marcellus Leccius; since then 215 cases have been observed. His patient was a man forty years of age in whom the curious anomaly was discovered by accident. The thoracic as well as the abdominal organs were all transposed. The curves of the esophagus proved to be placed in the opposite directions to their normal direction; the right testicle hung lower than the left, which normally is the lower of the two. No symptoms whatever were present that could be traced to the transposition of the viscera, the man's complaint being due to an arteriosclerosis and a hypertrophy of the heart of the usual types.

Deutsche medizinische Wochenschrift, October 8, 1908.

Treatment of Whooping Cough.—Feer says that the mortality from whooping cough in the first year of life is higher than that of diphtheria, of scarlet fever, or of measles; in the second year of life diphtheria and scarlet fever are more fatal than pertussis. The most important part of fighting the disease consists in prophylaxis, which is especially possible, as pertussis is transmitted almost exclusively by direct contact with the patient. The first duty of the physician is to isolate the patient or at least forbid his appearance in public playgrounds for children and in schools. As the disease is especially fatal in the first years of life, all infants should be jealously guarded from infection. There is no specific treatment for the disease. Hygienic, physical, and dietetic measures promise most for the recovery of the child. Of these, abundance of fresh air is the most important item, and patients that are not feverish ought to be kept outdoors as much as possible. The room ought to be well ventilated, and if possible two rooms should be used for the patient, so that one could be cleaned and aired while the other is being used. Change of residence to the country is advisable when convalescence sets in, and not at the height of the disease. Hydrotherapy has but little application in pertussis; compresses over the thorax, however, are often of benefit. Of special importance is the psychic treatment, the child being managed with all kindness and quiet. Medicinal treatment is of little use so far as the disease itself is concerned, but the various symptoms may be treated as they come up. Antimycotics and sedatives are the drugs most used: of the former quinine is of use. Codein may be given to allay the cough. Frequently heart stimulation with caffein is required. The sera prepared by various laboratories have proved useless.

Movable Cecum and Appendicitis.—Wilms says that many cases of chronic appendicitis are due not to any conditions in the appendix itself, but to the dragging of the mesappendix or the mesentery of the cecum by a long and very movable cecum. Almost one-fourth of all the cases of chronic appendicitis show a normal appendix on pathological examination; the cecum can usually be very easily brought out of the operation wound, which makes appendectomy an easy operation. However, a number of patients continue to suffer from attacks similar to those of the "chronic appendicitis" for which they are operated upon. Wilms has therefore made it a practice to fix very movable ceca during the operation; the symptoms disappeared even in such cases where the appendix was not removed. The temporary success of internal treatment in chronic appendicitis may likewise be explained by the fact that the laxative measures free the cecum from accumulated fecal matter and diminish its traction upon the mesenteries. Forty patients treated by Wilms in accordance with these views were all cured, thus showing that the cause of their disease was a mechanical and not an inflammatory condition in the appendicular region.

Practical Value of Serodiagnosis in Syphilis.—Ledermann says that patients in the first stage of syphilis may or may not show positive reaction according to the method of Wassermann. In negative reaction excision of the chancre ought to be considered, for the possibility exists that no general intoxication or infection of the organism has as yet taken place; if the reaction is positive treatment ought to be begun without waiting for secondary manifestations. All his patients in the second stage of syphilis gave positive reactions; vigorous specific treatment was followed by the disappearance of the reaction in several instances. The reaction is of special value in latent syphilis; treatment should certainly be insisted upon if the reaction is positive, though no symptoms whatever are present while a history of the disease is obtainable. Syphilitics in the tertiary stage usually give positive reaction, and the same is true of so-called "parasyphilitic" affections of the nervous system. Marriage should not be allowed to such patients as show a positive reaction, though free from symptoms, if much time has passed since their last course of treatment. They should be again thoroughly treated, but if the reaction persists we are unable at the present time to advise surely one way or another in reference to marriage. In the presence of a positive reaction in women who habitually abort treatment should be instituted ,though no symptom of the infection be present in either husband or wife. The fact that the blood, even post mortem, may give a positive reaction is of extreme scientific value, for it will enable us to verify diagnoses made during life even when anatomical lesions are absent.

The Suprarenal Capsules in Puerperal Eclampsia and Gravidic Nephritis.—J. L. Chirié has made a careful examination of seventeen pairs of suprarenal capsules obtained from patients who died of puerperal eclampsia, of which twelve showed retroplacental hemorrhages. He finds that there is a constant cortical and medullary hyperplasia of the suprarenal capsules in retroplacental hemorrhage, puerperal eclampsia, and gravidic nephritis. Medullary hyperplasia occurs before cardiac hypertrophy can be observed. Suprarenal hyperplasia is secondary to the renal lesions. This suprarenal hyperplasia bears a marked relation to the antitoxic function of the gland and may play an important part in the production of the increased arterial tension of puerperal eclampsia.—*La Tribune Médicale.*

Book Reviews.

The Muscles of the Eye. By Lucien Howe, M.A., M.D., Professor of Ophthalmology, University of Buffalo; Member of the Royal College of Surgeons of London; Member of the Ophthalmologische Gesellschaft, of the Société Française d'Ophthalmologie, and of the Ophthalmological Society of the United Kingdom; Former Chairman, Section on Ophthalmology, American Medical Association. In Two Volumes. Vol. II.: Pathology and Treatment. Illustrated. New York and London: G. P. Putnam's Sons, 1908.

The second and concluding volume of Dr. Howe's work is one of 481 pages, of which 374 are devoted to the text, 75 to bibliography, and the rest to index and appendices. Definitions of the various forms of muscular anomaly are given and discussed. Charts for recording the results of examination and history are described. Following this the various forms of intraocular and extraocular muscular imbalance are described separately in logical order. The phorias and trophias are treated of separately. Anomalies of torsion are fully described. The effects of imbalance of the ocular muscles on the eye itself, the nervous system, the digestive tract, in fact, on all parts of the body, and the reflex effect on the eye from abnormal conditions in other parts of the body are fully considered. A typical movement of the eye, such as those that occur in hysteria and the different forms of nystagmus, are described. The treatment of imbalance of the ocular muscles by the application of glasses, by means of orthoptic exercises, by medication, and by operation is entered into fully. The various kinds of operations employed and recommended by the author are described and the results of treatment are given. Appendix "B" consists of a list of questions relating to unsettled points concerning ocular-muscle imbalance which the author suggests as worthy of study. At the end of the volume are photographs and short biographical notes of six noted ophthalmologists who have aided in the work on muscular anomalies, one of whom is now living. This is a continuation of a series of biographical notes which was published in the preceding volume. The volume is sufficiently well illustrated. The second volume of Howe's work is probably of more practical value than the first. It is the superstructure the foundation for which was laid in Volume I. The complete work is monumental. It represents an enormous amount of original investigation and literary research, and cannot but be of great service to the ophthalmological world.

Manual of Psychiatry. By J. Rogues de Fursac, M.D., Formerly Chief of Clinic at the Medical Faculty of Paris; Physician in Chief of the Public Insane Asylums of the Seine Department. Authorized Translation from the French, by A. J. Rosanoff, M.D., Second Assistant Physician, King's Park State Hospital, N. Y. Second American from the Second French Edition. Revised and Enlarged. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1908.

The first edition of this convenient little manual apparently met with a ready sale. The present, or second, edition shows considerable revision by the author; also a number of useful additions by the translator, in the shape of notes. Some of these notes, for example, relate to psychotherapy, to lumbar puncture, to a recent theory of dementia præcox, and to after care of the insane. The author follows the Kraepelin classification. We hope the next edition will have a glossary for the student and general practitioner; but for a small book, it contains much of a useful nature, and the original is a decided advance in French psychiatry.

Ophthalmic Surgery. A Handbook of the Surgical Operations on the Eyeball and Its Appendages as Practiced at the Clinic of Professor Hofrat Fuchs. By Dr. Josef Meller, Privatdocent and First Assistant K.K. II., University Eye Clinic, Vienna. The Translation Reviewed by Walter L. Pyle, A.M., M.D., Member of the American Ophthalmological Society; Ophthalmologist to Mount Sinai Hospital; Sometime Assistant Surgeon to Wills Eye Hospital, Philadelphia, Pa. With 118 Original Illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

The work of Meller forms a volume of 262 pages, quite fully illustrated by excellent original drawings. The work presents the principal operations as practised by the author in the clinic of Professor Fuchs in Vienna. The first two chapters are devoted to a description of the indications for the extirpation of the lacrymal sac and the operation as devised and practised by Meller. Chapters on trichiasis, entropion, ectropion, ptosis, and strabismus operations follow; also chapters on enucleation of the eyeball, extraction of cataract, operations in glaucoma, extraction of foreign bodies from the interior of the eyeball, etc. The work is not exhaustive, but the operations that are considered are described fully and lucidly. There is much that is peculiar to the author in the methods and technique given which tends to make the work indispensable to those who desire to inform themselves fully on the subject of ophthalmic surgery.

Hay Fever, Hay Asthma. By William Lloyd, F.R.C.S., Surgeon-in-Charge of the Nose, Ear and Throat Department, Kensington General Hospital. Second Edition. London: Henry J. Glaisher; Chicago: W. T. Keener & Co., 1908.

This manual covers the general hay fever question without adding anything new. In the present edition certain matters under the heading of palliative treatment have been elaborated, especially in reference to the value of alcohol and coffee. The latter, says the author, should always be taken strong, hot, without sugar or milk, and on an empty stomach. For him the disease is a reflex neurosis. We are rather surprised at his lavish use of cocaine, and cannot wholly share his enthusiasm as to the good effects of the electrocautery in destroying sensitive areas in the nose. At any rate, the therapeutic problem is a more intricate one than is here represented. The author has but little faith in serum therapy, and declares that Dunbar's pollantin and Wolff Eisner's grammol "are altogether devoid of any reliable therapeutic activity and that even when employed prophylactically they are quite powerless in preventing the onset of an attack of hay fever."

The Air and Ventilation of Subways. By George A. Soper, Ph.D., Member American Society of Civil Engineers, American Chemical Society, Society of American Bacteriologists, American Public Health Association. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1908.

Dr. Soper has done a thoroughly commendable and careful piece of work in his efforts to determine the quality of subway air. His recommendations also are wholly sane and seem to be in accord with the best that there is in the modern science of sanitary engineering. However, he seems to hold the opinion that there has been a great deal of unnecessary fault finding on the part both of the general public and of those best fitted to speak through special training. The conditions calling for remedy which Dr. Soper enumerates in his investigation are: heat, dust, germs, odors, and noise. Subway heat, while unpleasant, is not unbearable, he says; at any rate its sources are concerned with the manipulation of trains and it is consequently irremediable in great measure. Dust is sucked in from the street and in part is composed of iron rubbings from rails and wheels. As for germs, the investigator finds twice as many in the street, save after a rain. Odors emanate from trap rock, oil, passengers, and employees. The noise is quite as unavoidable as the heat.

Cancer. Par P. Menetrier, Professeur Agrégé à la Faculté de Médecine; Médecin de l'Hôpital Tenon. Avec 114 Figures intercalées dans le texte. Paris: J. B. Baillière et Fils, 1909.

This book forms the thirteenth volume of the Nouveau Traité de Médecine et de Thérapeutique, edited by Brouardel and Gilbert, and is devoted entirely to the consideration of malignant disase, both sarcoma and carcinoma being included in its scope. A brief historical introduction is followed by the most detailed consideration of malignant disease, which Menetrier interprets as the morbid process consisting in the invasion of the organism by some of its own cells. The characteristics of the cells composing tumors, the effect of their proliferation upon the organism, the clinical and diagnostic features of tumors are first described. This is followed by the study of epithelial tumors which are considered according to the anatomical parts involved. This study is illustrated by drawings that bear the signature of R. Coquelin and present as good examples of the art of medical illustration as we have seen: the text gains very much from the objective character lent to it by the drawings. Tumors of the connective-tissue type are then treated with like thoroughness, every illustrative specimen belonging to the personal collection of Dr. Menetrier. A discussion of teratomata closes the special part of the volume. The remaining portion is devoted to the questions of etiology, pathogenesis, and treatment, much statistical material being found in the various chapters. The book is a notable one in the literature of malignant disease, and should prove of great value to the physician busied with the practical questions of medicine and surgery as well as to the pathologist in quest of well-considered study of cancer.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-Fourth Annual Meeting Held at Louisville, Ky., October 13, 14 and 15, 1908.

DR. ARTHUR R. ELLIOTT OF CHICAGO, PRESIDENT, IN THE CHAIR.

SURGICAL SECTION.

Hernia of the Pelvic Floor.—Dr. CHANNING W. BARRETT of Chicago said hernia might develop at any place in the abdominal wall, due to weak, defective walls and increased abdominal pressure, but the pelvic floor, by reason of its being the lowest part of the abdominal wall, and by reason of its having natural openings, furnished a frequent site for the development of hernia. Following the overstretching or laceration of the levator ani muscle, the pelvic floor sagged and the abdominal contents took a lower position. The abdominopelvic contents began to protrude through the defect, first the bladder or rectum or both, then the uterus and other organs. The terms "laceration of the perineum" and "prolapse of the uterus" were not comprehensive, and had led to erroneous treatment. Removal of a prolapsed uterus alone removed only a portion of the contents of the hernia, and not the most troublesome at that, and still allowed a hernial sac to be formed of the vagina with the rectum, bladder and intestines as contents. While we repaired the defects in the muscles it must also be remembered that a predisposition of the hernia to return was furnished by the vaginal and rectal outlets. The uterus, which had gotten in line with the vagina, must have its axis put at an angle with that of the vagina. In so-called "prolapse of the rectum" again we were dealing with a hernia. The support of the levator ani muscle was defective. The rectum had a congenital or acquired freedom from the levator muscle. The cure of prolapse of the rectum should deal with this muscle instead of being attempted by futile plastic operations upon the rectum.

New Process of Making New Noses.—Dr. R. H. ALLEN of Indianapolis said (1) a plaster-of-Paris mask or reproduction of the noseless space should first be made. (2) Model half a dozen or more different noses that were appropriate to the other features of the face. (3) If desirable, model other features of the face that needed improvement. (4) Construct a hollow metallic bridge or supporting frame, which would reproduce the shape of nose selected when placed beneath the skin. (5) Operation. The upper lip should be pulled forward, and then about one centimeter below the gingivolabial fold an incision should be made, about one-third the thickness of the lip and running parallel with the gum margins of the upper teeth. This incision should terminate about the first molar tooth. The incision should be completed vertically and the soft tissues of the nose and face dissected free from the skull. Care should be taken not to injure the nerves coming out from the infraorbital foramen nor the tear ducts. (6) Then place the nostril hook into the nostrils and pass the points around, so that they come out underneath the upper lip. (7) Traction should be made upward and outward upon the hook, and the entire field for supporting the nose frame then came into plain view. (8) The nasal tissues stretched forward and the foundation prepared for the bridge or metallic support for the new nose. (9) The new hollow metallic bridge should be placed under the lip, where it was to rest permanently. (10) The original wound was to be sutured.

Some Clinical Conclusions as to the Value of Vaccine Therapy in Surgical Infections.—Dr. JOHN C. HOLLISTER of Chicago gave a brief summary of clinical conclusions of a series of staphylococcal, tuberculosis, and gonococcal cases treated by vaccine therapy, guided for the most part by the opsonic index. Thirty-four staphylococcus cases were persistently treated; twenty-five by autogenous, and nine by stock vaccines; cases consisted of 12 of acne, 15 of boils or large furuncles, 2 of empyema, 1 mixed infection with case of lupus, and 2 fistula (mixed). Results: 38 per cent. plus cured; 38 per cent. plus improved; 20 per cent. plus not improved. Of the 25 cases treated by autogenous vaccines, 32 per cent. were cured; 36 per cent. improved, and 32 per cent. did not improve. Of the 9 cases receiving stock vaccine, 7 were cured, and 2 were slightly improved. Forty-one cases of tuberculosis were treated. These were bone and joint diseases, four of which had also pulmonary involvement, twenty-nine in all; two cases of urinary tract infection, three cases of pulmonary tuberculosis, four cases of glands of neck, one generalized (lung, genital tract, skin, conjunctiva), and one case of peritonitis. Results: 70 per cent. improved—15 greatly, 13 slightly; 30 per cent. unimproved, 13. Of the 13 unimproved ten were generalized. Regarding the opsonic index as a guide to treatment, the author said that the index was by no means an unfailing guide for determining the amount of vaccine and the time of administration. There was no normal index, but the opsonic index, when obtained with careful technique, was a distinct aid in diagnosis, especially in the chronic localized infections. A persistently low, or varying, index was a strong indication that the patient was suffering from a specific infection.

Administration of Ether Per Rectum.—Dr. FREDERIC A. BESLEY of Chicago had had sixteen cases in which ether was administered in this way, and felt justified in assuming that the method was perfectly safe, and when the ether was properly given, there was no danger of rectal irritation. In two cases the subsequent stools contained a slight amount of blood. Neither of these cases complained of any rectal irritation, and it was the author's opinion that the slight bleeding was produced by trauma from the rectal tube. One of the marked advantages obtained in this method of administration of ether was a quiet and even respiration with an absence of the excessive secretion of the mucus along the respiratory tract.

Bismuth Paste in the Treatment of Rectal Fistula.—Dr. J. RAWSON PENNINGTON of Chicago said that the paste consisted of bismuth subnitrate one part, and vaselin two parts. When a stiffer paste was desired, from five to ten per cent. each of white wax and soft paraffin were added. He had treated seventeen cases with this paste, in thirteen of which the discharge had stopped; the fistulæ had closed, and the patients seemed to be well. This gave 76 8/17 per cent. as cured, which he thought was rather high. He attributed this high percentage to his good fortune in getting susceptible cases. The patient's bowels were emptied before the injection of the paste was made. In using the paste the point of the syringe was pressed well into the main opening of the fistula, if more than one existed, and the emulsion slowly injected. Should there be an internal opening, the index finger of the hand not manipulating the syringe was passed into the rectum and made to close the internal opening of the fistula so as to prevent the paste entering the bowel and to aid in forcing it into all of the diverticula and tortuous tracts.

Surgery of Venereal Stricture of the Rectum.—Dr. GEORGE B. EVANS of Dayton, Ohio, read this paper. The site of the stricture was generally at or about the attachment of the fibers of the levator ani muscles. This possibly was an important causative factor indirectly, there being more or less constriction here, consequently if there was any ulceration the power of resistance in the patient was not sufficient to overcome the trauma. He was of the belief that rectal stricture might follow chancroidal infection as the result of absorption or lodgment of infectious matter on the mucous membrane or in the submucous or even perirectal tissue, and that rectal strictures might be but a latent manifestation of syphilitic infection.

Obstruction of the Bowel.—Dr. CHARLES T. SOUTHER

of Cincinnati discussed the symptoms and treatment of intestinal obstruction. Under treatment he spoke of the mechanical, medicinal, and surgical treatment. Enterostomy and colostomy, with local anesthesia, would greatly reduce the mortality from intestinal obstruction. The relief of distention and drainage were the essential features in the absence of gangrene.

Enterostomy; Its Value in Intestinal Obstruction.—Dr. Earl M. Gilliam of Columbus, Ohio, said there were times when the surgeon hesitated whether to advise a resection or an enterostomy. This would depend largely on the general condition of the patient and the pathological changes present in the affected structures. Enterostomy for intestinal obstruction was simple in its performance, and it might under certain conditions be classed as a life-saving measure, tiding the patient over the critical stage of the disease until a more opportune time presented for thorough work. This might apply to dynamic, paralytic or mechanical obstruction. Even in inoperable cases an enterostomy might be demanded to establish an outlet for effete matter, and such often contributed greatly to the patient's relief. Acute ileus might call for an enterostomy. Emptying the bowel by such means relieved the acute obstruction, diminished the congestion, and might arrest a fulminating or spreading peritonitis.

Etiology and Pathogenesis of Pancreatitis.—Dr. William D. Haggard of Nashville, Tenn., said that gallstones were etiologically associated with pancreatitis in nearly one-half of the cases. Anatomical peculiarities and variations of the terminal pancreatic ducts were the determining factors in the occurrence of pancreatitis in some cases of gallstones, and not in others. The lodgment of a stone in the ampulla of Vater temporarily or permanently causing the retrojection of bile into the pancreatic duct (Opie) produced acute hemorrhagic pancreatitis. The chronic indurative or interstitial type was caused by stones lodged in or escaping through the common duct. Bacterial invasion was secondary to some unphysiological or mechanical internal injury. Infection of the pancreas by the lymphatics in cases of cholecystitis was probably a more frequent avenue than by continuity. Gastroduodenitis appeared to be responsible for about one-third of the cases. Catarrhal jaundice was probably caused by inflammatory swelling of the head of the pancreas, compressing the common duct of the liver, in many instances. Mumps caused about ten per cent. of the cases of pancreatitis, and some other infections might likewise cause it by metastasis. Fat necrosis with acute hemorrhagic pancreatitis was caused by some injury of the gland cells, access of bile, or of enterokinase which activated the hemolytic property of pancreatic juice.

The Diagnosis of Pancreatitis.—Dr. A. J. Ochsner of Chicago presented a short review of the methods of diagnosis, and directed attention to an area of tenderness on deep pressure over the upper portion of the right rectus abdominis muscle to the right of Robson's point in the presence of pancreatitis complicating cholecystitis. This area was not so circumscribed as Robson's point, and corresponded nearly with the area of tenderness in duodenal ulcer. Especial stress was laid upon continued, careful examination of the pancreas in all surgery of the upper portion of the abdominal cavity in order to obtain reliable statistics.

Dr. J. Henry Schroeder of Cincinnati discussed the physiology and chemical pathology of the pancreas in pancreatitis.

Pancreatic Diabetes and Its Relation to Gallstones.—Dr. Alfred C. Croftan of Chicago called attention to the fact that the peculiar interrelationship existing between gallstone disease and pancreatic diabetes was important clinically, chiefly for three reasons: (1) because cases of persistent, usually very intractable, glycosuria, occurred that ran their course under the guise of an idiopathic diabetes mellitus, but that were in reality due to gallstone factors; (2) because cases occurred which presented all the essential clinical features of cholelithiasis, accompanied by continuous or intermittent glycosuria, which were in reality cases of chronic pancreatitis and not at all of gallstone disease; (3) because the two disorders occurred together much more often than was generally assumed and produced a complicated disease picture that was highly confusing and very commonly misinterpreted. Glycosuria (pancreatic diabetes) was a much more common symptom at the onset of pancreatic disease, especially when associated with cholelithiasis, than later. In occlusion of the pancreatic duct with damming back of the pancreatic secretion, glycosuria was rare, for the islands of Langerhans seemed to resist this insult very well, and underwent degeneration only when nearly all the other glandular elements of the pancreas were destroyed. The glycosuria was a symptom of peculiar value in pancreatic disease, its presence being indicative of pancreatic involvement, its absence not necessarily invalidating this diagnosis. In interpreting the occurrence together of pancreatic diabetes and gallstones, three possibilities were considered: (1) The gallstones might precede the pancreatitis; (2) the disorder about the pancreas might be the cause of the gallstone formation; (3) both the gallstones and the pancreatic diabetes might be due to some common cause acting simultaneously upon the liver and the pancreas.

The Surgical Treatment of Pancreatitis.—Dr. William J. Mayo of Rochester, Minn., said that immediate operation offered the best prospect of cure in acute hemorrhagic pancreatitis. While the mortality was very high, it was not prohibitive. Fat necrosis, the result of leakage of pancreatic ferments, was not necessarily a fatal condition. He had operated in a number of such cases in the convalescent stage. Localized septic accumulations in the pancreas should be opened and drained. If gallstones were present, they should be removed and biliary drainage furnished. The surgical treatment of subacute pancreatitis presented a much more favorable field, as the patient had lived through the most dangerous period and had developed great resistance. The fundamental principle of the surgical treatment of chronic pancreatitis consisted in relieving the common duct of as much of its bile-carrying function as possible. In 62 per cent. of cases jaundice would be present because the common duct ran through the head of the pancreas. In 38 per cent. the common duct lay behind the pancreas, but would usually be found more or less dilated, often without jaundice in all cases of chronic pancreatitis. In the large majority of cases gallstones in the gall-bladder or bile-duct were the direct cause of the chronic pancreatitis. With gallstones in the common duct, 84 per cent. would have a contracted gall-bladder from the connective tissue in the gall-bladder, the result of gallstone irritation. When the chronic pancreatitis was not the result of calculi, the gall-bladder would usually be distended. Chronic pancreatitis, when caused by gallstones, would usually be cured by the removal of the stone and temporary bile drainage. When not caused by stones, cholecystenterostomy was indicated.

Currents and Counter-Currents in Medical Advance.—The President, Dr. Arthur R. Elliott of Chicago chose this as the title of his address. He referred to the education of the public by the medical profession, and agreed with Burrell that public instruction should be placed in the hands of a special board and should not be taken up by the profession generally. Conceding the necessity for a systematic policy of instructing the public in matters of personal hygiene, public health, and the prevention of disease, we should not lose sight of the fact that our influence for good with patients depended very largely on the degree to which we were able to retain a personal hold upon their confidence and loyalty. During recent years there had been an increasing tendency to base not only diagnosis and prognosis, but treatment, on the results of laboratory research, on information obtained by

instruments, rather than on the knowledge gained of specially trained senses and clinical judgment ripened by experience. Careful clinical observation could not be substituted by laboratory investigation, or by mechanical aids. The ideal training of the physician was based as largely on the correct observation of clinical facts as upon skillful interpretation of laboratory findings.

Tropical Diseases and the Mississippi Valley.—Dr. George Dock of New Orleans, La., delivered the Address in Medicine. He emphasized the importance of thorough instruction of medical students in the nature, recognition, and treatment of tropical diseases. There was great activity in the search for new methods of treatment of many tropical diseases, but the most important part of the treatment was preventive. The essentials for this were quite the same in the case of tropical diseases as they were in those of temperate zones. They consisted, briefly, in keeping uncontaminated air, water, and soil, the extermination of vermin, both large and small, and the preservation of the general health at the highest possible pitch. In the carrying out of a campaign for the prevention of disease it was obvious that much could be gained by having the general direction in the hands of a Federal officer, a consummation now near realization.

The Present Status of Kidney Surgery.—Dr. Arthur Dean Bevan of Chicago selected this subject for the Address in Surgery. He presented a brief résumé of the change in kidney surgery and drew an outline of the surgery of the kidney to-day. Floating or movable kidney was first successfully handled by surgical treatment when in 1880 Hahn introduced the operation of nephropexy. Since Henry Morris in 1880 did the first nephrolithotomy there has been a steady improvement in the surgical treatment of kidney stone. Since the introduction of the *x*-ray this development had been much more rapid. The diagnosis of kidney stone could now, by the means at our disposal, intelligently employed, be definitely determined before operation, and the modern operative technique had made it possible to remove renal calculi in uncomplicated cases with a very low percentage of mortality. With reference to tuberculosis of the kidney, the disease was in 90 per cent. or more of the cases at first unilateral and limited to a single kidney. There should be a distinct line drawn between genital and urinary tuberculosis. Urinary tuberculosis began always in the kidney, and then later descended into the ureter and invaded the bladder. Three methods of treatment had been advocated, namely, the general hygienic treatment, which was employed in lung tuberculosis; specific treatment with tuberculin, and the surgical treatment. Primary nephrectomy for early unilateral kidney tuberculosis could be done with less than 5 per cent. of mortality. In unilateral renal tuberculosis early nephrectomy was the best treatment. This should be combined with the well-recognized hygienic treatment of tuberculosis. In bilateral renal tuberculosis the treatment should be hygienic, plus specific treatment with tuberculin, until at least the value of this method had been proven or disproven, and in some cases, where especially indicated, such palliative, surgical measures as nephrotomy and drainage might be of service. The author then discussed neoplasms of the kidney, and reported three cases of hypernephroma. He likewise discussed acute hematogenous infections of the kidney, hydro- and pyonephrosis, essential kidney hemorrhage, anuria, after which he stated that modern surgery could now offer much in the treatment of many diseases of the kidney.

The X-Ray Diagnosis of Stricture of the Esophagus.—Dr. Sidney Lange of Cincinnati gave a small bismuth capsule, a large bismuth capsule, and then several swallows of bismuth mush. From an *x*-ray study of the act of deglutition itself any obstruction to the passage was at once evident; the size and extent of the obstruction, and whether organic or spasmodic could be determined. Weak or deficient peristalsis was registered by the stoppage of the bismuth capsule, and thus an early diagnosis was possible before the stomach tube met with resistance and even before dysphagia was present. Increased mediastinal pressure could thus be recognized early by the stoppage of the bismuth capsule in the esophagus.

Dislocated Kidney.—Dr. Earl Harlan of Cincinnati emphasized the fact that dislocations of the left kidney were more common than formerly supposed, but were more frequently overlooked on account of the absence of gross pathological manifestations such as accompany dislocation of the right kidney, namely, appendiceal, bowel, gall-bladder, stomach, and duodenum, and stated that these cases should be carefully sought for in the presence of severe neuroses by the use of the Luys bilateral ureteral collector and measurement of the solid matter excreted by each kidney. The writer followed with a carefully prepared table of the operative steps and measures which have been employed in fixation of the kidney from the time of the first operation by Dowell of Galveston, Texas, in 1874, to the present, including a description of the technique as used by the most prominent authorities in this work at the present time, with a discussion of the merits of the several methods and their application.

Internal Urethrotomy; Its Indications and Technique.—Drs. Ferd C. Valentine and Terry M. Townsend of New York maintained that the vast majority of strictures of the urethra were better treated by methodical dilatation than by any other method. They specified among the principal indications for internal urethrotomy, urethral calculi; vesical calculi amenable to crushing; ureteral or renal involvements requiring ureteral catheterism; strictures of so irritable a character that instrumentation caused severe reaction; strictures whose resiliency prevented adequate dilatation; heavy callus upon which dilatations made no impression; all strictures of the anterior two-thirds of the urethra; strictures in patients who could not be regularly treated by their physicians; patients who could not be taught asepsis, or who were too awkward to safely entrust with sounds; those who would not refrain from sexual intercourse or alcohol; those who would have to be maintained in a hospital for the long period required by dilatations, and internal traumatisms from forcible instrumentation. They recited the steps of urethrotomy from the induction of urinary asepsis through vesical asepsis, urethral antisepsis and its difficulties, the uselessness of general anesthesia, the relative value of local anesthesia, the patient's position, and the choice of urethrotomies. They classed the instruments into antegrade and retrograde instruments. Of the former they gave preference to the Maisonneuve and the Fluhrer-Maisonneuve urethrotomes, and detailed their construction and use. Of the antegrade instruments, they employed the Albarran urethrotome when the stricture was too tight to admit the Otis, and the latter when sufficient division was not obtainable by the former. The Kollman bougie-à-boule urethrotome was employed by them in heavy strictures to make them thereafter amenable to dilatations, and the Oberlander intraurethroscopic knives when mere division of fine stricture bands partly encircling the urethra was demanded. After thorough division of the stricture by any instrument, they anchored fast a cut-off catheter for forty-eight hours to insure vesical drainage, to protect the incision from infection by possibly septic urine, and to prevent agglutination of the lips of the wound.

Gall-bladder Trouble in Gastric Ulcer.—Dr. J. A. Lichty of Pittsburg presented the following conclusions: 1. The coincidence of independent gall-bladder trouble and gastric ulcer is rather rare, only one in 321 cases of my series. 2. Gastric ulcer with its complications can easily cause an interference with the function of the gall-bladder and duct to such an extent as to produce definite gall-bladder pathology. 3. Gall-bladder disease with its complications may cause such a disturbance of gastric

function as to simulate, if not actually cause, gastric ulcer. 4. While a combination of these two lesions may produce a complexity of symptoms, which makes a definite diagnosis impossible, the indications for operative interference are usually so definite that to disregard them would be disastrous to the patient.

Gastric Ulcer, with Special Reference to Its Precancerous Influence.—Dr. W. D. Haines of Cincinnati said the belief that chronic ulcer of the stomach was often followed by carcinoma was founded on evidence obtained at the operating table and in the dead-room. It was the deep perforating ulcer which healed slowly or remained as a raw surface that most concerned the surgeon in considering the precancerous influence of gastric ulcer. Chronic stomach ulcer should receive the same consideration one would give a breast tumor, uterine fibroid, or other growth which past experience had abundantly proven was prone to undergo malignant change. The excision of the ulcer-bearing area, as recommended by Rodman, was the operation of choice when the surrounding circumstances would admit.

When Should the Prostate Gland Be Removed?—Dr. E. O. Smith of Cincinnati said each case should be considered separately and individually. Palliative treatment should not be persisted in too long. If symptoms were growing worse in spite of treatment, one should operate. Acute retention seldom called for immediate operation. The frequency of cancerous degeneration of the prostate gland argued for early removal.

Fracture of the Astragalus with Dislocation of the Fragments.—Dr. J. H. Stealy of Freeport, Ill., reported two interesting cases that had come under his observation and in which he operated. He concluded: 1. Where an injury to the ankle joint has been sustained, producing great pain and swelling, the diagnosis should be made. 2. Do not expect to make a correct diagnosis of the injuries of the astragalus without calling into service the *x*-ray, with radiographs of the parts. 3. Do not make a diagnosis and attempt reduction of the astragaloid fractures without dislocation before a radiograph has been taken, nor without an anesthetic. 4. Consider the manner in which the injury is received. 5. Remember that reduction of a dislocated fragment is almost always impossible. 6. Do not make yourself believe that these conditions will in time correct themselves, and the patient will come out with a functionally good ankle joint. 7. Remember that the dislocated fragment is liable to necrosis. 8. Destructive inflammation with suppuration may follow. 9. Generally, as soon as expedient, after a correct diagnosis has been made, the dislocated fragment should be extirpated. 10. Operation should be done through one incision, expeditiously, and without destroying important tissues, as nerves, tendons, arteries, thus giving a far more useful member than if left to nature.

Syphilitic Crises Simulating Surgical Emergencies.—Dr. Maynard A. Austin of Anderson, Ind., said that in the larger medical centers syphilis exhibited itself in its protean forms so frequently that its recognition and diagnosis were matters of frequent therapeutic reference. It was not an infrequent occurrence in the surgical clinic of the late Dr. Nicholas Senn to have supposed surgical cases sent home with a prescription for the iodides, with the result that on their return a few months later the supposed surgical condition had entirely disappeared. The external evidence of this disease most frequently resembled the slowly growing tumors, especially of bone, but these should give little trouble in their diagnosis. The abdominal crises might simulate a number of organic diseases. The author reported three cases, one of which simulated gallstones, another renal colic, and a third an obstruction of the bowel. All these patients were referred to him as consultant with the expectation that they would be operated upon, but all improved rapidly under specific treatment.

MEDICAL SECTION.

Differentiation of Oft-Recurring Gastric Pains From Gallstone and Other Visceral Pain.—Dr. Nathan Rosewater of Cleveland, Ohio, said that nearly all pains of the digestive organs occurred during functional activity, while those due to gallstones, visceral, and other causes were independent of the digestive periods. By giving nutritive enemata for periods of one, two, or more weeks, we could put the digestive functions of the stomach and duodenum at rest for so long a period that such pains as would occur during this resting period could scarcely be attributed to gastroduodenal function, but rather to independent causes. In this way the digestive function was eliminated entirely from consideration by this gastric rest test.

Systemic Effects of Chronic Infections of the Throat and Nose.—Dr. F. Gurney Stubbs of Chicago said that in view of the fact that so many systemic diseases were infectious in origin, the atrium of infection assumed a large place in prophylactic and hygienic treatment. The nose and throat offered a large field for local and general infection. Pure cultures of pneumococci, streptococci, and meningococci had been obtained in suppurative sinus discharges. The tonsils and adenoids offered a large percentage of systemic effects, particularly tuberculosis and acute articular rheumatism. The relation of chronic tonsillitis and rheumatism was discussed, and attention drawn to the tonsil as the atrium even of arthritis deformans, rheumatoid arthritis, and the like.

Some Experiences with Autogenous Bacterial Vaccines.—Dr. Oscar Berghausen of Cincinnati said that bacterial injections were of distinct therapeutic value. In most cases the improvement was a gradual one, although marked at the very start. As in all branches of therapeutics, negative as well as positive results would be obtained. He who wished results should follow the methods of Wright, including a careful bacteriological analysis in each case, the preparation of an autogenous vaccine in most cases, and a careful consideration of the clinical symptoms. The opsonic index, although it might only register one phase of immunity, could be of distinct value, especially in mixed infections.

The Cause of Failure in the Treatment of Tuberculosis.—Dr. F. M. Pottenger of Monrovia, Cal., gave a careful analysis of several hundred clinical histories of tuberculous patients, showing that the causes of the mortality in tuberculosis from a clinical standpoint were: (1) An apparent failure on the part of both medical men and laymen to appreciate the fact that tuberculosis was curable, and an especial failnre to appreciate the comparative ease with which the early cases were cured; (2) a failure on the part of both medical men and laymen to appreciate and recognize the signs and symptoms which accompanied early tuberculosis; (3) a failure on the part of both medical men and laymen to appreciate the necessity of prompt, energetic, intelligent treatment as soon as the diagnosis could be made. Tuberculosis must always be considered a serious disease. Delay in its treatment was always attended with risk. What was needed was a better appreciation of the early signs of the disease, a better understanding of the principles underlying its cure, and a determination on the part of both layman and physician to apply appropriate remedial measures as soon as the disease was discovered.

Mediastinal Sarcoma with Special Reference to Differential Diagnosis.—Dr. Robert H. Babcock of Chicago reported a case, not because of the difficulty attending the diagnosis, but because it was mistaken for either pulmonary tuberculosis or pulmonary syphilis. The patient was a young man, 27 years of age, who, when seen, was suffering from orthopnea, anasarca, and slight cough, with scanty mucous sputum. Inquiry into the personal history disclosed the fact that chancre had been contracted

three years before and had led to the use internally of mercury in such doses that its physiological effects were produced nine months prior to the author's visit. These symptoms had been mistaken for the secondary manifestations of lues, and they, together with the discovery by *x*-ray of a shadow at the right of the sternum, had seemed to confirm the supposition that the pressure symptoms subsequently developed were due to gumma in the right lung. Physical examination, however, revealed unmistakable signs of intrathoracic pressure with displacement of the heart, right-sided hydrothorax, and anasarca. Enlarged cervical and axillary lymph nodes were also detected. The subjective and objective symptoms were so plainly unlike those of consumption of the lung or of gumma of that organ, that he had no hesitation in diagnosing a tumor, probably sarcoma, of the mediastinum. A subsequent postmortem examination established the correctness of the *intra vitam* diagnosis.

Multiple Serositis.—Dr. Walter L. Bierring of Iowa City, Iowa, said that the diagnosis of this condition was somewhat dependent on the history of a previous attack of acute pericarditis, pleuritis, or perihepatitis, to the early appearance and subsequent disappearance of the edema of the legs; to the marked ascites, to the enlarged liver, to the absence and very late involvement of the spleen, attacks of pain, tenderness and rigidity in the right hypochondrium, to the rapid recurrence of the ascites, to the signs of pleural exudate, and to the physical signs of adherent pericardium, without which the disease was incapable of diagnosis.

Expert Testimony and the Medical Witness.—Dr. Leo M. Crafts of Minneapolis spoke of the character and essential qualifications of the medical witness in court, his duties, and his relation to the court, the patient, and to himself, as well as his manner, the sacredness of his oath, the full truth and nothing but the truth, the present disgraceful state of expert testimony, and said that the fault lay largely with the attorneys themselves, who wanted only such statements as would help their cases. He then discussed the conscious or unconscious prejudice of the witness, and the power of various nefarious influences. There was necessity for a complete change in the methods in use of expert testimony. The one great function of the medical man in court should be a clear, uncontrolled presentation of full and exact scientific facts and opinions, regardless of who it would help or hurt.

Hysterical and Neurasthenic Conditions Following Accidents.—Dr. B. F. Turner of Memphis summarized as follows: 1. That a plaintiff in an action for damages following an accident need not necessarily be considered as perpetrating a fraud because physical disability cannot be proven. 2. That to assume the grave responsibility of an expert witness demands extraordinary skill, knowledge, and experience, as well as a finely adjusted judicial temperament. 3. That it is no part of the office of the medical expert witness to support either side of the case. 4. That, rather than to run the risk of appearing ridiculous in the eyes of his fellow practitioners, the conscientious physician will decline an attractive fee and refuse to appear in a rôle for which his daily walk and well-established reputation appear to fit him but poorly.

Cerebral Rheumatism.—Dr. Herman H. Hoppe of Cincinnati reported a case. The onset was one of restlessness, delirium, delusions, and hallucinations during the second week of acute articular rheumatism; pulse high; temperature 101.2°. On the third or fourth day the patient rapidly passed into a state of coma; face pale, cyanotic, pupils dilated, respirations 60 to 72 per minute, very shallow, pulse 160, temperature 105° to 110°. Incontinence of urine and feces; exaggerated reflexes; profuse general perspiration. Either the patient died or after six to eight hours the coma gradually disappeared; pulse, temperature, and respirations fell. The delirium, delusions, and hallucinations continued for two or three days longer, and then faded away. The patient made a complete recovery.

Question of Legal Responsibility.—Dr. Albert E. Sterne of Indianapolis laid stress on the necessity for more careful examination and observation of persons accused of criminal acts, and for whom the plea of insanity was advanced. He took the ground that insanity, once established, was a clear basis for irresponsibility in a legal sense, but at the same time he emphasized the necessity for not permitting criminals who had been declared to be of unsound mind to be set at liberty.

Mental Responsibility.—Dr. Charles W. Hitchcock of Detroit said that the inquiry presupposed probable impairment of mental integrity, and this rendered difficult the problem of exact justice. He discussed responsibility both in the sense of legal liability and, on ethical grounds, of rightful liability.

A New Field of Practice in Spirit and Drug Neurosis.—Dr. T. D. Crothers of Hartford, Conn., said the number of persons diseased and suffering from the use of spirits and drugs was increasing, and the physician, who, of all others, should advise and treat such cases, practically ignored the whole subject; hence the field was occupied by laymen, reformers with moral remedies, and quacks with specifics. The profession everywhere recognized the intensity and magnitude of the subject, but the medical colleges gave no instructions to the students, and the physical side of the problem was thought to be mere theory, and hence little or no effort was given to the scientific study.

The Human Element in Medicine.—Dr. Philip Zenner of Cincinnati said that as practitioners we were prone to overlook the human element in diseases. We not only overlooked the characteristics of the patient, his special physiological or pathological reactions, but we were apt to forget that great factor in health and disease—his mental attitudes and aptitudes. He urged that each physician take an inventory of his cases, and by careful study or treatment test the question, what of present suffering was due to the mode of examination, the diagnosis or prognosis given, or the treatment instituted, and how much could be gained by remedying any harm thus done, or by well directed suggestions, or by a heart to heart talk with the patient as to what his mind had done, and might do, in the way of mental and physical health.

Some Object Lessons in Otology for the General Practitioner.—Drs. J. A. Stucky and S. B. Marks of Lexington, Ky., had endeavored to impress the general practitioner with the need of a careful and routine examination of the ears of children in all febrile conditions, especially in the acute exanthemata, as well as meeting such conditions when arising. The frequency of certain nasopharyngeal conditions, notably adenoids, as causal factors in middle ear disease and their complications should bring from every practitioner his hearty cooperation and insistence on the removal of these factors. The value of a microscopical examination of every aural discharge could not be overestimated, since the different organisms causing middle-ear suppuration and consequent mastoiditis differed so in their virulence. Every case where mastoid tenderness had been or was present should be carefully watched. The disappearance of pain and restlessness meant the same thing in mastoiditis as in appendicitis, a relief of local pressure, the pus escaping externally or internally, so that one must be ever on his guard for intracranial complications.

The following papers were likewise read: "Feeding and the Use of Alcohol in Typhoid Fever," by Dr. J. H. Landis, Cincinnati, Ohio; "Hyperchlorhydria and Its Treatment Based on Animal Experimentation," by Dr. M. Milton Portis, Chicago; "Pernicious Anemia," by Dr. J. A. Witherspoon, Nashville; "Causation and Treatment of Infantile Convulsions," by Dr. E. W. Saunders, St. Louis; "Observations on the Liver in Five Hundred Cases of Gastrointestinal Diseases," by Dr. M. H. Mack, Chi-

cago; "Nervous Children," by Dr. I. A. Abt, Chicago; "Consideration of Certain Factors in the Production of Pulmonary Edema," by Dr. Joseph L. Miller, Chicago; "The Treatment of Sciatica by Means of Deep Perineural Infiltrating Injections of Salt Solution," by Dr. D'Orsay Hecht, Chicago; "An Interesting Case of Pulmonary Tuberculosis," by Dr. S. G. Bonney, Denver; "The Problem of Relapses after Apparent Cure in Cases of Pulmonary Tuberculosis," by Dr. Charles L. Minor, Asheville, N. C.; "Early Treatment of Squint," by Dr. George F. Suker, Chicago; "Clinical Facts Speaking for the Identity of the Pneumococcus and Meningococcus," by Dr. Robert B. Preble, Chicago; "Improved Methods for Preparation of Glycerin Jelly for Macroscopic Specimens," by Dr. George I. Hogue, Milwaukee.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. John A. Witherspoon, Nashville, Tenn.; *First Vice-President*, Dr. Louis Frank, Louisville, Ky.; *Second Vice-President*, Dr. Albert E. Sterne, Indianapolis, Ind.; *Secretary*, Dr. Henry Enos Tuley, Louisville, Ky.; *Treasurer*, Dr. S. C. Stanton, Chicago, Ill.

St. Louis was selected as the next place of meeting; time, October, 1909.

WILLIAMSBURG MEDICAL SOCIETY.

Stated Meeting, Held May 11, 1908.

Dr. Leon Louria in the Chair.

Marked Laryngeal Stenosis During the Course of Measles.—Dr. J. H. Bailey of Brooklyn read this paper. He reported a case of measles complicated with hoarseness and a rapidly increasing dyspnea, with all the distressing symptoms of air-hunger. The case, being one of spastic laryngitis, terminated favorably with the routine treatment. Important points in the differential diagnosis between this condition and diphtheria of the larynx were as follows: In the former the dyspnea was chiefly inspiratory, while in the latter it was both inspiratory and expiratory; in the former the quality of the voice was greatly altered, but there was no aphonia as in the latter; in diphtheria there was often a history of exposure to the specific infection, while in spastic laryngitis there was a history of previous attacks; in the former the symptoms were gradual in their onset, while in the latter they occurred suddenly, usually at night, with amelioration and recurrence the following day; in the former there were no systemic or toxic symptoms, nor albuminuria, while a few whiffs of chloroform relieved the spasm; in diphtheria the lower plane of the fauces showed an intense hyperemia, while bacteriological examination revealed the specific organism.

Pneumonia in Children.—Dr. Le Grand Kerr of Brooklyn read this paper. He said that while in the adult the signs of pneumonia conformed to well-defined physical laws, and while the diagnosis was not usually difficult, in the infant and child the physical signs of pneumonia differed materially from those of adult life, and the relative value of the individual signs was not the same during the two ages. Disregard of these facts readily led one into error. As an instance, lobar pneumonia in the adult gave the three cardinal symptoms—chill, pain, and rusty sputum; while in infancy these were all absent. The differentiation between lobar and bronchopneumonia was of recent origin, owing to the greater facility and skill in auscultation and to the application of the principles of histology. Bronchopneumonia was much more frequent during infancy and old age. It was, however, not uncommon during the other periods of childhood, while lobar pneumonia was fairly common even during infancy. Bacteriology was of little help in the differentiation. Lobar pneumonia, due in the majority of cases to the pneumococcus, affected the child at any age, and was even congenitally acquired through the placenta. The occurrence of a crisis was not essential to the diagnosis of the disease, but was at least suggestive, and a termination of the disease by lysis made one suspicious of pleuritis as an accompaniment. A seeming crisis sometimes occurred, followed by a rise of temperature lasting for a few hours or days. In some mild cases the entire duration of the disease did not exceed three or four days at most. In one not uncommon anomalous type there was a complete clearing up of the symptoms in seventy-two hours, the infection not going beyond the stage of congestion. The onset was sudden, in older children accompanied with chills and in younger children possibly with a convulsion, or coldness of the extremities, or cyanosis, most marked about the lips. Characteristic of the disease was the sudden onset with high temperature (103° to 107° F.), independent of a preceding bronchitis or other diseases. A high and continued fever in young children, with little or no remission, was suggestive of lobar pneumonia, and if there were in addition real dyspnea and a marked disproportion between the pulse and temperature, the diagnosis could be made without waiting for physical signs. Vomiting, and, in warm weather, diarrhea, were common at the onset. In older children headache and muscular pains were complained of, and on the second or third day pain in the side, which was increased by coughing or deep inspiration. In the child under five the pain was referred to the loin, epigastrium, or to any part of the area of distribution of the intercostal nerves. This pain was never exactly located. In infancy evidences of abdominal pain, with vomiting and high temperature, were suggestive of lobar pneumonia, for at this age gastric disturbances were not accompanied early by abdominal pain. Suspicion of pneumonia was warranted when there was a rapid rise of temperature, with markedly increased respirations, and the diagnosis was strengthened when there was also vomiting, short dry cough, coated tongue, etc. Increased respiration was to be valued as a sign only when there was a marked increase. It was out of all proportion to the increase in the pulse rate. The respirations were usually jerky, and accompanied by a short moan or sighing effect, characteristic if associated with the other symptoms. Prostration occurred early, the pulse was in the beginning full and frequent, but soon became weak, small, and compressible, and sometimes very irregular. Weill's sign, lack of expansion in the subclavicular region of the affected side, was present in a large proportion of the cases at some time, and was an early sign in the majority of all cases. Cough was usually not present until the second or third day, and continued dry, short, and restricted until just before the crisis, and in children old enough to expectorate there was then usually an abundant expectoration. After the first abrupt rise of temperature there were daily fluctuations of one to two degrees until the time of crisis, when there was an abrupt fall. Cerebral symptoms, suggestive of typhoid or of meningitis, sometimes predominated. The earliest physical signs were those due to acute congestion, with a diminished resonance over the affected area and exaggerated resonance elsewhere. Failure to outline the affected area by percussion was either because the area was limited in extent or covered with healthy lung, or deep-seated, or because a gas-distended stomach or intestine interfered with the examination. On auscultation at first there was feeble, high-pitched respiration over the affected area, while over the healthy part there were frequently exaggerated sounds, sometimes mistaken for bronchial breathing, but differing from the latter in being intensified only during inspiration, while bronchial breathing was of equal intensity both during inspiration and expiration. With consolidation and resolution the usual signs were present. The diagnosis was not difficult. The sudden onset with vomiting might lead one to think of scarlet fever or tonsillitis as the cause. During the first day, in infants, an acute gastroenteritis might be suspected, for vomiting and diarrhea were so common at this time. But in pneumonia the temperature and prostra-

tion were both out of all proportion to the mildness of the intestinal condition. Dullness over the base of the lung was sometimes due to pleuritic exudate, but associated with the dullness there was a weakened vesicular breathing, and not bronchial respiration, as in pneumonia. The presence of herpes excluded pleurisy, in which, moreover, there was not so sudden an invasion of temperature, which persisted for three or more weeks and ended by lysis. Pneumonia in children with obscure symptoms had a remarkable tendency to locate in the more obscure portions of the chest, as high in the axilla or just beneath the clavicles. In the beginning, and in the absence of physical signs, the presence of cerebral symptoms sometimes suggested meningitis. In cerebral pneumonia the symptoms differed according to the period of life—infancy or later childhood. In infancy there was either a sudden onset with vomiting, followed by convulsions and semi-consciousness of short duration, or the convulsions were repeated and the child was in stupor for days. Other cerebral symptoms then appeared, as rigid neck muscles, dilated pupils, possibly strabismus, or temporary facial paresis. In older children the convulsions were usually absent and the somnolent condition suggested the typhoid state more than meningitis, with dry, coated tongue, delirium at night, and possibly involuntary defecation and urination, with rigidity of the neck, general hyperesthesia, constipation, and possibly sunken abdomen. With such cases the character of the fever was important: with a constantly high temperature that had developed suddenly, meningitis was practically excluded. Sudden development with convulsions was peculiar to but one form of meningitis, the purulent. In pneumonia, subsidence of the convulsions was followed by clearness of the mind, which was not true of meningitis. In pneumonia the pulse was not slow and intermittent at first, nor was the respiration somewhat slow and irregular. In meningitis there was a more profound stupor, and a steady increase in the nervous symptoms for three or four days, while in pneumonia they were very marked during the first twenty-four hours and generally subsided quickly as the pneumonia developed. In older children with symptoms resembling those of the typhoid state the history of an initial chill almost positively excluded typhoid fever, while the early somnolence and typhoid symptoms so quickly after the first signs of illness were suggestive of pneumonia and against the diagnosis of typhoid. Bronchopneumonia was a disease essentially of infancy and early childhood, and in a great many aspects it was impossible to decide whether it was a distinct disease or not, at times seeming to be a combination of two or more diseases. Clinically there was a decided element of mixed infection, but in its multiplicity of forms there was one common lesion, capillary bronchitis. Capillary bronchitis, even though it was frequently not detected during life, was to be classed as a form of bronchopneumonia. One chief difference between this disease and lobar pneumonia was that the former was invariably preceded or accompanied by catarrh of the smaller bronchi. Bronchopneumonia was always secondary, and even in cases that were apparently primary the real primary condition was overlooked. The chief predisposing causes were infancy and malnutrition, including marasmus, rachitis, syphilis, etc. Other predisposing causes were poor hygienic surroundings, changeable climate, the cold season, the aspiration of foreign substances, the infectious diseases, etc. Bronchitis was the leading predisposing condition. The mode of onset was gradual or very sudden; the temperature was high or remained only slightly elevated throughout the disease. The only certain thing about the disease was its remarkable uncertainty. The commonest form developed during bronchitis, with an intensification of all the symptoms, chiefly the temperature, This was high, markedly fluctuating, and in rare instances nearly continuous. Low temperatures were apt to be the rule in delicate or marantic infants. Dyspnea was an early symptom, and easily induced by crying, nursing, coughing, etc. The early occurrence of dyspnea was associated with abundant small râles, particularly in the lower portion, behind. Cough was a more constant feature than in lobar pneumonia. The respirations were between 50 and 100 to the minute, and associated with dilatation of the nostrils and sinking in of the soft portions of the chest. The amount of percussion dullness was exceedingly meager in proportion to the extent of the consolidation, and as an indicator it often proved misleading. Bronchopneumonia could exist in a child and run its full course without the signs of consolidation having been present at any time during the disease. This was particularly true of the protracted cases. The well-known auscultatory signs were dwelt upon. Even with its variable symptoms the diagnosis of bronchopneumonia was presumptive if there was a high temperature, with marked daily fluctuations, associated with much increased respiration, cough, and dyspnea, the positive signs of other diseases being absent. From bronchitis it was distinguished by the more marked intensity of all the symptoms except the cough. Real dyspnea was not present in bronchitis. Subcrepitant râles, heard at the base of the lung, and increased percussion resonance were indicative of bronchopneumonia. The distinction from lobar pneumonia was usually easy. In the latter the inflammation at once occupied the lung tissue without a preceding bronchitis; it occurred in later childhood usually and in previously healthy children, with sudden onset of well-defined symptoms, and running a typical course. The temperature was high, and, with slight oscillations, maintained the same level for several days, ending with a crisis. In bronchopneumonia the temperature was not so suddenly developed, nor did it rise to such a height, exhibiting considerable variations daily and with a termination by lysis lasting from three to seven days. When bronchopneumonia was protracted the question of the presence or absence of tuberculosis arose. This was especially the case with bronchiectasiæ present, and with large consonant râles audible upon examination. The onset of tuberculosis was gradual, although sometimes apparently sudden, in which case there was nothing in the physical examination or in the constitutional symptoms that would aid in the differentiation except that at times there was a loss of flesh which was disproportionate to the severity of the symptoms. No positive diagnosis was possible until the time of expected resolution in bronchopneumonia, and then, instead of its occurrence, there was sometimes a persistence of symptoms that at once suggested the possibility of tuberculosis. No reliance was to be placed upon the character of the temperature. Examination of the sputum was of little value. Wasting, out of all proportion to the severity of the symptoms, and the presence of a marked anemia were indicative of tuberculosis. The latter usually developed anteriorly at first, and bronchopneumonia posteriorly. If the condition had developed insidiously during the convalescence from one of the infectious diseases the strong probability was that it was tubercular. Occurring in pertussis, a bronchopneumonia occasionally persisted until the latter had run its course. No matter how irregular the course or how persistent the disease, if thorough examination revealed that the child was previously healthy, with no family tuberculous history or probability of infection, with good surroundings, with the development of the disease under one of the usual etiological factors of bronchopneumonia, then tuberculosis could be excluded as the cause. The confusion of bronchopneumonia with malaria was possible, particularly if the malaria had been preceded by a bronchitis or if the onset was accompanied with congestion of the lungs, as it sometimes was. Watching the temperature was necessary in order to make a diagnosis; in bronchopneumonia there were remissions of the temperature that could be marked, but there was never an intermittence, as in malaria. Enlargement of the spleen favored the diagnosis

of malaria. The test of treatment and the discovery of the plasmodium settled all doubt as to the presence of malarial infection. In differentiating between bronchopneumonia and congenital atelectasis, one noted that the former existed from birth, with difficulty experienced in getting the infant to breathe, while its physical signs were absent or doubtful and cyanosis was not proportionate to the lung involvement, but was excessive.

Dr. Joseph E. Winters of Manhattan said that Dr. Kerr had so ably and comprehensively covered the subject of the diagnosis of pneumonia in children, that there was no room left for its further discussion. He therefore thought it would be well to say a few words about the treatment of this condition. Any such discussion had to be prefaced by the statement that the disease in mind, as indicated by the title of the paper of the evening, was the one caused by the pneumococcus. Usually the amount of lesion and the degree of infection were commensurate, but sometimes the lesion was so slight and circumscribed as not to give rise to a single physical sign to account for the infection. In treating the disease one had to take into account the following variable factors: The patient's susceptibility and resistance to infection, and his physical and constitutional condition. Anatomically, lobar pneumonia was croup of the alveolar walls, which were covered with the exudation of fibrin into the alveoli. The walls of the latter were densely pervaded with a fine network of capillaries, which projected into the alveoli in the form of loops. The pulmonary arteries did not anastomose, but the capillaries anastomosed freely. This rich anastomosis and the capillary loops projecting into the alveoli were matters of importance in the consideration of the treatment. The pulmonary veins had a smaller area than the pulmonary arteries. This fact tended to favor an increased pressure in the pulmonary capillaries. Moreover, the blood in the latter had to pass from and to the heart in the same time as the blood in the systemic capillaries. The first change in pneumonia was an acute distention of the pulmonary capillaries, which became enormously distended, bellying into the alveoli. This explained the fact that one got physical signs before the appearance of the exudation. The distention gave rise to laceration of the vessels and hemorrhage, as first noted by Virchow. The stage of distention and laceration lasted from 24 to 36 hours. At this time it was the physician's duty to lessen the pressure in the alveolar capillaries, and this was to be accomplished in two ways: by means of dilatation of the cutaneous capillaries, and by the use of either aconite or veratrum viride. The latter drug was unsuitable for children on account of its causing nausea. The good effect of aconite, as ably expressed by Wood in his "Therapeutics," consisted in its power of stimulating inhibition. It was the drug *par excellence* in the first twenty-four hours of lobar pneumonia. It not only lessened distention and laceration, but it also lessened the danger of the second stage. Another drug of great importance in the first twenty-four hours was opium. Every case of pneumonia was accompanied with intense shock, and it was the physician's duty to lessen this shock in both adult and child. Opium was indicated in the shock of pneumonia, just as much as in the shock of surgical conditions. The best form for the administration of opium in children was Dover's powder. What one obtained in the average drug store was not Dover's powder, for in lieu of the sugar of milk the druggist substituted sulphate of potash. It was this that caused the free perspiration. In the second stage of the disease the alveoli were distended by fibrin, which also distended the bronchi up to one-fifth of an inch. The circulation in the vessels was blocked by the lateral pressure of the fibrinous exudate upon them. It was necessary to diminish this occlusion. The second stage began at the end of from 24 to 36 hours, and revealed itself by the prolonged expiration accompanying it. This was the time for the use of oxygen, which was to be continued throughout the disease, and not reserved merely for the crisis. Another thing to be thought of was the complications of lobar pneumonia. On the walls of the alveoli there was an abundant network of lymphatics, which were the drainage tubes of the pleural sacs. Overdistention of the vessels cut off all drainage from the pleura. Any lack of tension increased by a hundredfold the danger of pleural complications. The speaker was very much impressed with this phenomenon as a factor in the cause of empyema. He had noted that physicians who had followed the rational method of relieving the distention in the alveolar walls were the ones who rarely or never had any cases of empyema in their practice. To lessen the distention of the pulmonary capillaries it was necessary to keep the cutaneous capillaries dilated throughout the disease. Neglect of this measure increased the danger of pleural complications. The pleural cavity when once filled up with pus and opened was not the same pleural cavity again. There were always adhesions left behind. It required great caution on the part of the medical attendant to prevent the spread of the pneumonic process. Anything that tended to contract the cutaneous capillaries invited a wandering pneumonia. The origin of this was frequently to be found in the cold and ice packs. It was of supreme importance that the sleep of the child should be uninterrupted. A sick child asleep was never to be awakened. It was never to be disturbed for treatment. During sleep its pulse was twenty less than during the waking state. It was important that the abdomen should be kept flat in order that the action of the diaphragm be not interfered with.

Philadelphia County Medical Society.

At a stated meeting held October 14 Dr. Achilles Rose of New York read by invitation a paper entitled "Displacements of the Abdominal Viscera and Their Treatment." He contended that the underlying cause for the disorders in question resided in a weakness or relaxation of the abdominal muscles, the transversales, the oblique, and the recti. For this condition he employed the term "atonia gastrica," pointing out that this referred not to the stomach, but to the abdominal wall. As a result of such relaxation any or several of the intraabdominal structures might suffer displacement downward, with a more or less characteristic train of symptoms, embracing digestive derangement, urinary irregularity, disturbance of menstruation, and especially nervous phenomena. In some cases jaundice might result from interference with the entrance of bile into the duodenum. In other instances so-called mucous colitis had been observed. In Dr. Rose's opinion all of the symptoms noted in these cases were attributable to the want of tone in the abdominal muscles, and the appropriate therapeutic procedure consisted in the restoration of this tone. This he had best succeeded in accomplishing by means of broad strips of adhesive plaster applied firmly to the abdomen, overlapping in the back and passing between the pubis and the crests of the ilia below, the ribs above, and the vertebral column behind. By this means not only was the abdomen given support and its contents elevated, but circulatory and functional activities were facilitated, with relief of symptoms, improvement in appetite and digestion, and gain in weight. The dressing might remain in place for from four to six weeks and its presence was, as a rule, attended with little or no inconvenience or discomfort. Dr. Rose gave a demonstration of the method of application on two patients. In lean persons, with flat or scaphoid abdomens, the application could be made in the erect posture, while in obese persons and in those with relaxed and pendulous abdomens it was better made with the patient in the recumbent posture. Dr. T. Turner Thomas presented a communication entitled "Habitual or Recur-

rent Dislocation of the Shoulder, with Report of a Successful Operation and Exhibition of the Patient." He dealt at some length with the causes usually assigned for the production of the disorder in question, such as abnormalities in the humerus or the glenoid cavity, or the capsule of the joint, but as a result of study upon the cadaver he came to the conclusion that the ultimate cause was a rupture of the capsular ligament. On the basis of this knowledge he undertook in a case under his observation to expose the capsule from the axilla, holding vessels and nerves out of harm's way by means of retractors. He was able to demonstrate a laceration in the capsular ligament, and this he repaired with sutures, with the result that in a short while the function of the affected member was wholly restored, so that at the present time the patient was able to perform all of the movements of the part, and without fear or risk of recurrence of dislocation. Similar operations had been performed in some thirty-four cases that Dr. Thomas had been able to collect, and in almost all instances the result had been equally successful.

Special Article.

THE ROYAL INSTITUTE FOR INFECTIOUS DISEASES IN BERLIN.

By N. MEYER, M.D.,

BAD WILDUNGEN, GERMANY.

THE stranger bent upon visiting the Berlin Royal Institute for Infectious Diseases is directed toward a region in the northern part of the city, which lies quite outside of the busy metropolitan traffic. This site was selected because the authorities desired to remain in close neighborhood to the newest of Berlin's hospitals, the Rudolph Virchow Hospital. It is of course evident that an institute for infectious diseases that is poor in material cannot fulfill an important part of its purpose, while on the other hand it does not seem advisable to bring the patients with general maladies under the same roof with those suffering from infectious diseases, there always being some danger of spreading infection to the general wards. Practical experience in reference to the advantages of such cooperation between clinics and scientific laboratories has already been gathered at the former site of the Institute at the Charité Hospital. In considering

FIG. 1.—The main building.

the past of the Institute we shall also communicate a few details of the arrangement of its former quarters at that hospital.

When Robert Koch communicated the results of his work with tuberculin to the Tenth International Medical Congress, the importance of this study aroused a great deal of public interest and the Prussian House of Representatives devoted several sessions to the discussion of the subject. The outcome of the discussion was the general conviction that the government must provide the means for the continuation of Robert Koch's work. The Min-

FIG. 2.—Rear of the main building, showing the stable and the house for the attendants.

ister of Education at that time was able to make known the fact that arrangements were already being made according to which Koch would receive a ward in a general hospital and a scientific institute for the research work in the subject of infectious

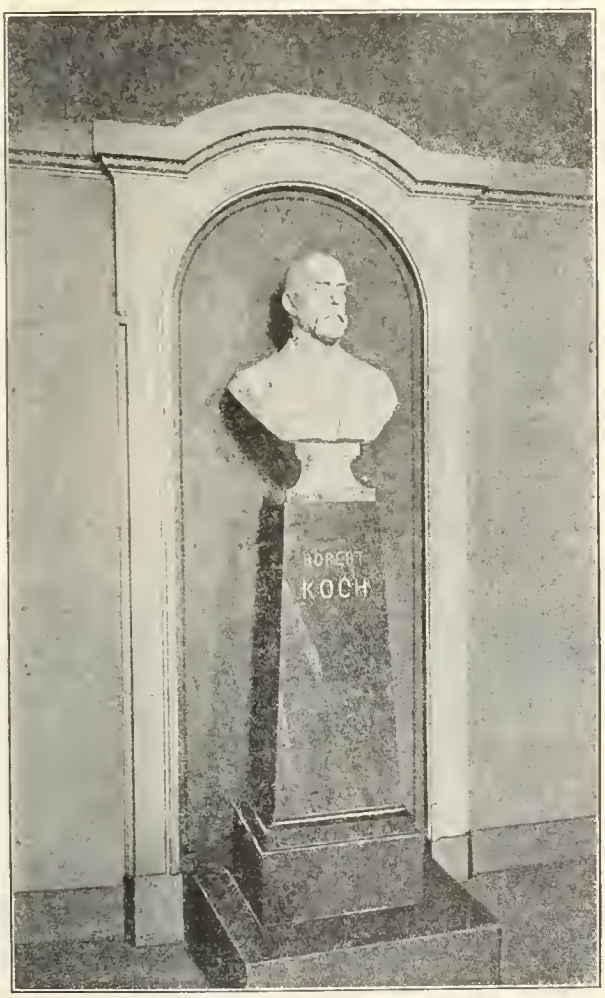

FIG. 3.—Bust facing the entrance of the main building.

diseases. By the first of July the scientific institute was placed at Koch's disposal and a month later a ward of 128 beds in the Charité Hospital was also given up to his work. The scientific institute consisted of a chemical and a bacteriological division. In addition to a large number of prac-

ticing physicians who worked in the institute there was a permanent staff counting among its members at various times such men as Brieger, Pfeiffer, Pfuhl, Frosch, Petruschky, Kossel, Wassermann, Beck, Kitasato, Ehrlich, Donitz, and Cornet. In addition to the work on tuberculosis a great many

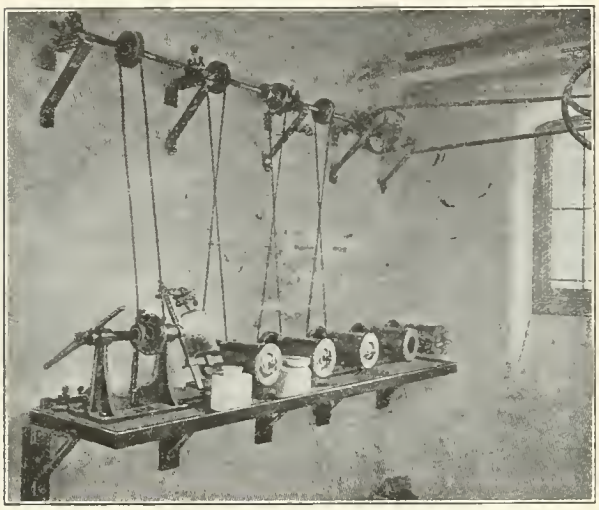

Fig. 4.—Showing mills for pulverizing bacteria, and a shaker.

other subjects were taken up in the Institute. Behring prosecuted his studies on antitoxin immunity in diphtheria, Ehrlich investigated ricin and abrin immunity, Ffeiffer and Wassermann worked up cholera immunity, Loeffler and Frosch studied the foot-and-mouth disease of cattle, Pfeiffer discovered the bacillus of influenza, and a host of other workers, who cannot be named here, contributed to our knowledge of infectious diseases and of immunity. Tropical diseases received special attention from the director of the Institute, Robert Koch, himself. The "ordeal by fire" was gone through by the Institute in the year 1892 when Asiatic cholera appeared in Germany, being especially localized in Hamburg. The most important investigations in this connection were made at the Institute, members of the staff were sent to various places to lead the fight against the scourge, and a great many physicians were instructed in the prophylaxis and diagnosis of cholera and other infectious diseases. The data furnished by the members of the staff who traveled in tropical regions were further worked

Fig. 5.—Chemical laboratory.

up in the Institute. There was established at about that time a division for the treatment of rabies which soon became very busy. Before long the space given up to the Institute proved to be quite inadequate for the many branches of its activity and the authorities decided to build a new establishment in the northern part of the town in connection with the Rudolph Virchow Hospital.

The new Institute has been built in accordance with the directions and specifications of Koch. A twenty years' contract was entered into with the city of Berlin according to which a ward of 100

Fig. 6.—Bacteriological laboratory.

beds for patients suffering from infectious diseases in the Rudolph Virchow Hospital was entrusted to the supervision of the Institute under certain conditions. In addition a special autopsy room was provided for the postmortem examinations of patients dying of infectious disease.

The new Institute is built in the shape of a triangle with apex toward the North, the Spandau Canal forming its base; it is separated from the Hospital by only one street, while direct entrances from the outside connect both buildings. The principal structure fronts on the canal, as is shown in Fig. 1. The view of the rear of the building (Fig. 2) is hidden somewhat by the two buildings, one containing the stables, the other the rooms for attendants, etc.*

The main building contains laboratories, workshops, teaching rooms, a lecture room, offices, rooms for collections of specimens, and a library. Facing the main entrance of this building there stands an impressive bust of Robert Koch (Fig. 3).

In studying the construction of the building we shall describe it story by story, beginning with the cellar. This contains the heating plant for the entire building, a special furnace for cremating cadavers of animals, a laundry, baths, toilet rooms, workshops, storage rooms, and dining-rooms for the attendants. In addition some of the laboratory

Fig. 7.—Thermostat room.

apparatuses have been placed in this basement, among them a distilling apparatus, large centrifuges, a press, and a filter for bacteria, all constructed

*The illustrations in this article are copied by permission from Gaffky's description of the Institute published by Gustav Fischer of Jena.

upon a large scale. The apparatus for drying sera is also located in the basement. Fig. 4 shows a shaker and a number of mills for pulverizing bacteria. A special room is set apart for the examination of the action of gas-forming substances, such as sulphur anhydride, as disinfectants, and another room is provided with a separate gas-heating plant

Fig. 8.—Laboratory washroom.

and serves for other special purposes. All the basement windows are provided with netting of close meshed wire which is intended to prevent the entrance of mice and rats.

The basement floor contains in its western wing a lecture-room seating seventy-six, two smaller rooms for preparation of demonstrations and for the storing of charts and other paraphernalia of teaching adjoining this lecture hall. The same floor contains in addition a room for photography with complete arrangements for the taking of microphotographs. The east wing contains a large chemical laboratory fitted up for twenty-two workers (Fig. 5), and adjoining this there are several other rooms for use by the chemists, such as a room for the weighing scales, a special laboratory for working with offensively smelling substances, a washroom, a dark room, and the private rooms for the chief of this division of the Institute.

The middle part of the basement floor is occupied by offices of the administration and by six rooms devoted to the prevention and treatment of hydrophobia. The western wing of the first story is occupied by a large workroom for bacteriology (Fig. 6) with adjoining smaller laboratories and other rooms for various accessory purposes, such as the

Fig. 9.—The animal cage room.

washing of utensils, for thermostats, etc. The chief of the serum division which is connected with the department of bacteriology has his offices near the laboratory. Similar rooms of the eastern wing serve for the purposes of research into the nature of tropical diseases, while the middle portion of the floor contains on each side a writing room, two laboratories, a washroom, and a thermostat room. These suites of rooms form two independent divisions, one of them being reserved for the use of Robert Koch, who has for the last few years been away on scientific expeditions, the other being occupied by the Director of the Institute, which office is at present filled by Professor Gaffky.

The thermostat rooms (Fig. 7) deserve special mention. The middle of each thermostat room is occupied by a structure which does not appear in the photograph and which consists of an apparatus about two meters high and long; it is warmed by a small water oven and is kept at a constant temperature by means of very accurate adjustments. All the burners used for warming the thermostats are supplied by a separate gas plant. The smaller side rooms contain ice boxes and centrifuges run by hand and by electricity. Fig. 8 gives an idea of the construction of the laboratory washrooms.

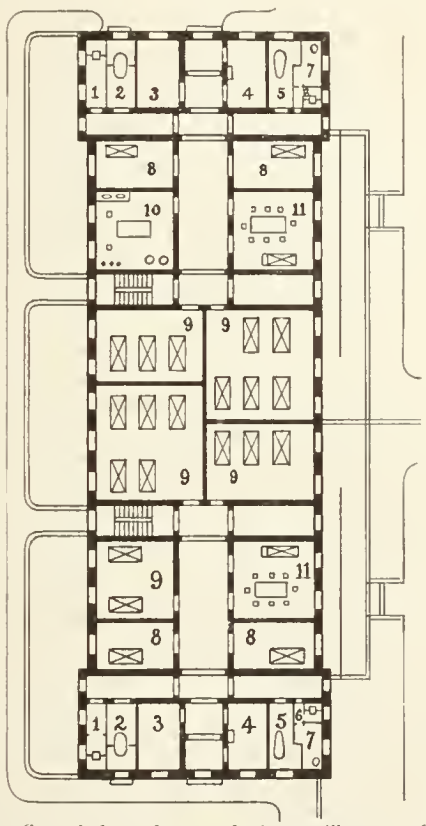

Fig. 10.—Ground-plan of one of the pavilions.—1. Closet for attendants; 2. Room for steam disinfection of clothing. 3. Nurses' room; 4. Kitchen; 5. Bathroom; 6. Patients' closet; 7. Fecal incinerator; 8. Private rooms for patients; 9. Wards; 10. Operating room; 11. Recreation room.

In the second story are found the division for the specially dangerous diseases, such as plague and cholera, and all precautions in reference to the floor, walls, and doors have been taken to prevent accidental spread of these diseases and escape of the animals inoculated in this division. Here also are located a large and well stocked library, a reading room, the Institute museum, and a large room for photography.

We shall now leave the main building in order to pay a visit to the stable house. This contains a separate room for small animals used for experimental purposes; the middle portion of the floor space is occupied by a large disinfecting apparatus for disinfecting animal cages. Another room is used for examination of the heads of dogs suspected of having suffered from hydrophobia. The two large side rooms contain cages for rabbits and

guinea pigs in the middle, while along the walls are arranged cages for apes, dogs, and hens, together with baskets and stalls for feeding (Fig. 9). The upper story contains an operating room with sterilizing apparatus, and the side rooms contain cages for animals, except such as are used for the study of hydrophobia. The horse stable contains two rooms where large belly straps and pulley weights are arranged so that the horses may be suspended in the air when needed. A large operating room occupies the middle of this stable. There are two compartments set apart for smaller animals—calves, donkeys, goats, sheep, dogs, and the larger fowl. Feeding rooms and feeding kitchens are placed in the middle of these compartments, as well as rooms for the utensils and living rooms for the attendants. All the animal houses have exercising yards, are lighted by electricity, are very easily cleaned, and have lately been provided with a separate hot-water heating apparatus. The whole structure, including the interior work, walls, fences, garden, and street changes, has cost in the neighborhood of 831,000 marks.

Of the six pavilions for infectious diseases in the Rudolph Virchow Hospital, one is given up to diphtheria patients, one to typhoid fever patients and the rarer diseases such as smallpox, cholera, plague, epidemic cerebrospinal meningitis; one-half of another pavilion serves for whooping-cough patients, the other half being devoted to women and children suffering from erysipelas; the male erysipelas patients are kept in one-half of another pavilion, while the other half of that pavilion is occupied by patients suffering from measles.

Fig. 10 shows the ground floor of each of four similar pavilions. The two remaining pavilions, the one serving for quarantine purposes, the other as a diphtheria station, contain many separate rooms, a large operating room, and a room for bacteriological examinations. The upper stories of all the pavilions contain living rooms for physicians and nurses, with bathrooms for the attendants. The model autopsy room is provided with special arrangements for preventing the spread of infectious disease; it occupies one end of the whole structure consisting of the pavilions for infectious diseases.

In conclusion we shall give a few data about the organization and the work of the Institute. The medical staff consists of a Director, four Chiefs of Divisions, two Superintendents of Divisions, nine Assistants, and three Sanitary Officers; in addition, there are two scientific assistants, several officials and their subordinates, eight men servants, and five women who do washing and cleaning. During the year 1907 the total expenses for running the institution, including the outlay for salaries, amounted to 250,000 marks. Six divisions, the scientific, the division for especially dangerous diseases, the serum division, the one devoted to tropical disease, the hydrophobia division, and the chemical division, examine all material suspected of being infectious, prepare sera, issue certificates of examinations for the government, and do work on various hygienic problems including that of dealing with sewage. New disinfecting substances are examined in regard to their composition and efficacy, and the chemical division gives special attention to the examination of milk. The scientific papers of the Institute are published for the most part in the *Zeitschrift für Hygiene und Infectionskrankheiten*. During the year a great number of courses of instruction are given and many volunteer workers receive thorough training in the work to which the Institute is devoted.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending November 7, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	443	147
Diphtheria	291	16
Measles	137	6
Scarlet Fever	143	6
Smallpox	—	—
Varicella	91	—
Typhoid Fever	53	12
Whooping Cough	9	3
Cerebrospinal Meningitis	5	2
Malarial Fever	—	—
Totals	1172	192

Orrhotherapy in Diphtheritic Lesions of the Kidneys.—Alfredo Villa advocates the use of renewed doses of antidiphtheritic serum when albuminuria appears in diphtheria. This is generally from the second to the eleventh day of the disease. The author considers it to be due to the activity of the diphtheritic poisons and believes that the best way to combat it is to increase the dosage of antitoxin. He gives an injection of from 1,000 to 2,000 units of antitoxin when the albumin is first detected, and repeats it the following day, if the condition of the kidneys has not improved. He gives four cases treated thus with the result that the albumin disappeared rapidly. The best effects are obtained in those cases in which albumin persists late in the disease. Since the immunizing effect of antitoxin lasts only three weeks he believes that the persistence of the albumin indicates that the poisons are still active and there is need of more antitoxin. There are found lesions of the epithelium of the convoluted tubules and the ascending branch of Henle's loop. That these tubes may regenerate their epithelium it is necessary that the effect of the toxins should be removed. This is done by the use of antitoxin. The albumin and casts soon disappear. The author gives six cases of this nature successfully treated by himself.—*Rivista di Clinica Pediatrica.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending November 6, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.

THE POSSIBILITY OF AVOIDING CONSPICUOUS SCAR FORMATION IN SOFTENED TUBERCULOSIS OF THE CERVICAL GLANDS.*

BY WILLY MEYER, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN HOSPITAL; CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND NEW YORK INFIRMARY.

EVERY surgeon when confronted with the necessity of operating for broken-down tuberculous glands of the neck has pondered the question as to how best to proceed in order to cause the least possible scar formation.

In boys and men the matter is not usually of very particular importance, and we rarely hesitate to advise radical operation, especially if the question of saving time is a consideration. It is different, however, with the opposite sex. Here the conscientious surgeon will welcome any means that may tend to improve the cosmetic result of his work.

It is true that if we make the skin incision—even if it be one several inches in length—within the normal folds of the neck, transversely, the result is far superior to that obtained from incisions made anteriorly or posteriorly, parallel with the borders of the sternocleidomastoid muscle. Still, there will be a more or less conspicuous mark for lifetime. Hence, a method that reduces such scar formation to a minimum, requiring the incisions to be made only one-fifth to one-tenth as long as before, should be greeted with enthusiasm. The greater amount of time and trouble such a procedure may in these cases call for from the surgeon and his attendants should not act as a deterrent, when the result is taken into consideration. The treatment alluded to is Bier's artificial hyperemia.

The personal material I am able to offer in this connection is rather small. The hospital with which I am principally associated is not yet in possession of a large children's ward. The few beds we have are designed for emergency rather than chronic cases. These patients, anyway, are dispensary rather than hospital cases; or better still, patients that should be treated in the surgical division of country sanatoria, no matter whether they be children or adults.

Three of my patients have been observed in dispensary and office practice. After some improvement at the end of a few weeks I lost sight of them, so that I cannot report final results. Two others are of too recent date to be considered. Still, in every one of these five patients I have observed the same satisfactory course as has been reported by others.

*Read before the Pediatric Section of the International Congress on Tuberculosis, Washington, 1908.

I made these patients wear the elastic neck band eleven out of every twelve hours for a longer or shorter period. The band made of the same material as the black elastic rubber bandage, with a button in one end and a number of buttonholes in the other, is a very comfortable appliance. The one made of the ordinary garter elastic, with a hook and a number of eyes, comes next. The compression of the deep jugular veins should not be sufficient to cause the patient annoyance; he must be able to talk, eat, drink, breathe, and sleep without discomfort. In fact, he must hardly be aware of the presence of the band. It is astonishing how quickly children, even babies, usually get used to the band. The appearance of fluctuation at the site of the trouble is carefully watched for. It may be hastened by the continuous application of a warm wet-gauze (Priessnitz) dressing. As soon as it appears a short cut is made in the course of the neckfold through which the pus is evacuated. If the muscles or some subcutaneous fat tissue have the tendency to overlap the incision, a drain of small size is introduced for 24 to 30 hours. Otherwise, the wound is simply left open and suction treatment started 4 to 6 hours later.

It is advisable to use the cup once daily for a period of 45 minutes, *i. e.* 6 x 5 minutes with 2 or 3 minutes intermission each time, soon after the bandage has been removed. Packing or injections of iodoform emulsion or bismuth paste are never used. It will be observed that glandular débris are aspirated with the pus. It is natural that the fistulous tract, as well as the entire diseased area, is placed under suction, thus combining the hyperemic depth effect on the tuberculous tissue with regular gentle evacuation of the abscess. If the treatment is properly carried out, a mixed infection will not occur. Soon the purulent secretion becomes serous. In favorable cases the opening closes rapidly. The remaining slight infiltration gradually becomes absorbed under the continued use of the elastic neck band.

It stands to reason that a patient in whom a sinus has already developed, when first seen, can be equally successfully treated by this method, but the elastic neck band should always assist the suction treatment.

Bier himself seems to be satisfied with suction treatment alone. From what I have seen, however, I believe it worth while to use the remaining 20 to 22 hours trying to influence the tuberculous tissue by hyperemia produced with the neck band.

Klapp, among others, has seen a most striking case of this kind.*

With the kind permission of a colleague who called me in consultation not long ago I would here relate the following case:

Boy, 5 years of age, the only one surviving child of a number of children, developed a package of tuberculous glands in front of the sternocleido

*A. Bier, On Hyperemia, page 219.

muscle, right behind the angle of the jaw, following some throat trouble. His parents, on account of the delicate condition of the boy, live in the country all the year around. They are as greatly adverse to placing him in a hospital as they are to radical extirpation, as they have only recently lost another child soon after an operation. The glands are softened; deep fluctuation can be made out. The parents want to know if there is no other means of help. The family physician is familiar with hyperemic treatment. He favors its use in this case and asks my advice. I could but consent to his proposition, as the case seemed especially adapted for this procedure. Consequently an elastic neck band and a set of cups were procured and a trained nurse was engaged. The band did not give the little fellow the slightest annoyance: he seemed to be perfectly at ease, riding his bicycle and playing around as ever, to his heart's content. Under ethyl chloride spray and local cocaine anesthesia the abscess was opened by a short transverse incision in the course of the neck-fold and suction treatment started. In this way, with the little patient in his former surroundings, all day long in the fresh air, with milk-feeding from their own cow, etc., the trouble took a most favorable course. The wound closed definitely four weeks after incision. All the glandular enlargement gradually disappeared. To-day, four months later, a minute scar, about three-quarters of an inch long, well hidden in the natural fold of the neck, is the only remaining sign of the previous existence of a tuberculous gland affection.

Just think, if this had occurred in one of our own children, or even in one of our own girls! Must we not hail with delight and enthusiasm a method that renders possible such an outcome? Must we not at least consider it worth a trial in suitable cases?

Of course, the method will not work in every case; artificial hyperemia is no panacea.

It need hardly be stated that proper hygienic conditions and thorough understanding of the treatment on the part of the attending physician and nurse, or mother, greatly facilitate the efficiency of the procedure. In the more serious cases, *e. g.* multiple softened glandular tuberculosis of the neck, general anti-tuberculous treatment with tuberculin injections may be advantageously added.

The lung-suction mask, too, may well be drawn into service in these cases. For it has been proven that it not only produces hyperemia of the lung tissue by suction, but constitutes one of our best means of improving the condition of the blood in all its components on a physical basis. It surely deserves a much wider use than it has been hitherto accorded. And should further experience show that the present device does not fully answer all the requirements, let something else, something better, be constructed by ingenious minds. The principle, certainly, is correct and should be made use of in our fight against pulmonary, as well as other tuberculous disease; in the latter cases on account of the concomitant anemia.

It is unfortunate that Kuhn's mask is protected by patents which render it costly of importation and difficult of repair.

In conclusion I would say that my personal results from the combined use of the elastic neck band and the suction cups have been most brilliant and surprisingly rapid also in cases of broken down cervical adenitis following tonsillitis, for instance of scarlet fever, or following suppurative periostitis of the jaw and other causes.

But, no matter what the etiology, I am convinced that the treatment above outlined merits the full and most careful attention of every physician and surgeon, and is of particular value in female patients.

The cases of the other type of glandular tuberculosis of the neck, forming the well-known chains of hard tumors in smaller or larger packages, are distinctly operative.

OBSTINATE VOMITING, OR THE PERSONALLY CONDUCTED BABY.*

By W. P. NORTHRUP, M.D.,

NEW YORK.

PROFESSOR OF PEDIATRICS IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE following experience occurred in the practice of Dr. Harlow Brooks. "The whole story is," said the doctor (and his style of utterance was "projectile"), "the baby vomits—everything. It takes three ounces and vomits four; simply can't keep a thing down."

Here was the position: A young mother with her first child, wishing to leave town for the summer, her breast full of good milk which she could not use, her mind full of dread of laboratory prescriptions and daily milk deliveries, and a long summer before her.

The baby had lived three months and had "bothered with its food" two of those months. At present it seemed well, looked well. The mother had huge breasts, "big as derby hats," the doctor said, "milk enough for three babies," well formed nipples, easy flow. In fact while the baby nursed from one nipple it was necessary to soak up the leakage from the other in a bath towel. The total fats by laboratory test had been 8 per cent., but by regulated diet and exercise had been reduced to 6 per cent. The child could take various foods from other sources, could even take its own mother's milk when given it in a bottle through a rubber nipple. It was always hungry. The whole trouble with the baby was that it persisted in vomiting the entire intake from its mother's breast.

The doctor had tried everything, exhausted all the familiar resources without success. The baby vomited all breast feedings. He had given the baby diluents by bottle before nursing, shortened the time of nursing, required rest before and after nursing, had varied the intervals, compelled the baby to nurse through rubber shields, had drawn the milk and fed it in bottles. The last two methods were at first successful, the baby retaining the milk in both instances. It seemed, then, the quality of milk was not alone at fault. The shields and the pumping so fretted the mother that it was necessary to discontinue them. The next expedient was putting the baby on laboratory feedings to stop the vomiting. Everything, in fact, succeeded in stopping the vomiting, until the baby was put back upon the breast. *Whenever it nursed naturally from its mother's breast it promptly vomited the whole intake.*

The original question again presented itself: Must the baby be weaned? Must it leave for the country depending for its summer supply of food upon cow's milk? It seemed really pusilanimous to stand up before these parents and tell them to wean the baby from a full breast of good milk. Once more we went over the history. The baby always vomited when it took the food the normal way, but retained anything taken from the bottle. We ex-

*Read before the Pediatric Section of the N. Y. Academy of Medicine, November 12, 1908.

amined the breasts, nipples, general condition of the mother. All conditions were favorable except that the mother was worried over the behavior of the baby. She looked every form of human appeal for help. It was quite plain that if we could induce the baby to retain her milk she would go to the country free of all anxiety concerning bottles, feedings, trains, hot weather, and nursemaids. The mother had done her part, now for the doctor's part! Here we stood, two grown-ups, before this forbearing, polite young mother (for she never told us what she thought of us) and looked puzzled.

"When in doubt, take history," Dr. Thomas W. McBride used to say. "If still in doubt, take more history," and so on he repeated again and again, "until the diagnosis is made." We asked the mother to nurse the baby before us. Just then something in the history occurred to our minds—"milk plenty" —"flow easy." Then we reflected that when a baby is very weak and exhausted we lay it on its back and have the mother lean over that gravity may assist to make nursing easy. It helps. Here was a case where the nursing for a vigorous child was too easy. Why not reverse the process and make it difficult?

The mother was asked to lie on her bed, turning so that the breast to be used would be the lower. The baby was then laid across the mother in such a way that its head would be lowest and it must *drink up-hill.* From the breast and nipple to the baby's stomach was all up-hill. The baby had to work for his food. The result was he took his food slower, took less of it, and stopped when he had enough.

During and after this novel proceeding, the household (the husband had arrived from his downtown office) stood around, realizing that, at least, one new resource had been suggested and they hoped. The baby was allowed to nurse ten minutes by the watch, when he seemed willing to rest. He was at once removed and laid on his back, head and shoulders elevated. He spat up a little before our departure, yet we hoped. It may be said that from the first this upside-down attitude really promised something. The sprawling baby, lying face and head downwards in a straight line from its mother's elevated left chest to the very lowest point, viz., the right nipple, necessarily bored its nose into the large, flabby breast and breathed with difficulty. It was hungry and worked hard for its food, alternately sucking and stopping to get its breath. In this manner it took and kept its first normal nursing.

Three days later the doctor reported that the baby had kept down every feeding. Besides, the mother had discovered a further improvement in technique. She now sits in a rocking-chair, slinging the baby over one shoulder and the baby crawls down head first to the opposite nipple. The upside-down position is a success and the much relieved mother is going to the country carrying in her breasts a summer's supply of properly modified baby-feedings. The doctor has ascertained the amount of time necessary to take in three ounces and the baby does not spit up a mouthful. Occasionally, he can take a feeding lying on his back. Whenever he vomits, the mother simply slings him over her shoulder so that he crawls down head foremost to his food. *The method succeeds.*

Conclusions.—1. A nursing baby may vomit because its food enters the stomach too rapidly and consequently in too great quantities.

2. The causes of this over-distention may be sought in the large quantity of breast milk, easy flow, large nipples, vigorous nursing.

3. The above conditions may be overcome by imposing mechanical obstructions, "drinking up-hill," being here suggested.

In the above case the successful position was, sprawling head-downwards and face-downwards over the mother's shoulder to the nipple, *like a squirrel coming down a tree.*

57 East Seventy-ninth Street.

ENDOTHELIOMA OF THE PLEURA.*

By H. BEECKMAN DELATOUR, M.D.,

SURGEON-IN-CHIEF JEWISH HOSPITAL AND METHODIST EPISCOPAL HOSPITAL; ATTENDING SURGEON NORWEGIAN AND ST. JOHN'S HOSPITALS, BROOKLYN, N. Y.

New growths of the pleura are most frequently secondary to growths of the chest wall or lung. They may occur by metastasis. Endothelioma is the most common variety of primary new growth of the pleura, and was first described by Wagner, in 1876, under the name of endothelial cancer. Lord, in Osler's "Modern Medicine," gives carcinoma as the more appropriate name. While most writers on medicine pass this over as a very rare condition, yet if we look up the literature we will find many reported cases, and from my own experience I am led to believe that many cases are overlooked and diagnosed as pleurisy, tuberculous pleurisy, or maybe as a pneumonic condition.

Even so recent a work as Butler's "Dignostics" passes over the subject in these words: "Primary carcinoma of the pleura affords simply the evidence of chronic pleurisy, with or without effusion. Irregular, slight fever with occasional subnormal falls may be present; there is pain rather greater than with pleurisy; and cachexia may develop. The diagnosis is rarely made during life." It seems to us that this is hardly a fair statement of the case and that with care and diligence a diagnosis can frequently be made and a proper prognosis given. Primary sarcoma of the pleura also occurs and produces the same symptoms and physical signs as endothelioma.

Glockner up to 1897 collected about fifty cases sufficiently well reported to be included under the classification of endothelioma. To this may be added two reported by Lord (Osler's "Practical Medicine") and from Delafield (Medical Record, N. Y., Vol. 62, No. 20.)

The growth is usually diffuse and the whole pleura of one side is converted into a dense resisting tissue varying in thickness up to two centimeters or even more. In some cases it occurs in the form of a number of scattered nodules or as in the case reported by Butler (*New York Medical Journal*, 1898), as a single large tumor occupying the pleural cavity. Fluid may or may not be present—when present this fluid is usually blood stained.

Microscopically the tissue is found to consist of a fibrous stroma in which are enlarged lymph spaces containing polymorphous cells. Small areas of necrosis are sometimes present. The epithelium of the free surface of the pleura is usually absent over the whole or greater part of the sections, and in most cases has not apparently taken part in the new growth. The lymph vessels and spaces appear to be the principal site of the new growth, and many observers believe their epithelium the point of origin (Lord).

Metastases have been observed in the supraclavicular and axillary glands and along the needle punctures after aspiration. The chest may be contracted in its lateral and posterior regions. The

*Read before the Medical Club of Brooklyn.

lung may be compressed and contain secondary nodules.

The growth of these tumors is slow and the symptoms and physical signs are those of pleural effusion. Pain is quite a constant symptom, in some being acute and sudden as in an acute pleurisy, in others a constant dull ache over the affected side.

Fever is present in some and absent in other cases. Dyspnea is present according to the amount of encroachment of the growth or pressure of the accumulated fluid on the lung. The pulse is usually not markedly affected until late in the disease, when exhaustion is pronounced—at this period the pulse is likely to become very rapid and weak. When large quantities of fluid accumulate in the chest, the pulse may become very rapid and weak and the heart may be displaced as in a simple pleurisy with effusion. Cough is present in some and absent in others, apparently dependent on the effusion—or compression of the lung. In Butler's case, above referred to, cough was probably due to a coincident tuberculosis of the lung. The axillary and cervical glands are frequently enlarged and if removed and examined microscopically may show suggestive changes. Loss of flesh and strength is usually progressive and marked.

The physical signs are those of a marked pleuritic effusion. A very suggestive condition is the persistence of the physical signs after the removal of the fluid. The fluid after removal tends to recur rapidly, and in large amounts, as in Case I, here reported. The fluid may not be blood stained at first, but usually becomes so as the disease progresses. Respiration, according to Frankel, over the affected side is usually bronchial. When a tumor is formed there may be a decided bulging of the chest wall with marked signs of compression of the lung.

Leucocytosis is always present and, according to Cabot, may be so high as to suggest a suppurative condition. Cachexia develops as the disease progresses.

The diagnosis in the early stages is not easy and in the cases without effusion is exceedingly difficult. If there is no effusion, it must depend primarily upon the discovery in the chest of an area of flatness, which has an atypical shape and position, with diminished respiratory and vocal signs. Combined with this there must be some cachexia, with or without enlarged axillary or cervical glands (Whitney). One of these glands may be removed and microscopically show the presence of malignant disease.

In most cases the diagnosis is made after obtaining by puncture a hemorrhagic serum, which on examination may show microscopic elements suggestive of endothelial growth. The serum in these cases is usually of a deep red color, much more marked than in tuberculous pleurisy. It must be remembered that the fluid withdrawn in all cases of pleural cancer is not hemorrhagic. Benda (*Berliner klin. Woch.*, March 1, 1897) reports a case in which sixteen aspirations were made, three liters being withdrawn the first time, and the fluid remained clear throughout. Netter states that it is present in not more than two-thirds of the cases. The first fluid withdrawn may be a clear serum, while that drawn later may be decidedly bloody. This may be due to the withdrawal of the pressure from the surface of the growth and thus allowing hemorrhage to take place into the vacuum created, as the thickened pleura prevents expansion of the lung and the closure of the cavity produced by aspiration. This also may account for the rapid reaccumulation of the fluid. The failure of the lung to expand frequently produces severe pain after aspiration.

Free fat is frequently found in the fluid withdrawn and may be so abundant that the fluid is distinctly chyliform, as in Case V. This is said to be more chracteristic of cancer than of tuberculosis. In introducing the needle for the withdrawal of fluid when the growth is disseminated, a decided sensation is imparted to the operator of passing the needle through thick and resisting tissue and for a greater depth than the normal pleura. A. S. Warthin, after microscopic examination of the exudate from a large number of cases of pleural effusion, and having succeeded in making a diagnosis of primary sarcoma of the pleura in one case by this examination, concludes that if fixed cover-glass preparations of the fluid are made immediately after its withdrawal, in order to preserve the appearance of mitosis, the diagnosis may be usually made. In early simple pleurisy the exudate contains endothelial cells and no fibroblasts. In fibrous pleurisy, either tuberculous or septic, the sediment contains endothelial cells and numerous fibroblasts. In sarcoma the presence of a large number of round or spindle-cells, often in bunches, and the occurrence of frequent mitoses, will make the diagnosis positive. Mitosis is the most important evidence, as this rarely occurs in any other disease.

The prognosis is uniformly bad. These patients usually progressively fail and die within from four to six months. One of my patients lived a year.

General treatment directed to sustaining the patient and relieving symptoms is all that we can command. When fluid accumulates sufficient to produce pressure symptoms it should be aspirated under strict aseptic precautions. It has been recommended to draw off only enough fluid at a time to relieve the dyspnea and to do this as frequently as necessary. Resection of a rib should never be done when this condition is present, for the cavity is unable to contract, infection is likely to occur, and the patient may die of pyemia, as in Benda's case.

Five cases of this disease have come under my observation in the past five years, and as the histories are quite different I will present all five.

Case I.—Female, 38 years of age, wife of a physician. No family history of tuberculosis or tumors. Two children strong and well. Had been in good health until the latter part of February, 1902, when she began to suffer some pain in the chest and was troubled by a dry cough. This condition of pain in the chest with cough persisted and was accompanied by very decided loss of flesh and strength. During the following May dyspnea became very marked. The cough persisted but was accompanied by little expectoration. She was first seen by me early in June, when she was supposed to be suffering (because of the loss of flesh and strength) from pulmonary tuberculosis.

Examination showed a woman of average build but very anemic and emaciated. The slightest exertion produced marked dyspnea. Over the left chest all respiratory sounds were exaggerated; over the right side there were practically no respiratory sounds to be heard, and on percussion there was absolute flatness from the clavicle down. There was no evidence of pulmonary involvement, but it was quite evident that the right chest was full of fluid and that this was the cause of the dyspnea. Two days later by aspiration 32 oz. of clear serum was withdrawn. There was evidently more fluid present, but as the pulse had become very feeble and rapid and as dyspnea was markedly increased the needle was withdrawn. After withdrawing the needle the physical signs remained the same. As the needle was withdrawn, just as it left the cavity

there was a flow of bright fluid blood. The introduction of the needle was through denser tissue than one usually encounters and the needle had to be passed to a depth of a little over two inches before fluid was obtained. Five days later it was decided to try to empty the pleural cavity and on this occasion 44 oz. was obtained, but this was not clear serum as before; it was a brownish fluid. Two weeks later 64 oz. were withdrawn and a week later 56 oz.; and at intervals varying from one to two weeks, up to the middle of September, when the patient died, aspiration was done, from 30 to 40 oz. being obtained each time. During the progress of the case absence of fever was a very marked feature. On one or two occasions only did the temperature reach 99° or 99.5°, and then only when some outside condition seemed to be the cause. The pulse was very rapid from the first, varying from 120 to 160, and during the last month almost uncountable at times.

There was a progressive loss of flesh and of strength until the patient became confined to her bed about the middle of July. The nervous system became much affected; she was very irritable, lost all interest in her surroundings, and it was very difficult to get her to take any food. She died exhausted seven months from the onset of the disease.

No post-mortem could be obtained. Dr. Hermann Biggs saw the case in consultation and took some of the fluid for pathological examination. From this examination he reported the findings as suggestive of endothelioma.

Case II.—A lady of 65 years was taken ill in January with pains in the chest and prostration. For two months she was treated for intercostal neuralgia and muscular rheumatism without improvement. During the first week in April following a change of physicians was made and the new attendant diagnosed the case as one of pleurisy with effusion. I was requested to see the case in consultation and to aspirate. The lady who had always been very fleshy was much reduced in weight although still stout. Physical examination gave flatness over the entire chest. On introducing the needle we passed through resisting tissue and were compelled to introduce the needle to an unusual depth. About 36 oz. of clear fluid was withdrawn. After withdrawal of the fluid the physical signs were not perceptibly changed. Because of the resemblance to the previous case I ventured a diagnosis of endothelioma of the pleura. I did not personally attend the case again, but learned that all through the summer at intervals aspiration was done and large quantities of fluid were withdrawn, but never bloody. In October she was taken to one of the New York hospitals and operated upon for carcinoma of the uterus. She never rallied from the operation, dying the same day. She never showed any improvement in her condition after I saw her, continuing to lose both flesh and strength, and at the time she was taken from her home for operation, had to be carried out. There may be some room for doubt as to this being a primary endothelioma of the pleura, but it is certain it was not an ordinary pleurisy. The occurrence of carcinoma in the uterus would apparently confirm the diagnosis, and yet it may be said this condition was primary in the uterus. There were no symptoms of uterine disease at the time I examined the patient.

Case III.—Male, over 60 years of age. I was asked to operate upon this gentleman for empyema. On examination I found the entire left chest flat and no respiratory sounds to be heard. The man had had no fever to warrant a belief in pus being present and symptoms had been present for some weeks. On aspiration I withdrew about 50 ounces of clear fluid without relief of symptoms. The needle was introduced to an unusual depth before fluid was withdrawn. Here, again, because of the similar physical conditions and history, I ventured a diagnosis of pleural cancer. The old gentleman lived a little over a week and died from exhaustion.

Case IV.—Lady, 49 years of age, patient of Dr. Charles B. Story. Patient began to complain of pains in her side in April, 1904, and was treated for a few times until August 1 of that year, when the physical signs of pleurisy with effusion were present. She was aspirated September 1 and 36 oz. of serum removed; at this time the temperature was 99°, pulse 86, respiration 26; marked dyspnea was present. She was again aspirated on October 6, 72 oz. of serum being withdrawn; at this time the temperature was 98.5°, pulse 108, respiration 24. She was again aspirated on October 23, and one quart of serum was removed. I first saw her about November 10, at which time she was suffering great distress from the embarrassment of respiration, was unable to lie down; temperature 99°, pulse 96, respiration 24. Physical examination of the right chest gave on percussion flatness over the entire chest, front and back. There was marked loss of flesh and strength, dyspnea was extreme. Aspiration at that time removed two quarts of a pink-colored serum. The emptying of the chest was followed by much pain, which persisted for about 24 hours. The patient's condition continued about the same except for the continuous loss of flesh and strength up to the time of her death, on June 25, 1905.

During the period of her illness she was aspirated seven times, the largest quantity of fluid obtained at one time was on February 23, when three quarts of a dark fluid were withdrawn; the last aspiration was on June 23, the second day before her death. On June 25, with no apparent change in her general condition, a sudden cyanosis appeared and the patient died rather unexpectedly. Before death, at the site of the aspiration punctures, indurated nodules developed and showed a marked tendency to enlarge; contraction of the affected side took place late in the disease. No post-mortem was permitted.

This patient lived about fourteen months from the onset of the symptoms. The fluid withdrawn was twice examined at the Lederle Laboratories; the first specimen gave no positive findings; the second specimen, examined February 24, 1905, was reported as follows: The fresh centrifuged specimen shows no shreds of tissue, but the sediment packs down into a coherent mass which, upon microscopic examination, is seen to consist almost wholly of pus, with a small admixture of red blood cells and an occasional endothelial cell. The stained specimen shows the pus cells to be very largely of the polymorphonuclear neutrophile variety, eosinophiles and lymphocytes in much smaller proportion. There are a moderate number of bacteria and many examples of bacilli enclosed in pus cells, showing phagocytic action. The endothelial cells are few in number, and none were found undergoing mitosis. As compared with a previous specimen examined from this case, there is a diminution in the red blood cells and a decided increase in the white cells, amounting to a distinct purulent condition. The endothelial elements appear to be diminished and the bacteria much less numerous. The fluid has all the features of an inflammatory exudate. This may or may not be associated with a new growth, as the presence of endothelial cell mitosis is the only reliable factor, except the finding of actual fragments of cancer tissue; and, on the

other hand, the absence of both findings does not necessarily preclude the existence of such a condition. The occurrence of secondary nodules at the puncture points is very significant in the history of this case.

Case V.—For the privilege of presenting this case we are indebted to Dr. Jos. Merzbach, in whose service the patient was treated at the Jewish Hospital from May 9 to June 29, 1907. Male, age 40, baker. Family history—Parents died from causes unknown. Of brothers and sisters eight are living and well. Children, three, living and well. No history of tuberculosis or carcinoma. Appetite has been good up to the present illness. Bowels have moved twice daily. Drinks whiskey to excess, three or four glasses daily. Had gonorrhea 20 to 22 years ago and was cured. Denies syphilis. At 13 years he had typhoid fever with no sepuelæ. Otherwise the previous history was negative. The present trouble began eight months ago with symptoms of muscular rheumatism: there was pain with cramps in the muscles. Then he had an attack of bronchitis, and steadily became worse, with shortness of breath. Had to get up two or three times a night to pass water. He then developed orthopnea. He still complains of his cramps. Bowels regular, appetite poor. Has lost about 60 pounds in weight. He coughs and feels feverish. No hemoptysis. The man is pale, anemic, and emaciated. Pupils normal, react to light and accommodation. Tongue is broad, moist, and coated. Postcervical lymph glands are much enlarged. Patient breathes rapidly, respiraory movements are labored. Less motion on left side. Urine shows the changes of a chronic nephritis. Tactile fremitus is diminished over the left chest posteriorly and the right chest posteriorly; anteriorly negative. There is dullness on percussion over the same area. Râles of all kinds are heard over both chests. Posteriorly the voice sounds are very much diminished or absent. The outlines of the heart cannot be made out by percussion on account of the dullness in the chest. Heart sounds muffled; the apex beat is regular and of fair force in the sixth space outside the nipple line.

The upper border of the liver cannot be made out; the lower border is at the free border of the ribs. The abdomen is distended. Dullness is present in the flanks. A fluid wave is present. No masses can be detected and there is no rigidity. Some tenderness is present.

May 11. The left chest was aspirated, withdrawing a pinkish tinted fluid, 2,000 c.c. This was repeated on May 14, of a creamy fluid, 1,800 c.c. being withdrawn, and again on May 16, when 2,500 c.c. of the same creamy fluid was removed. A cervical gland was excised for examination.

May 19. Left chest aspirated and about 1,000 c.c. of creamy fluid slightly darker than on previous occasions evacuated. This fluid shows the presence of methylene blue which was given on the day previous in capsules. Right chest aspirated and about 800 c.c. of a serosanguineous fluid obtained free from methylene blue (to naked eye). A very marked pericardial friction murmur was heard over the pericardium near the apex.

May 22. Abdomen aspirated suprapubically and 2,000 c.c. of a milky fluid obtained, of same microscopic appearance as the pleural fluid.

May 25. Left chest aspirated and 700 c.c. serosanguinolent fluid obtained, not chylous as on previous aspirations.

May 26. Much abdominal distention. Cardiac dullness obliterated by gastric tympany. Heart sounds weak and heard best over the fourth interspace (left) near the border of the sternum. The abdomen was aspirated and 2,000 c.c. of chylous fluid withdrawn.

May 30. Abdomen aspirated, 3,200 c.c. of chylous fluid being withdrawn.

During June aspiration was repeated a number of times. Fever was never present at any time.

During treatment the right pleural cavity was aspirated once and 800 c.c. of a bloody fluid withdrawn. From the left pleural cavity repeated aspirations give 8,000 c.c. This was usually chylous in character but occasionally bloody. From the abdomen in all 30,000 c.c. of chylous fluid was withdrawn.

The patient died June 29, much emaciated. No post-mortem could be obtained.

Pathological reports of gland removed, Endothelioma. Fluid from right chest contained many endothelial cells and numerous red blood cells; fluid from the left chest showed the same findings plus some fat. The fluid from the abdominal cavity was sterile and contained fat.

Whether or not to include this case as one of primary carcinoma of the pleura is a question. The abdominal ascites can be accounted for by the old kidney condition. The character of the fluid withdrawn from the abdomen can be explained by obstruction to the thoracic duct by pressure of the growth within the chest. The presence of chylous fluid in the chest is said to be indicative of endothelioma.

The microscopical examination of this fluid showed endothelial cells present, and the gland removed was reported as an endothelioma. It would seem fair to consider this a case of primary new growth of the pleura complicating a case of chronic Bright's disease.

In conclusion we would draw attention to this condition because, although rare, it is of sufficiently frequent occurrence to be considered in all cases of pleural effusion or subacute pleuritic affections with signs of thickening of the pleura. It is exceedingly important to diagnose this condition correctly when it comes to giving a prognosis. And lastly, in this disease we must not be led into the error of opening the chest for drainage.

LOCOMOTOR ATAXIA: A NEW THEORY AND TREATMENT WITH CASES.*

By LE GRAND N. DENSLOW, M.D.,

NEW YORK.

As long ago as the time of Hippocrates writers described a condition associated with spermatorrhea and sexual excess which they attributed to wasting of the spinal cord. It is possible that this was the tabes of the present time if we do not accept the general opinion of to-day regarding its purely specific origin.

Medicine and surgery during the whole of the middle ages was in such a chaotic stage that it is not possible to form any opinion as to whether or not tabes occurred before the appearance of syphilis in the fifteenth century. Numerous writers commencing with Ollivier in 1824, described what was undoubtedly tabes, but Todd (1847) was the first to differentiate paralysis and incoordination, and to attribute the latter to disease of the posterior columns of the spinal cord. Romberg (1840 to 1857) in his "Lehrbuch der Nerven-Krankheiten" was the first to give an extended account of tabes.

*Paper read at a meeting of the New York Academy of Medicine, October 1, 1908.

He described the characteristic gait and the exaggeration of the ataxia upon closing the eyes, the lightning pains, the anesthesia and paresthesia, the urinary troubles and the occular disturbances, and for the prognosis said: "To none affected by this malady is there any hope of recovery; über alle ist der Stab gebrochen." He gives as the post-mortem appearances, atrophy of the posterior roots of the spinal nerves—the anterior remaining normal—with destruction of the lower lumbar cord and the nerve substance in the cauda equina at times leaving only neurilemma-sheaths. The roots of the higher nerves are also frequently affected. The next most notable addition to the knowledge of tabes was the publication by Duchenne in 1858 of his researches under the title "Ataxie locomotor progressive." He differentiated it from muscular paresis, gave an exhaustive description of its symptoms, and was under the impression that he had discovered a new disease. He considered it due to disease of the cerebellum. It was that masterly clinician, Trousseau, who first considered the changes in the cord as secondary; in his words they were probably only the secondary results of the functional disturbances created by "Some obscure general condition." Isnard, a pupil of Trousseau, regarded it as a neurosis of the muscular sense. Before this, however, many observers in France and England were satisfied that the symptoms of tabes and degeneration of the posterior columns were coincident. The first microscopical investigations were made by Virchow, 1855, and Rokitansky, 1857, and it is of interest to note that these fathers of pathology recognized its true character as a non-inflammatory destruction of the nerve elements proper. Bourdon and Luys, 1861, described the change as chronic inflammatory; Charcot, Vulpian, Gull, and many others agreed with them. V. Leyden, 1863, took the original views of Rokitansky that it was a simple atrophy of the sensory tracts of the cord generally progressing from below upward, and further that such inflammation as showed in the membranes and blood-vessels were secondary. Although he recognized the character of the change, he did not, however, causally connect the degeneration of the posterior columns with the process in the sensory roots; as to the degeneration being caused by extension of inflammation from the pia mater, he says: "But the view that the atrophy of the posterior roots caused by inflammation of the pia mater leads to a similar degeneration of the posterior columns, is very unlikely. Moreover, the disease of the posterior columns progresses more from the posterior or periphery and middle line, rather than follows the distribution of the roots." Pierret eight years later, 1871, localized the degeneration process "in two symmetrical islets of small extent, situated in a special region of the posterior columns" and not invading the columns as a whole. Thus tabes was looked upon as a system disease. Without going into the details of all his speculations and arguments, which the scope of this paper would not permit, we may state that Vulpian in 1879 proposed the formula "sclerosis of the posterior roots" instead of "sclerosis of the posterior columns," thus being the first to inaugurate the root theory which is held by most neuropathologists to-day.

Many theories have been advanced as to the cause of the progressive dystrophy of the posterior roots and their intermedullary terminations—among them the alteration of the cells of the spinal ganglion, the trophic centers of the fibers in question. The strongest argument against this is that the peripheral process as it emerges from the distal pole of the ganglion practically shows no abnormality; while the central process, the posterior root, may be degenerated into the ganglion itself. V. Leyden and Goldscheider look upon the peripheral nerve endings which often show dystrophic changes, as more probably the starting point of the process. Against this, however, is the fact that degeneration of the peripheral nerves does not always precede the changes in the cord, neither is it always associated with tabes. At present it is not considered a satisfactory answer to the question. Nageotte, Redlich, and Obersteiner are of the opinion that the origin of the tabetic process is an inflammatory condition of the meninges affecting the posterior roots. As against this is the fact that meningitis is not constantly present, in fact is more often absent, and when it is present is more often of the character of a secondary thickening than an inflammatory process.

Again in the early stages of tabes it is found that the intramedullary degeneration is often well marked when the posterior roots exhibit no appreciable change and no indication of a local neuritis. Another fatal objection is that the neuritis Nageotte finds in the anterior radicle is evanescent, while that of the posterior is so profoundly destructive. Redlich and Obersteiner hold that where the posterior roots penetrate into the pia mater there is a constriction, and that during meningeal inflammation they become strangled. The weak point in this theory is that meningitis is not always present, and when it is, rarely causes degeneration of the posterior roots.

The degenerations of tabes occurring as they do in widely separated situations throughout the cranium and sympathetic system as well, would seem to be sufficient argument against these theories. That there is a point where the posterior root fibers are specially prone to degeneration at what is known as "Obersteiner's ring," due to the loss of their neurilemma sheath and the thinning of the myelin sheath is well known, and that the absence of the neurilemma cells is the cause of the greater proclivity to degeneration of the intermedullary terminals than of the other branches of the sensory protoneurones in the tabetic dystrophy. Ferrier says "some conditions probably exist favoring the incidence of noxious influences in this portion of the protoneurone. Marie and Guillain attribute the tabetic degeneration to a syphilitic affection of the posterior lymphatics and derive the lymphocytosis of cerebrospinal fluid from the elements of this system. Antisyphilitic treatment has not given results in support of these views. There is in tabes a marked lymphocytosis, but it is also present in a number of other conditions. An argument that this condition is not primarily due to syphilis is the fact that it does not yield to antisyphilitic treatment. Ferrier says "I am inclined to adopt the hypothesis of Thomas and Hauser that the essential lesion of tabes is a dystrophy similar to that induced by certain toxic agents, affecting the protoneurone as a whole and manifesting itself in degeneration of the peripheral and central terminations, of which the intermedullary are the more vulnerable and are usually the earliest to exhibit anatomical changes. The process, however, is not confined to the spinal protoneurone, but may affect among others the optic, the sympathetic, and certain other motor neurones." Ford Robertson has found in living tabetics a bacillus which he has named paralyticans, but he has not as yet produced sufficient evidence to prove that its toxins are an etiological factor in the production of the disease. The prevailing ten-

dency at present is to search after a toxin that will account for all the various degenerations in tabes, and it is acknowledged that no remedy, chemical or physical, has as yet been discovered, which materially influences the morbid process.

This being the present status as to both the etiology and treatment of tabes, I would venture to present a new theory believing that it answers better than others the etiological and pathological questions and has the merit so far as treatment is concerned, of meeting the requirements in relieving many of its most distressing symptoms in the greater number of cases, and in many apparently restoring them to ordinary health.

In the light of my clinical experience during the past four years, I am firmly of the opinion that the dystrophic changes that occur in the neurones of the posterior roots and their connections in tabes are the result of continuous sensory impulses conveyed from some peripheral point to the sensory roots in the cord.

That such continuous impulses, kept up perhaps for years, exhaust the central nerve substance, which, having no rest or intermission from such impulses, and having no time or opportunity for recuperation, finally succumbs from exhaustion and takes on dystrophic degeneration. In other words, not a toxin, specific poison, strangulation, or bacillus, but a purely physical cause. The best of batteries by constant use without replenishing becomes useless; then why not that most wonderful battery in existence, the cerebrospinal system?

The changes found in situations other than the cerebrospinal, such as the sympathetic and peripheral nerves, are probably due to the force of the sensory impulse passing on through their spinal connections, and expending their force at the points of least resistance; as for example, their terminations in the skin and muscles, and in the ganglia of the sympathetic.

I think this theory of damage done at the most vulnerable point well illustrated while the impulse is still in the direct line, in first destroying the neurone where it has lost its neuroglia in the posterior roots—at the "ring of Obersteiner."

This would account for the "tabetic degeneration being selective in character, unlike the Wallerian which affects all tissues indiscriminately, attacking in succession fibers and tracts of perhaps different function significance."

Since formulating this theory four years ago I have learned that Prof. Mathews, formerly of University of Chicago, at present of the Leland-Stanford, has made observations that may explain the manner in which the dystrophy takes place, and it certainly accords with the present theory. It is known that the conducting nerve substance or neurone is a very simple tissue, almost protoplasmic, being little more than highly phosphorized fats in a weak saline solution. In other words, this portion of the nerves consists of colloid particles in suspension. Prof. Mathews found that when a nerve is stimulated electrically the colloid particles of these fats are precipitated, and that coagulation to a certain extent takes place.

It has also been proven (Howell's Physiology) that the effect of fatigue (either natural or artificial through electrical stimulation) is shown by histological changes, characterized by shrinkage of the nerve cell. In the resting condition these cells are turgid with large round nuclei, whereas fatigued cells are vacuolated and shrunken, with corresponding changes in the nuclei. It has been found that the amount of shrinkage increases in geometrical ratio to the length of time during which the stimulus has been allowed to act. This would seem additional evidence that nerve impulses can, as the result of incessant irritation, produce the change I claim takes place.

A new point of view for the origin of nervous diseases was brought out by Cornelius (*Aerztliche Sachverständigenzeitung* No. 20, 1906), who assumes the existence of an independent circulation in the nervous system analogous to the circulation of the blood. The causes of nervous disease are referred to (1) the pathological irritability of the nervous system due either to heredity, or to increased stimuli affecting the body (overexertion, exposure, disease); (2) some obstruction of the free nerve current, all stimuli which affect the body being received and transmitted in such a way that there is no rest for the center.

According to the views advanced by Edinger (*Med. Klinik*, No. 28, 1908) the fatigue or exhaustion induced by overwork of a healthy nerve, or simple use of a poisoned or degenerating nerve, may never be recovered from, so that the outcome is paralysis and atrophy.

Syphilis is no doubt a prime factor in tabes, but only so far, probably, as it is responsible for a tissue condition necessary to render such tissue more susceptible to the continuous sensory explosions or impulses. Whether all cases of tabes have a prior syphilitic history is a question beyond the scope of the present paper to discuss; it is certain that other causes that have been supposed to be direct factors in the etiology of tabes, such as exposure to cold, overexertion, alcoholism, are only, in so far as they lower the resisting power of the system in general, and the nervous centers in particular. Sexual excesses, I think, have a direct bearing where the irritation is in the genital tract, by aggravating and perpetuating the points of irritation.

In the present paper we will only recite cases where such irritation was found in the male urethra and bladder, although it is known that other points in the body may be the seat of the initial irritation; notably the urethra, bladder, and uterus and appendices in the female, and the rectum in both sexes. Eyestrain and intestinal putrefaction have been thought of as possible factors in aggravating the condition when peripheral irritation already exists.

Since reading the announcement of my theory before this academy last year, I have reason to expect that it may explain the etiology of other nervous diseases of unknown origin, and possibly general paralysis and taboparalysis which Fournier, Mott, and many other neuropathologists of the present day believe have an essential pathological identity with tabes. In Ferrier's* opinion "these are merely different aspects of the same polymorphic disease, and that the morbid process underlying both is identical."

The physiological pathology of tabes whereby we would attempt to refer each symptom of the disease with its organic base, is so vast a subject that only a word is possible at this time, in so far as it attacks the cord.

"From these posterior roots are given off the variously named tracts that constitute one continuous system of descending commissural fibers receiving and giving off fibers at different levels of the gray matter, and connecting together the various segments, as well as the upper and lower spinal centers with each other. The change that takes

*I wish here to express to Dr. Ferrier my thanks and obligations to him for the liberal use I have made of his Lumleian Lectures.

place in the roots, according to most recent research, is a progressive dystrophy or demyelization and ultimate destruction of the nerve fibers. The myelin sheath breaks up, becomes granular, and finally disappears; a proliferation of the neuroglia network occurs only in proportion to the atrophy of the nerve tissue proper. These changes are, as a rule, most pronounced in the lumbar and lower dorsal regions which contain the long fibers from the lumbosacral regions in their course up to the nuclei gracilis of the medulla oblongata."

In the following cases the peripheral irritation was found to be situated in the urethra and bladder, and the lesions found varied from slight local to general irritability, with erosions, with and without contractions and from simple irritation of the bladder to a chronic cystitis with or without incontinence of urine and faces or both. In each case as far as possible all the resources of surgery were brought to bear changing it from time to time in each case as seemed best to suit individual requirements. No hard-and-fast rules can be laid down nor are they necessary to the skilled surgeon. A careful and definite diagnosis must be made of the condition of the urinary tract, and an equally careful aseptic course of treatment carried out until it is put into as nearly a normal condition as possible. A word of warning may be permitted when the deep urethra and bladder are to be invaded even for examination, not only on account of the well known danger of infection and shock, but from the knowledge the writer has that cases of tabes have a special sensibility to the slightest access of irritation, at this point. I would state that the line between relieving and producing still more irritation is a narrow one, and that careless manipulation would probably be followed by an aggravation of symptoms, probable precipitation of crises in cases where they have occurred before, and the possibility of an even more embarrassing situation, rather than cause for mutual congratulation. This special sensibility of these patients to the slightest access of irritation, leads me to incline more strongly if possible to the belief that this method of treating tabes is correct in those cases where the source of irritation is found to be in the male bladder and urethra. The importance of urinary analysis before commencing treatment to determine more particularly whether renal disease or diabetes is present, will be appreciated. The lesions most generally found are erosions which have probably existed for years, and which by producing continuous irritation, keep up such a constant succession of sensory nerve impulses as to cause the dystrophy found in the posterior roots of the cord. It is thought that these erosions are a peculiarly offending factor; they are best treated locally per urethroscope.

During 1905-6, some ten cases were treated successfully. They all had characteristic symptoms of tabes. The gait was affected, from a slight ataxia and staggering to utter helplessness and inability to stand. In nearly all the cases there was incontinence of urine besides pain; all had loss of knee reflex and Argyll-Robertson pupils. All recovered from the incontinence, and their pains were relieved; two helpless ones were able to walk again with the aid of a cane, while others practically recovered a fairly normal gait. The helpless had only been so for less than three months.

Although three and four years have now elapsed since these patients have received any treatment, there have been but two instances where there has been any relapse, and this only in the gait; not in general condition or any other symptom although incontinence of urine existed. Both these patients had but a short course of treatment followed by neglect on their part.

As in those cases the diagnoses had not been verified authoritatively at the time, and as it has been doubted whether the cases in which I have had success were tabes, I prefer to give only the histories of the following, they having come to me with an authoritative diagnosis.

Case I.—H. B. Feb. 27, 1907. Male, age 47. Duration of disease seven years, syphilis sixteen years ago. Weight 102 pounds; general condition very low. Gait fully 50 per cent. off normal; Romberg and Westphal symptoms present, also Argyll-Robertson pupils; frequent gastric crises. Has severe pains, also girdle sign. Has analgesia and anesthesia, and incontinence of urine day and night. Examination revealed erosions in middle third of urethra. These were treated per urethroscope during seven months when all symptoms disappeared, patient walking normally and weighing 138 pounds. A gain of 36 pounds. Can walk in dark. He has not had treatment for over a year and a half, has gained in every way, and is about to resume his work as an actor. He came to me from the Incurable Hospital at Fordham, earlier was in the New York Hospital, suffering from gastric crises. I saw him first at his rooms, he being too weak to go out.

Case II.—L. S. April 19, 1907. Male, age 40. Duration of disease six years; no history of syphilis. Weight 145. General condition poor, unable to walk alone; Romberg, Westphal, and A.-R. symptoms present. Severe pains daily and nightly. Analgesia and anesthesia. Examination revealed erosions in middle and lower third of urethra. Treated with urethroscope three months. When he could walk alone and pains had ceased, this patient went away and has neglected treatment for a year and a half but has not relapsed.

Case III.—J. M. Nov. 25, 1907. Male, age 49. Duration five years; no history of syphilis. Weight 148. General condition poor; gait 50 per cent. off. Stumbles and has fallen. Romberg, Westphal, and A.-R. present; girdle pain; frequent and severe pains in legs and heels; severe, intestinal pain constant. Hyperesthesia intense over body; unable to bathe. Examination revealed middle third urethra erosions and sensitiveness. Treatment local for three months, when gait became nearly normal. All pain gone; incontinence of urine stopped, gained ten pounds in weight, bathes with comfort. Since March there has been continued general improvement; can walk in dark. Although he has not had any treatment for eight months he has been travelling alone extensively, and is at present carrying on a high pressure campaign.

Case IV.—P. K. Nov. 25, 1907. Male, age 45. Duration one year; syphilis sixteen years ago. Weight 158. General condition very bad; unable to walk alone. Romberg, Westphal, and A.-R. present; severe pains almost daily; but little sleep at night. Micturates every hour with great pain; has been told he could live but a short time. Examination—Middle third of urethra sensitive, slightly contracted, and erosions. Treated locally during four months and contraction dilated. Incontinence and frequent micturition stopped; no more pain; gait almost normal; can walk in dark. Weighs 180 pounds, gained 22 pounds and works hard all day. No treatment since April; no relapse.

Case V.—J. G. Dec. 23, 1907. Male, age 43. Duration of disease one and one-half year; no history of syphilis. Weight 165. General condition

good. Gait is off normal fully one-half. Romberg, Westphal, and Argyll-Robertson signs present. Pain moderate at night; tires easily when walking. Examination—Erosions at three one-half inches, otherwise normal. Treated by urethroscope until Aug. 1; gait improved. Sept. 28 returned after two months' vacation with marked improvement in gait, no pain, and able to walk during ordinary occupations without fatigue.

Case VI.—H. P. Dec. 26, 1907. Male, age 50. Duration six years. General condition poor; gait about 50 per cent. off; uses cane. Romberg, Westphal, and A.-R. Severe pain every two or three days; girdle and chest constriction. General anesthesia and analgesia. Micturition very difficult. Unable to walk without cane. Examination—Lower third of urethra erosions. Treatment local during four months. All pains stopped; can walk without cane; general condition good; micturition free. No relapse during five months.

Case VII.—W. L. Jan. 9, 1908. Male, age 51. Duration ten months. Syphilis twenty-five years ago. Weight 136. General condition very poor; Westphal, A.-R. pupil right eye, left injured. Absolutely helpless, carried in to me; cannot move hand nor foot. Intense hyperesthesia and pain in head and face, also some general pains. Incontinence of urine and constipation. On March 23, 1907, this patient was struck by a street car, after which all his present symptoms developed rapidly. Prior to this he was apparently well. This was a case where possibly all the factors were present for the development of tabes, but the cord was able to resist until a great shock put it below par; a similar case was treated in 1905 when rapid development of tabetic symptoms followed within six months after the patient was knocked down by an omnibus, and he as quickly recovered upon removal of the irritation. On examination erosions found in middle third of urethra, with slight contraction of anterior portion. For erosions local treatment per urethroscope carried out for four months; contraction cut. Very early in treatment all pain, and hyperesthesia of head and face, and incontinence of urine stopped. He was able in a month to sit at table with his family, and while lying down or in sitting position to move all his limbs and take all kinds of exercises. Bowels regular. He has had no treatment now for three months; during that time has steadily gained in strength, general health, agility, and weight—148, 12 pounds gain. One thing he cannot do, that is, stand alone or walk. It has been noticed in another case of rapid development—when the patient like this one has remained in bed or in a chair for three months, the ability to walk was not recovered. Whereas in two cases when helplessness had existed less than two months, the gait was recovered. What is lost by this short time of disuse we do not know, when in a case of ten years' duration, five of which had been spent in bed in a helpless condition, the ability to walk, with the aid of an assistant, was recovered in two months.

Case VIII.—F. T. Feb. 8, 1908. Male, age 49. Duration ten years. Syphilis fifteen years ago. Weight 117. General condition poor, practically carried in between two attendants, and helpless since October 30, 1907. Westphal and A.-R. present. Incontinence of urine for six years, incontinence of feces when bowels loose. Anesthesia and analgesia. Examination—Middle third of urethra was found contracted, also erosions. Treatment of erosions local for about three months, with dilation of contraction. Patient could soon walk, with aid of an attendant's arm, a half mile daily. Incontinence of urine and feces stopped. Patient is still doing well. Weight 124; gain of 7 pounds.

Case IX.—J. L. Feb. 21, 1908. Male, age 41. Duration eight or nine years. Syphilitic history not obtainable. Weight 140. General condition wretched; weak and unable to walk over a block without great fatigue. Romberg and Westphal present. Pupils slow. Principal complaint severe pain in abdomen; hyperesthesia abdomen and back. Has been operated on three times for gallstones and appendicitis; no lesions found at either time. Examination—Anterior two-thirds of urethra contraction and erosions. Treatment for erosions, contractions cut and dilated to normal, local only, during four months with great improvement in general health and relief of abdominal pains. Can walk without fatigue whenever he is obliged to in pursuit of his work. No relapse in last three months.

Through the courtesy of Dr. Starr, the following eight cases were sent me from the Vanderbilt Clinic, College of Physicians and Surgeons. Dr. Cunningham made the diagnosis when sent, and Drs. Starr and Cunningham verified the results as given here on September 23, 1908.

Case X.—C. F. A. June 17, 1908. Age 39. Duration ten months; no history of syphilis obtainable. Weight 164. General condition fair. Can only walk with assistance. Pain intense and frequent, lasting from one to three days; Romberg, Westphal, and A.-R. present. Both legs anesthetic and analgesic; incontinence of urine and feces. Examination—Upper and lower third urethra contracted and erosions. Treated locally during three months, upper contraction cut, lower one dilated. Patient could soon walk alone with ease. Pains ceased; return of sensation to legs; incontinence of urine and feces stopped. General health much improved.

Case XI.—W. S. June 26, 1908. Age 44. Duration two years. No history of syphilis obtainable. Gait ataxic; pain almost daily. Romberg, Westphal, and A.-R. present. Incontinence of feces and diarrhea; has eight or ten movements a day. Examination showed lower half of urethra contracted and erosions. Treated locally for three months; contraction dilated. Almost immediately after treatment commenced, the incontinence of feces stopped and the bowels moved with normal formation morning and night. Gait nearly normal, and he resumed his occupation of cook on a steamboat. Pain ceased.

Case XII.—E. M. July 15, 1908. Age 38. Duration two years; syphilitic history. Weight 125. General condition fair. Can just manage to get about with aid of two canes; no pain since last winter except girdle. Romberg, Westphal, and A.-R. present. Incontinence of urine for a year and a half; constipation. Examination—Middle third contracted and erosions. Treatment same for two and a half months past. Incontinence of urine stopped; bowels regular. Gait so much improved that with the aid of one cane he gets about for from six to eight hours a day canvassing.

Case XIII.—J. L. June 17, 1908. Age 46. Duration four years. Weight 150. Syphilitic history. Gait ataxic and stumbles; pain very severe almost daily; Romberg, Westphal, and A.-R. pupil present. General hyperesthesia over trunk; unable to go into water for ten years. Examination—Slight erosion middle third urethra. Treated locally three months. Gait practically normal, can walk in dark. Pains ceased; sensation over trunk normal; has been swimming during summer.

Case XIV.—G. A. June 17, 1908. Age 42. Duration six years. Weight 131. No history of syphilis obtainable. Gait ataxic; cannot attend to his work as waiter; pains very severe two or three times a week. Romberg, Westphal, and A.-R. present; incontinence of urine. Examination—Whole urethra sensitive: first third contracted and lower third erosions. Treated locally during three months and contraction cut. Pains relieved. For past two months has been able to resume his occupation as waiter. Incontinence of urine stopped; gait nearly normal. This patient did not report for examination by Dr. Starr.

Case XV.—T. O'R. Aug. 2, 1908. Age 44. Duration of disease seven years. Weight 144. General condition fair. Gait ataxic; Romberg, Westphal, and A.-R. present. Pain severe two or three times a week. Incontinence of urine and feces and constant diarrhea. Examination—Lower half of urethra sensitive and erosions. Treated locally. Early in treatment incontinence of urine and feces stopped; stools became normal, moving once or twice a day, and pain is relieved. Gait much improved.

Case XVI.—H. F. Aug. 2. 1908. Age 42. Duration of disease nine years. No syphilitic history obtainable. Weight 124. General condition poor. Using cane for six months; much difficulty in walking. Pain very severe, sometimes lasting two weeks; Romberg, Westphal, and A.-R. present. Incontinence of urine, also feces after taking cathartics. Examination—Contraction anterior urethra, also in lower half with erosions. Treated locally for two months; anterior contractions cut, lower dilated; incontinence of urine and feces stopped; pain relieved and gait improved.

Case XVII.—C. A. Aug. 10, 1908. Age 37. Duration three years. Gait good but staggers in dark. Romberg slight, Westphal and A.-R. present, with right ptosis and paralysis of internal rectus. For three years has had gastric crises twice a month, lasting from three to seven days. Examination—Slight erosion and contraction in middle third of urethra. Treated locally and dilated for six weeks. Ptosis relieved, internal rectus acts, and no gastric crises has occurred since commencing treatment. Can now walk in the dark.

From present experience it is thought that the following conclusions may be safely advanced.

(1) That peripheral irritation can produce pathological change in the central nervous system by creating continuous nerve impulses which exhaust the substance of its nerve centers.

(2) That the peripheral nerve degenerations of tabes are probably due to the same impulses carried on past the central system expending its force upon the points of greatest vulnerability or least resistance.

(3) That symptoms occur in certain cases of tabes with a severity out of all proportion to the actual pathological change that has taken place in the nerve centers, and that such symptoms are caused by the initial change creating a zone or aura of irritability beyond such change which extends to the cerebrum, cerebellum, and sympathetic, and at times appears to cover almost the entire nervous system including that of nutrition.

(4) That removal of this causal irritation resulting in recovery from such grave symptoms, as loss of balance, ataxia, incontinence of urine and feces, anesthesia and hyperesthesia, etc., etc., would appear to indicate the existence of such zone of functional irritability beyond the actual pathological change.

The physiological pathology further than that merely touched upon here had of necessity to be reserved for a fuller paper which I trust to present at some future time. My opinion as to prognosis in the different stages of the disease in its relation to individual cases would also lead too far and be of more value with added experience.

My object will have been accomplished for the present if I have this evening said enough to attract the serious attention of the medical profession.

15 East Forty-eighth Street.

PANCREATITIS; WITH ILLUSTRATION OF CRYSTALS OF PANCREATIC REACTION, ACCORDING TO CAMMIDGE'S TEST.

By MILTON R. BARKER, M.S., M.D.,

CHICAGO.

The physiological anatomy of the pancreas is essentially the same as that of the salivary glands. It is made up of lobes, which are formed of lobules, which in turn are made up of alveoli. It has two excretory ducts, Wirsung and of Santorini, the most important of which is the former, which performs by far the largest part of the function of pancreatic excretion. The duct of Santorini usually joins the duct of Wirsung soon after their exit from the pancreas. The duct of Wirsung usually joins the common duct at the ampulla of Vater, where the bile and pancreatic secretions unite and flow together through the papilla into the duodenum.

The pancreas is liberally supplied with blood by branches of the splenic and pancreaticoduodenalis arteries, and its nerve supply is from the solar plexus. The head of the pancreas lies in the curve formed by the three divisions of the duodenum and is situated in the median line, an inch and a half above the umbilicus. The body extends to the left and is in relation with the first and second lumbar vertebræ; it terminates in the tail which is in relation with the hilum of the spleen.

The pancreas is not enveloped by a capsule, but is surrounded by loose areolar tissue, which dips between the lobules connecting them together.

The average weight of the pancreas is three and one-half ounces, the extreme weights being two and a half and six ounces.

It has been demonstrated by Mayo Robson of London and others that the ductus communis choledochus in 62 per cent. of cases traverses the head of the pancreas. It is an important discovery by reason of which we are able to classify and place in proper categories disease symptoms that were before misunderstood and erroneously interpreted.

The pancreas normally secretes from thirty-five to thirty-seven grams for each kilogram of body weight every twenty-four hours (Bidder and Ochnidt), or approximately one and one-fourth ounces for every two and one-fifth pounds of the body weight daily. In other words, the pancreas secretes seventy-three ounces for every one-hundred and sixty pounds of body weight daily, or an amount not varying greatly in quantity from the amount of bile secreted by the liver during the same time.

The pancreatic secretion and bile, aided by the various intestinal secretions, are sufficiently potent to perform all digestive functions, the secretions from the stomach and salivary glands being eliminated. The reverse of this, however, is not true; but with the addition of the bile the stomach secretions and saliva are much enhanced in digestive

power, and the system could be maintained in a fairly healthful condition for a long period of time with the pancreatic secretion eliminated from the digestive process, provided the system could be safeguarded from the pernicious effects of this secre-

Fig. 1.

tion, when diverted from its natural channels and function.

In all cases of chronic pancreatitis the head of the organ is first involved, and in a large proportion of these cases the inflammation does not extend beyond this, hence the secreting power of the larger portion of the gland is not disturbed. It is probable the diseased portion also secretes in a measure, but the secretion is not that of the normal gland, hence is itself abnormal.

In all types of pancreatic inflammation two conditions universally prevail, the gland, or that portion of it involved, becomes swollen and its excretory ducts become in a measure occluded, and in 62 per cent. of all cases, according to the discovery of Mayo Robson and others, the ductus communis choledochus is also more or less occluded.

When pancreatitis prevails the disturbances wrought in the digestive process are more or less grave, according to the degree of occlusion of these ducts.

If such large quantities of bile and pancreatic secretion are necessary to maintain a perfect digestive process, any marked reduction of them must interfere with that process, and in a like degree bring disaster to the general system. Pancreatitis, therefore, may, by pressure upon the bile and pancreatic ducts, cause any degree of digestive troubles, and corresponding degrees of trouble to the general system. If the occlusion of these ducts is total, the destruction of the general system must be rapidly inevitable from digestive disturbances alone. But the digestive disturbances caused by the occlusion of these ducts in pancreatitis is not the only, and probably not the most grave, condition that is produced by this misfortune. According to the degree of occlusion of the common duct, in 62 per cent. of all cases the bile is dammed back into the liver and taken up by the lymphatics and emptied into the blood stream, and in all cases, according to the degree of occlusion, the pancreatic secretion, which is always more or less diseased, is dammed back into the pancreas and is taken up by the lymphatics and also poured into the blood.

Just what effect upon the blood this invasion of it by these combined foreign substances has we do not know, but we do know that the general system suffers more and more as these secretions are increasingly withheld from their digestive function and poured into the blood, and that in cases where complete occlusion occurs and the blood receives the total bile and pancreatic secretions, the patient soon succumbs to the profound conditions thus produced. Thus the general system suffers, when chronic pancreatitis prevails, both from digestive disturbances and from conditions due to blood contamination.

We believe that it is not frequent in chronic pancreatitis that total occlusion of the common duct takes place, even in the 62 per cent. of cases in which this duct traverses the head of the pancreas, neither do we believe that total occlusion of the duct of Wirsung occurs frequently in this condition. We seldom meet in chronic pancreatitis such profound conditions as follow the total occlusion of both of these ducts at the same time. It is also true that this unfortunate condition does occur, and is liable to occur in any case.

In the 38 per cent. of cases in which the common duct does not traverse the head of the pancreas, bile may or may not be dammed back into the liver. This depends upon whether or not the bile ducts are the source of the infection. If they are not, and if the infection has invaded the pancreas from some other focus, the common duct not being involved, bile will flow normally into the duodenum. In such cases the location of the common duct is most fortunate, but in cases where the pancreas has become secondarily involved from the common duct, which is true in a large majority of cases, there is always some degree of occlusion of the common duct, either produced by gall-stones, or narrowing of the lumen of the duct by a chronic cholangitis or the partial closing of the papilla by disease of the duodenum. The degree of occlusion in these cases may vary as much as in those cases in which the occlusion is due to pressure by the enlarged head of the pancreas. In such cases the system profits little by the more fortunate location of the common duct.

From a surgical standpoint, the joining of the common and pancreatic ducts is an unfortunate ar-

Fig. 2.

rangement. In the acute or fulminating form of pancreatitis the whole gland is involved from the first. The whole organ becomes enlarged and is infiltrated with the round cells and other products of inflammation. In this condition all of the pancre-

atic secretion is abnormal, being produced, as it is, by a totally diseased gland. We don't know how restricted or free the secretion may be in these cases, but, be it little or much, it is totally diseased. In this form of pancreatitis the secretion is not taken up

Fig. 3.

by the lymphatics of the pancreas (at least not all of it) and carried into the blood, probably because of the involvement of these organs in the diseased process. That the glands of the pancreas functionate, and that their products are not carried off by its lymphatics, is proved by the presence of pancreatis secretion, found free, in the retroperitoneal tissues, in operative cases, in contact with the adipose of this tissue as well as that of the omentum and mesentery. We know the pancreas is not enveloped by a capsule, but surrounded by loose areolar tissue. In acute pancreatitis its secretion is poured out, but cannot escape by the natural channel, neither can it be carried off by its own lymphatics, hence it escapes into the areolar tissue between the lobules, and from thence into the retroperitoneal spaces where it comes in contact with the adipose tissue of this part.

Fat necrosis is the most peculiar phenomenon accompanying acute pancreatitis. As above stated, a diseased gland produces a diseased secretion. In these cases the diseased secretion from the diseased pancreas coming in contact with the adipose tissue produces fat necrosis. What peculiar element may be present in this diseased secretion that produces its peculiar action on adipose, but is harmless to other tissues, we do not know, but we believe the fat necrosis prevalent in this disease is rationally accounted for in this manner.

Acute pancreatitis is characterized by a sudden onset, excrutiating pain, and marked prostration. The bowels are usually constipated, and symptoms of intestinal stoppage prevail, though, as a rule, flatus is expelled per rectum, and is the best evidence, in the case, that we are not dealing with an ileus.

Chronic pancreatitis frequently during its course exhibits acute exacerbations which markedly simulate in symptomatology the acute disease, though frequently its manifestations are less pronounced. The manifestations of chronic pancreatitis, including its acute exacerbations, often closely simulate partial occlusion of the colon due to malignant disease. In two cases that have come under my personal observation the similarity to malignancy of the colon has been enhanced by bloody stools, and my diagnosis in these cases was held in abeyance until proctoscopic examinations were made of the rectum and sigmoid, though Cammidge's test was positive.

The prognosis of the acute form of the disease is grave, death frequently occurring in a few hours, especially if the hemorrhagic form develops. The tendency of the chronic form is never towards recovery, but constantly towards a worse condition.

We believe the dire effects of chronic pancreatitis upon the general system and its peculiar symptomatology are due only to a limited extent to the intrinsic condition of the gland itself, but to the more or less profound conditions produced upon the digestive system by depriving it of its essential fluids, and the grave conditions, simultaneously produced, by the emptying of these fluids into the blood stream. But in the acute or fulminating form of the disease, especially in hemorrhagic or suppurative cases, the intrinsic condition plays the major role in the destructive process.

The etiology of all forms of pancreatitis is infection, which in most cases is acquired from infected gallducts, and which is superinduced, in a large proportion of cases, by gallstones, though in some cases, rarely, I believe, the infection of the common duct may be acquired from a diseased duodenum.

The differential diagnosis of either the acute or chronic form of the disease is difficult without the aid of laboratory procedures. A certain group of symptoms, to which we have alluded, should, however, arouse our suspicions, and a sample of urine, of a pint or more, should be sent to a laboratory and Cammidge's test made for the crystals of pancreatic reaction. We do not mean by this any laboratory will do, we mean a laboratory adequately equipped, in which persons skilled in making chamical analyses will do the work. I have long since ceased to trust myself, or internes in a hospital, with complex chemical analyses, upon which I must base in a large degree an important diagnosis. Such analyses should be made by those who have all needed appliances, and who have extraordinary skill by reason of constant experience. In such a labora-

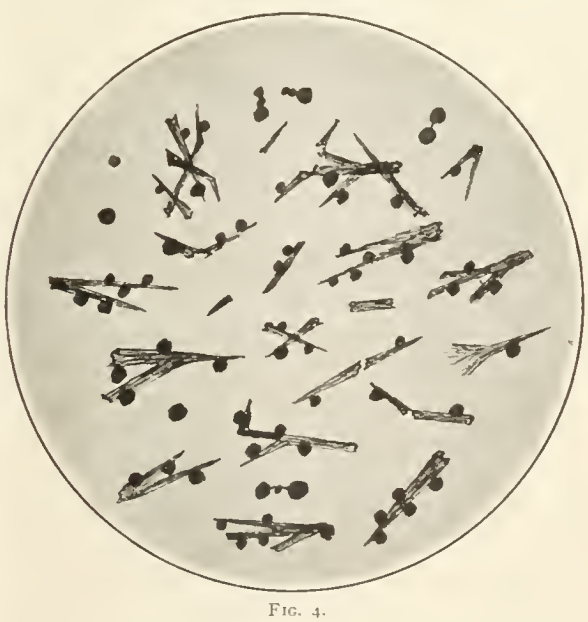

Fig. 4.

tory Cammidge's test may be made, and the result relied upon. If the crystals of pancreatic reaction are found, a positive diagnosis of pancreatitis may be made; if not, such diagnosis must be rejected. In my experience Cammidge's test is one of the most

valuable diagnostic measures ever promulgated. We must, however, recognize the fact that this test does not differentiate between the different forms of inflammation that may invade the pancreas. In other words, the crystals of pancreatic reaction are present in malignant disease as well as in infections. Hence from this test alone we cannot differentiate cancer from the common infections, or acute from chronic conditions.

We have attempted in the accompanying illustrations to illustrate the crystals of pancreatic reaction according to Cammidge's test. The crystals are bright yellow in color, sheaf-like in form, and covered more or less thickly with small bright red spheres which vary in size. The crystals are fragile, and when carried in a bottle or otherwise, unless with great care, break in small fragments. These drawings are made from different fields of a twelfth power lens, and are about one-half larger than they appear under the lens. Figs. 1, 2 and 3 represent fairly well the perfect crystals. Fig. 4 represents a large number of microscopic fields, and shows fragments of crystals.

The aim of treatment in all cases of pancreatitis is to undo that which disease has done, by restoring as far as possible the pancreatic and biliary secretions to their normal functions as digestive fluids, and preventing as far as possible the drainage of the pancreas and liver into the blood. Whenever systemic and local conditions are such as to make us suspicious of pancreatitis, and Cammidge's test is positive, we should not hesitate to advise operative measures as the best procedure in the case.

Our object should be to increase as far as possible the excretion of bile and pancreatic secretion through their natural channels. This is best accomplished by removing all gallstones and débris from the gall-bladder and gallducts and by dilating the common duct and papilla by the passing of proper instruments through them into the duodenum. A complemental drainage should also be established, by doing a cholecystoduodenostomy. This is the plan recommended by Mayo Robson. By this maneuver drainage for both bile and pancreatic secretions is afforded through the cystic duct and gall-bladder into the duodenum. Thus the bile is at once restored to its proper function, and at once the blood is relieved from its vicious effects. The operation also affords a better drainage for the diseased pancreas, by enlarging and clearing its natural outlet, and giving it two avenues for drainage instead of one. If for any reason the above cannot be done, external drainage of the biliary and pancreatic ducts through the gall-bladder should be maintained for a considerable time. Chronic pancreatitis entails a long and painful invalidism, but seldom of itself terminates life. It, however, so enfeebles the system that it becomes an easy prey for acute conditions of every nature, and life is usually terminated by some of these.

Case I. Mrs. H., aged 50 years. I saw this case first in the fall of '07. Clinical history covers ten years. At first it was that of gallstones. The first year she had three well defined attacks of hepatic colic without jaundice. During the next five years these attacks were more frequent, varied in severity, and were sometimes followed by slight jaundice. During the last four years she has been an invalid, though at times able to perform some of her duties, both household and social. A slight jaundice has prevailed most of the time, and marked constipation has been the rule. Her invalidism has been characterized by marked exacerbations, during which pains of a severe colicky nature, at first appearing in different parts of the abdomen, but later centering in the umbilical region. At these times a stubborn constipation prevailed for several days, in spite of every effort to produce evacuations; gas, however, escaped per rectum frequently. She had during these attacks typical "subjective intestinal stiffening," described by Willy Meyer of New York as a characteristic symptom of cancer of the colon. During the subsidence of these attacks the stools were, as a rule, more or less bloody. The proctoscope did not reveal a diseased condition of the rectum or sigmoid, and a tumor could not be palpated. Emaciation was slight. Nausea usually prevailed during the exacerbations, but seldom vomiting. The loss of strength and energy were marked at all times, and insomnia was the rule. Cammidge's test was positive. A diagnosis was made of chronic pancreatitis due to infection from the gallducts, superinduced by gallstones. Operation was advised and accepted. Several gallstones were removed from the gall-bladder. The cystic common duct and papilla were dilated, and cholecystoduodenostomy was performed. The systemic condition due to contamination of the blood at once improved, and the digestive troubles rapidly disappeared. The patient is now, May 1, 1908, symptomatically well. A second Cammidge's test has not been made.

Case II. Mr. P., aged 57 years. The clinical history in this case extends over three years. The primary attack was typical of gallstones. The patient, however, did not fully recover his normal condition after this attack, and never had another attack like it. Six months later he developed an irregularly intermitting type of fever which continued for two months. During this fever he was jaundiced several times. He also became markedly emaciated. Recovery from this was tedious, but resulted in a fairly satisfactorily degree of health. This continued for only a short time, when he developed colicky pains throughout the abdomen, followed by marked jaundice. He was sometimes constipated, and at other times the stools were loose and pasty and accompanied with much flatus. Exacerbations were frequent, sometimes occurring once a week, but usually at longer intervals. At these times constipation was persistent, though flatus frequently was expelled. The pain during these exacerbations was always excruciating and centralized in the umbilical region a little to the left and below the umbilicus. Nausea and vomiting were never prominent in the case. Cammidge's test was positive. Operation was advised and accepted. Gallstones were not present. The gall-bladder was adherent to everything in the neighborhood. The head of the pancreas was enlarged, hard, and nodular. I believed we were dealing with a malignant condition. The common duct and papilla were searched and dilated. Cholecystoduodenostomy was done. Improvement was marked from the first, and at the end of six months complete recovery symptomatically was attained. This case teaches, among other things, that it is wise to give the patient the benefit of the doubt, when we believe we are dealing with cancer of the pancreas.

Case III. Mr. B., aged 78 years. Clinical history of ten years, the first five or six years of which are typical of gallstones, the patient recovering from each attack and remaining well until the next attack. Jaundice was never present during this gallstone period. Following this period the patient developed a typical cholecystitis, from which he never fully recovered. The primary attack lasted for three months, after which he slowly recovered a comfortable degree of health. Still at intervals he continued

to have attacks of chills and fever of an irregular type. I did not see the patient during this period, or for about eight years of his clinical history. When I was called into the case the patient was suffering with colicky pains, which were present most of the time, but had no special location except at the times of his spells, as he termed them. These spells were acute exacerbations of the disease and recurred about once a month, lasting two or three days at a time. At these times the pains centralized in the umbilical region to the left and a little below the umbilicus, and were excruciating. The bowels never moved during these attacks, regardless of any measures used; flatus passed freely. In the intervals the bowels were constipated, never loose nor pasty. Jaundice was never marked. The patient was seldom nauseated, and never vomited. Cammidge's test was positive. Because of the age and enfeebled condition of the patient operative measures were not advised. Salicylate of sodium in combination with other agents seemed most beneficial, and undoubtedly did produce a certain degree of well-being. The patient contracted a bronchial pneumonia, and because of his feeble condition succumbed to the disease.

Case IV. Mr. G., aged 70 years. The clinical history covers a period of twenty years, for the first fifteen years of which it was that of gallstones, cholecystitis, and chronic cholangitis. Five years ago pains of a colicky nature began in the abdomen without definite location; they were accompanied by the expulsion of large quantities of gas. The bowels were always constipated. Jaundice was never marked. The exacerbations were frequent, and the pains so excruciating that morphine was resorted to as a rule to give relief. A peculiarity of this case is the large quantity of gas that collects in the stomach during each exacerbation, and as quickly as relief from this accumulation is obtained the pains cease and the attack is at an end. The pain during these attacks always centralizes in the umbilical region and radiates towards the chest. These attacks last for several days. Nothing but gas passes the bowels during an attack. Food never distresses the patient. He is never nauseated, and has never been markedly jaundiced. The patient is greatly emaciated and quite feeble. He has come under my care within the last six weeks. Cammidge's test is positive. The enlarged head of the pancreas can be distinctly palpated in the median line an inch and a half above the umbilicus. The patient is too feeble for operative interference, and probably cannot be brought into such condition as to justify it.

4625 Greenwood Avenue.

THREE VERY UNUSUAL CASES OF APPENDICITIS.*

By C. W. TRUEHEART, M.D.,
GALVESTON, TEXAS.

At the repeated suggestions of professional colleagues, and believing the cases sufficiently interesting and instructive to justify their being put on record, I am moved to report three very peculiar cases of appendicitis. These cases were characterized by abnormality of location and strange behavior on the part of that anatomical abortion, that physiological enigma, that ubiquitous pathological pest of humanity—the appendix vermiformis.

Case I.—R. D. L., a healthy looking man of about forty-six years of age, gave an intelligent history of frequently recurring attacks of "partial obstruction of the bowels," as he called it; the fecal accumulation at times, so he stated, causing marked distention and tumefaction, especially on the right side of the abdomen. This condition was relieved only by repeated doses of some saline, pushed until watery evacuations were produced. Indeed the bowels never moved without recourse to salines. Marked dullness over the area of the appendix and ileum was present, with dull pain on deep pressure; but tension of the recti abdominis or tympanites was not appreciable. A diagnosis was made of chronic appendicitis.

In the operation, which was resorted to without delay, I was assisted by Dr. Cary H. Wilkinson of Galveston, and the then house staff of St. Mary's Infirmary. On opening the abdominal cavity a condition of things most difficult to trace out and accurately determine, presented itself. Through an opening, apparently a separation of the tissues in an imperfectly developed iliac mesentery, the unusually long appendix had, snake-like so to speak, crept behind the ileum, from right to left; then passing in front of the intestine, from left to right, its distal extremity was found firmly adherent to the parietal peritoneum in front of the right kidney. The condition of things present was evidently of long standing. The appendix and its mesentery had formed adhesions to everything within reach. These adhesions too were so highly organized that numerous ligatures (sterilized catgut) had to be applied to control hemorrhage. The separation of the adhesions and the disengagement of the coil of appendix from around the ligated and seriously occluded ileum close to its junction with the cecum, without rupture of the gut, proved tedious and difficult. The constriction and the adhesions, between the folds of mucous membrane on the inside and between the folds of serous membrane on the outside of the intestine, caused by the coil of appendix, were broken up and the lumen of the intestine restored with difficulty, and only by persistent external manipulations of the parts; the raw surfaces at the points where the adhesions to adjacent viscera were broken up were covered as well as possible with omentum. There being no pus formation present the abdomen was closed, the layer method being used. Healing by first intention was secured.

During the several weeks after the patient left the hospital and remained under observation, I was kept in continual apprehension on account of obstinate constipation and recurring pain and tenderness in the region of the operation, fearing lest postoperative ileus was developing. Some months later, however, I learned by letter that Mr. L. had made a fairly good recovery. It would, I take it, be difficult indeed even to conjecture what train or coincidence of forces and processes, pathological or otherwise, may have come into play to bring about such an anomalous state of things.

Case II.—In the person of Mrs. J. McY., a large, well nourished woman of fifty-eight years of age, weighing nearly two hundred pounds, by reason of an unusual development of adipose tissue in the abdominal wall, a positive diagnosis was possible only after an exploratory incision. Some jaundice and an enormous distention of the gall bladder being present, obstruction to the outflow of bile by an impacted gallstone was assumed, so I cut down upon the gallduct at once.

In the operation I was assisted by Dr. George H. Lee of Galveston, and the then resident staff of St. Mary's Infirmary. The first thing encountered on

*Read and discussed before the Galveston County Society and the Texas State Medical Association.

opening the abdominal cavity was the appendix. Passing across the ductus communis, to which it was matted down by adhesions, its distal extremity was firmly adherent to the under surface of the left lobe of a large liver, about two inches to the left of the mesial line.

Some ten or twelve ounces of normal bile having been removed from the gall-bladder by aspiration, careful palpation revealed the absence of calculus in duct or bladder, the obstruction of the duct being due entirely to the pressure of the matted down appendix. The adhesion of the appendix where it crossed the gallduct, and that to the under surface of the left lobe of the liver were carefully separated, and the abdominal incision extended downwards sufficiently to reach and deal with the appendix dix at its junction with the cecum. The appendix in this patient was estimated to measure ten to eleven inches; was unusually large, and from the point of adhesion to the gallduct to its union with the cecum, was perfectly normal and unusually large and patulous. The extensive abdominal incision was closed with chromicised catgut, continuous sutures, the layer method being used, and silkworm gut for closing the integumental incision. Convalescence was speedy and uneventful.

Now the question arises, how came the appendix to become adherent to the under surface of the left hepatic lobe? Probably the most plausible explanation is this: at that certain period of intrauterine development of the fetal alimentary canal, the intestines, so embryologists teach, shift over from the left to the right side in the abdominal cavity, and it must have been when this change of position was in progress that the adhensions between the appendix and liver occurred.

Case III.—In a married woman, D. N., of twenty-two years, a cystic ovary and large pus tube on the right side were diagnosed. A most striking symptom in this woman's case had existed for many months. While the first part of urination was free from pain, the latter part of the act was attended with most agonizing, sharp, lancinating, dragging pain on the right side, extending from above downwards and inwards and subsiding only when the involuntary tenesmic contractions of the bladder and bearing down ceased.

Assisted by Dr. Joseph Jones, of Galveston, and the other members of the then house staff of St. Mary's Infirmary, I made a free incision in the median line. The first thing encountered and anterior to everything else was the appendix; the distal extremity firmly adherent and matted down to the fundus of the urinary bladder, well to the front. The peculiar symptom alluded to was now unmistakably accounted for. The appendix was carefully separated from the bladder and abscised in the usual way. The very large pus tube and cystic ovary, the size of a large orange, on the right side were tied off and removed without escape of any of the contained pus. Now, a large encysted hematocele came into view and was dissected out; behind this, in Douglas' cul-de-sac, a collection of several ounces of bad-smelling pus was evacuated, the abscess mopped out with peroxide of hydrogen, etc., and free drainage through the vagina secured; the abdominal wound was packed with 5 per cent iodoform gauze and treated by the open method. The patient made an uneventful and complete recovery. Three-fourths of the left ovary was cut away on account of numerous small cysts; and nevertheless this woman menstruated normally and for many months while remaining under my observation following the operation.

An overdistended bladder pushed upwards, and pressed by a gravid uterus into contact with a displaced appendix, would account for the adhesions between the two viscera. The woman had been pregnant three years previously.

CLINICAL OBSERVATIONS ON MALARIA ON THE ISTHMUS OF PANAMA.

(PRELIMINARY NOTE.)

By W. E. DEEKS, M.A., M.D.,

CHIEF OF MEDICAL CLINIC, ANCON HOSPITAL, PANAMA.

Three and possibly four distinct types of malarial parasites are found on the Isthmus, although the quartan type is not endemic there. These types differ microscopically, in the development or not of crescents, in their life history, in their perniciousness, and in the course of the fever which they cause. One type apparently migrates into and out of the red blood corpuscles without causing their destruction. Most of the malaria is visceral in character and yields readily to the administration of quinine by mouth. Sometimes, however, the organism seems to localize, or, at any rate, to cause localization symptoms, particularly in the cerebral tissues. Some of the following cerebral symptoms have been observed: Sighing respiration, neuralgias (recurring and localizing), vertigo, mania, aphasia, hemiplegia, coma, etc. In some of the cerebral cases very few constitutional symptoms may be present.

The ordinary types usually yield readily to the administration of quinine by mouth in doses of from thirty to forty-five grains daily. In the cerebral types, however, quinine must be administered hypodermically. In these cases we give twenty grains every two hours until a total of sixty or eighty grains has been taken. The preparation is the hydrochlorate of quinine and urea for hypodermic purposes. If the circulation is extremely poor or great anemia is present abscesses will certainly follow, no matter how much care is used in its administration. When such large doses are indicated it is best to give either strychnine or whisky to mitigate the depressing action of the quinine.

The most common and important complication of malaria is the post febrile toxemia which occurs often in comparatively mild cases. During a malarial attack probably forty per cent. of the cases develop a more or less severe albuminuria. Usually this subsides with the fever and the patient enters on a speedy convalescence. Sometimes, however, it proves rapidly fatal, death occurring in from three to eight days. Postmortem, these cases show microscopically diffuse degenerative nephritis, parenchymatous degeneration of all viscera, sometimes ecchymotic hemorrhages into the serous membranes, and occasionally terminal bronchopneumonia. If death does not occur, the acute nephritic condition passes gradually into a form of chronic interstitial nephritis with all its clinical manifestations. The development of this acute toxemia may usually be detected clinically not only by the nephritic symptoms, but also by the presence of a pulse of extremely low tension. The acute nephritis is not accompanied by edema. Anorexia and intense weakness also usually characterize the toxemic conditions, and occasionally a severe enterocolitis is the terminal manifestation. Malarial toxemia seems to be much more common in the colored than in the white patients. Malarial organisms have not been found in the blood when a leucocytosis of fifteen thousand or over has been present.

Medical Record.

PROFESSIONAL INTOLERANCE.

One of the most frequent accusations brought against the medical profession to-day is that it is illiberal, opposed to progress, and intolerant of any doctrine that is not in harmony with the prevailing fashion of medical thought. In view of the revolutionary changes that have taken place in the last thirty years, of the entire recasting, indeed, of medical and surgical practice following upon the discovery of the microbic origin of infectious diseases, such a charge seems ill-founded enough, yet there is truth in it. The profession is often intolerant of novelty, even cruelly so, and men have died of broken hearts in consequence of the ridicule and abuse heaped upon them by their fellows for their advocacy of theories which are now taught as axioms in every medical school in the world. Semmelweiss was killed by the revilings of his colleagues because he dared to make the outrageous assertion that puerperal fever was a filth disease. Oliver Wendell Holmes was held up to the scorn of the profession by the leading obstetricians of the country for advancing the same heretical idea. He did not die under the abuse, for his sense of humor saved him, and he lived to see the general acceptance of the truth he had preached. But he was potentially a victim as much as Semmelweiss to professional conservatism; both were martyrs to the truth because they were before their time. Their professional brethren were not to blame, they acted only as men of strong convictions would inevitably act in opposition to the subversive doctrines of daring innovators.

The mind of the profession must of necessity be conservative and illiberal, and it is well that it is so. However much injustice it may work in individual cases, the science of medicine profits in the end through this opposition to innovations. In the long run truth prevails, but it must prove first that it is truth. At the beginning truth and error look alike, and the natural presumption is that anything which is opposed to the general consensus of medical opinion is erroneous. As Dr. Morris said in a recent letter in these columns, "Most new ideas are batted down, and they belong down." If they are true they may stay down for a time, but not for all time.

Accepted medical opinion has an authority which cannot be overthrown at will by the individual. If this individual believes that the existing opinion is erroneous he can oppose it, but he must be prepared for opposition and must sustain his thesis in the field of debate. He must be prepared, too, for martyrdom. We may apply to medicine what Mrs. Wilfrid Ward, in her interesting novel "Out of Due Time," says of Modernism in its relation to the existing theology. "I don't think," says one of her characters, "only that there would be danger of tyranny . . . if the many always adopted the guidance of the intellectual men of the moment, but I think it is actually in the interests of thought in the long run that they should act as a drag upon progress. . . . I think this difference in pace is in the nature of things, because the men of action have a true instinct that mankind to decide truly must decide slowly, and I believe that those men of thought who are before their time must of necessity suffer, and suffer very much."

Were it not for this natural ballast, this opposition to novelty, inherent in the medical profession as well as in the Church, all would be chaos, there would be no stability and no tradition, and we should be tossed about by every wind of doctrine, the dupes of every silver-tongued charlatan. As it is, all alike are distrusted—the adventurer and the true investigator. If a man with a new idea is given the opportunity to lay this idea before the profession it is all that he can ask. He will have a united profession against him and it may overwhelm him for a time; it will prove his theory and will prove him, and if either rings false it will be cast aside; if both are true one at least will in the end prevail; the man may go down, but the truth which he proclaimed will live and will become an integral part of medical science. If the truth lives, what matters it to science that its discoverer perishes? Science is impersonal and cares naught for individuals.

DECOMPRESSION IN UREMIA.

The clinical phenomena of uremia are usually explained by the supposition that some harmful products of metabolism are retained in the body because of the failing function of the kidneys or that abnormal poisons are formed, either condition leading to the appearance of a toxemia. The fact, however, that mere suppression of urine does not lead to the appearance of any uremic symptoms militates somewhat against the above view and the older hypothesis of Traube, who assumed the cause of uremic phenomena to be edema of the brain, receives a great deal of support from this observation. Edema of the brain, moreover, is a condition that can be fairly successfully combated by such modern therapeutic measures as lumbar puncture or a decompression operation, the results of which have proved to be quite favorable in other intracranial conditions, such as tumor, accompanied by an abnormal accumulation of fluid about and within the brain. Such an operation for the relief of uremic symptoms is described by Drs. Cushing and Bordley in the *American Journal of the Medical Sciences* for October, 1908. Their patient suffered from the usual symptoms of uremia occurring in the course of a chronic nephritis, the existence of increased intracranial pressure being evidenced by the condition of the eyes. A decompression operation performed by Dr. Cushing led to a steady improvement in both the condition of the eye grounds and the general health of the patient, although the renal condition

was of course unaffected by the operation. The patient was improved sufficiently to leave the hospital a few weeks after the operation; she returned, however, two weeks later, this time in a comatose condition which could not be relieved by lumbar puncture or any other measures; the autopsy which followed her death in this attack disclosed the fact that a cerebral hemorrhage had occurred.

Cushing's experience in this case is supported by the results of an operation mentioned by Byrom Bramwell which was performed on a patient in whom cerebral abscess or tumor was suspected; an uninterrupted recovery followed the evacuation of a good deal of fluid from the cranial cavity, although no abscess or tumor was discovered. On the strength of these two cases Dr. Cushing is quite justified in suggesting the propriety of similar operations in uremic patients threatened by blindness and suffering from marked cerebral symptoms that medical treatment has failed to relieve. Aside from this practical issue, the experience recited by Cushing is of interest in that it calls attention once again to the mechanical factors that may be responsible for uremic phenomena; toxic causes for these manifestations have received almost exclusive attention in the recent experimental and clinical studies of chronic nephritis.

INTERNATIONAL ENGLISH.

The members of the Second International Congress of Surgery, which took place in Brussels from September 21 to 25, received in advance abstracts of most of the papers that were to be read before the Congress. These résumés were printed in English, French, and German. The idea of thus acquainting the participants of the Congress with the subject-matter of the deliberations was certainly a good one. The reading of the paper beforehand detracts but little from the pleasure of hearing it delivered by the author, who is an authority in the special question discussed, if the author possesses the necessary attributes of a public speaker, that is, a good voice, a clear enunciation, and a moderately rapid delivery. Moreover, many members are but superficially acquainted with one or the other tongue that has the right of citizenship at the Congress and the previous reading of an abstract of the paper will help them very much in following the discussions. But however good may be this idea, its success depends very much upon the care with which it has been put into practice, and it is in the short résumés that accompany each paper and that were supposed to acquaint the members with the topics for discussion that we see the shortcomings of the plan. No provision was made to insure competent translation of the theses from the original tongue into the two remaining languages used at the Congress, and the result ranged from slight, sometimes amusing, mistakes to expressions that could not be recognized as at all belonging to the language in which they were supposed to be written.

Thus a Parisian surgeon read a paper on the Treatment of Cancer of the Female Generative Organs. The following are some of the expressions from the English abstract of his paper: "Cancer of the laver third part of vaginum want to be treated in the same way as cancer of the vulva. . . . Hunting for remoted ganglia has more inconvenience as advantages. . . . I have nothing to say on the treatment of cancer in external genitalia, uterus and dependances on which we all agree." The following are from a paper on General Anesthesia: "The association of morphine with chloroform or ether diminishes the dangers of impregnating the organism." Another surgeon is made to speak thus of the Bassini operation for the cure of inguinal hernia: "This last is exposed in details with indications of the chief modifications following the various forms of hernia, especially the abolition of the inguinal course, the ebbing of the twist, its transposition in the diverse plans of the wall, the plastic processes for special cases, etc." Still another surgeon is libeled when it is asserted that he says, in treating of Cancer of the Urinary Organs: ". . . When the tumor is located in the kidney, testicle, or verge, and especially in these two last organs, cancer is not so grave and surgery counts a great number of cures." An authority on gallstones is made to say: "Patients suffering from severe and continuous colics should be operated upon when they are entraved in their career or when the pain empoisones their life."

It is clear that the writers of these abstracts had to depend upon the dictionary meanings of single words in translating into English and the results are anything but edifying. "It is to laugh," indeed, yet it is also painful and rather disappointing to those optimistic souls who think English is becoming an international tongue. Rather than this the dead and gone Volapük, or even Ido or some other of the several forms into which Esperanto now threatens to disintegrate.

Icterus Gravis of the Newborn.

Slight jaundice is such a common event in the newborn that it attracts but little attention from the parents and usually requires no treatment; the whole interest of this condition to the physician lies in its obscure pathology which has not been cleared up even by the most recent studies of the diseases of the newborn. Intense jaundice is a rare condition usually accompanying general infection of the infant's organism and the hemolysis produced by such infection goes far to explain the appearance of pigment in the skin and the mucous surfaces. Writing in the *Münchener medizinische Wochenschrift* for October 27, 1908, Pfannenstiel discusses still another form of icterus of the newborn, apparently so rare that he can name but five authors who have published similar cases. The interest of the disease observed by him lies in the fact that it is habitual in character attacking in succession several childen in one family. Thus Beneke has observed three such cases in a family of five children, all three ending fatally; Bushfield has reported nine instances of the condition in another family, six children dying of the disease; Pfannenstiel himself reports three successive labors followed by grave icterus of the newborn that proved more or less rapidly fatal in all three cases. Two autopsies that were performed in these cases showed a tendency to exudation in the large serous cavities, punctate hemorrhages in the internal organs, increase in the size of the spleen and of the liver, and, of course, generalized icteric discoloration of the skin and internal organs, as well as of portions of the brain. All the children attacked in this way were born of

healthy parents and appeared quite normal in the first few days of their life; no infection could be discovered, syphilis being especially carefully excluded. Pfannenstiel thinks that this form of jaundice in the newborn has nothing to do with the well known icterus accompanying Buhl's disease, characterized by parenchymatous changes in the large glandular organs ending with fatty degeneration, nor with Winckel's disease with the marked cyanosis, hemoglobinemia, and multiple hemorrhages of that condition. Both these affections are probably of infectious nature as evidenced by their great rarity since the introduction of aseptic technique in midwifery; such infection could not be supposed to have taken place in the cases described by Pfannenstiel and by the authors quoted in his paper. The author concludes that habitual icterus gravis is nothing but an intense form of the usual jaundice of the newborn; its pathogenesis, of course, cannot be explained at present because the nature of the usual form of jaundice is so little understood. It is quite probable, however, that fatal icterus of the form described by Pfannenstiel is of much more frequent occurrence in the newborn that the literature of the subject would lead one to believe. As such cases are quite frequently followed by autopsies it would pay to publish complete clinical and pathological findings so that not only this form of jaundice may become better known but light may be thrown upon the peculiar tendency of the newborn to icteric discoloration.

The Functions of the Placenta.

Formerly looked upon as merely a filtering organ for the foodstuffs that reach the fetus from the maternal blood, the placenta has gradually proved to be a much more important and active organ in the metabolism of both the mother and the fetus. So far as the mother is concerned there is a growing disposition to look for the causes of many diseases of pregnancy in the disturbed function of the placenta; the source of the toxins responsible for eclampsia, for instance, is almost certainly placed in the placenta by the most recent investigations of this condition. On the other hand the importance of the rôle played by this organ in the metabolism of the fetus is shown by almost every recent discovery in the subject. In a review of such findings in the *Münchener medizinische Wochenschrift* for October 27, 1908, Bergell and Falk mention the work of Zweifel, who had demonstrated the passage of oxygen through the organ; of Bunge, who proved the importance of the placenta for the resorption of iron; of Bergell, Liepmann, Ascoli, and numerous others who showed the presence of various ferments in the extracts of the organ. The mere presence of ferments in such extracts, however, could be interpreted to show that the placenta acts as a gland furnishing digestive secretions, and not as an active organ of metabolism. Bergell and Falk have, therefore, attempted to clear this point by trying to wash out the ferments from placental tissue and have discovered that this is impossible, if the cells of the organ have not been damaged in the procedure. The conclusion seems, therefore, to be warranted that the placental ferments are intracellular, that is, that the placenta acts not merely as the source of ferments for the metabolism of the fetus but actively metabolizes within its substances the food material intended for the fetus. The amount of ferment, too, proved to be quite considerable; enough proteolytic ferment remained after the washing out process to digest at least 0.75 gm. of tyrosin which would be equivalent to the digestion of 15 gm. of a substance like casein. The authors, accordingly, compare the work of the placenta not with such digestive organs as the pancreas or the stomach but with a great organ of metabolism like the liver. They see still closer analogy between the functions of the placenta during the intrauterine life of the fetus and the functions of the mammary glands after the birth of the child; the latter do not merely transmit the food material obtained from the blood, but metabolize it so that it becomes both in form and in composition most suitable to the needs of the young animal.

Marmorek's Serum.

The extensive literature called forth by every new remedy in the treatment of tuberculosis makes it extremely difficult for the busy practitioner to estimate its average success in the hands of the numerous observers. The profession is, accordingly, under great obligation to such workers as summarize the results obtained in a general review of the subject, a service which has been performed with reference to Marmorek's serum by Dr. Frey of Davos (*Zeitschrift für Tuberculose*, Volume XIII, No. 2). The seventy papers that have appeared in the five years since the introduction of the remedy detail the results obtained in the treatment of 938 tuberculous patients; of these, cure or improvement is reported in 67 per cent., while 33 per cent. of the patients either died or remained unimproved. Surgical tuberculosis shows slightly more favorable results than the disease involving the lungs or the larynx, while the best figures are given for tuberculosis of the eyes. Complete findings of the authors quoted in regard to the best methods of using the serum, the indications and contraindications for its employment, and the phenomena following the injections are given by Frey so that anyone using the remedy may get all possible information from his valuable paper. In his opinion the results justify the modest claims put forth by Marmorek at the time of the introduction of the remedy; certainly, no such vociferous claims were heard at the time as have attended the discovery of some other quasi-specific remedies for tuberculosis. The figures detailed by Frey should encourage further use of Marmorek's serum in suitable cases of tuberculosis.

News of the Week.

The New York State Board of Medical Examiners.—Dr. William Warren Potter of Buffalo has been elected president of the State Board of Medical Examiners and Dr. William S. Searle of Brooklyn, vice-president. The board at its meeting on November 16 placed itself on record in favor of the six year combined baccalaureate and medical course. Arrangements were made for the preparation of a medical syllabus in keeping with the suggestions of prominent medical educators, and the committee of which Dr. Lee H. Smith of Buffalo is chairman was continued in power. The assignments to the various subheads of medicine were voted as follows: Physiology, Dr. R. H. Williams of Rochester; Anatomy, Dr. William S. Ely of Rochester; Hygiene and Sanitation, Dr. Eugene Beach of Gloversville; Chemistry, Dr. F. S. Farnsworth of Plattsburg; Surgery, Dr. F. S. Crandall of New York; Obstetrics and Gynecology, Dr. W. W. Potter of Buffalo; Bacteriology, Dr. Adriance of Elmira; Pathology, Dr. Lee H. Smith of Buffalo;

Diagnosis, Dr. William S. Searle of Brooklyn. The following were elected members of the question committee: Drs. Smith, Potter, Adriance, and Williams.

Third Harvey Society Lecture.—Prof. Graham Lusk of the University and Bellevue Medical College will deliver the third lecture of the present Harvey Society course on Saturday, November 21, at 8.30 P.M., at the New York Academy of Medicine, 17 West Forty-third street. Dr. Lusk will take for his subject Metabolism in Diabetes.

The New York Pathological Society.—At the regular meeting of the society, held on November 11, Dr. F. C. Wood presented specimens from a case of adenomyoma of the round ligament; Dr. H. L. Celler described a case of gastrointestinal pseudoleukemia; and Dr. W. T. Longcope of Philadelphia, the guest of the society, gave the results of a study of cases of Hodgkin's disease and lymphosarcoma which he had begun at the Pennsylvania Hospital some time before, and was now carrying on with material sent to him by various other physicians. The paper was illustrated with lantern slides. Later the paper was discussed by Dr. F. C. Wood, Dr. James Ewing, Dr. Richard M. Pearce, and Dr. E. Libman.

Death Rate in New York.—The weekly percentage of deaths in New York continues to be less than that of last year. For the week ending November 7, there were 1,140 deaths, a percentage of 13.45. For the same week of 1907, there were 1,248 deaths, a percentage of 15.19.

Colony for Epileptics in Illinois.—At the meeting of the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics, held November 10 and 11, at Indianapolis, a memorial was drawn up to be presented to the representatives of the people of Illinois, petitioning the forty-sixth General Assembly to complete the good work planned by the forty-first General Assembly by appropriating sufficient funds to build, equip and maintain, until the next Legislature, a State Colony for Epileptics. The memorial was presented to the convention by Dr. Everett Flood of Massachusetts, and was unanimously adopted.

Foot-and-Mouth Disease in Pennsylvania.—An outbreak of foot-and-mouth disease has occurred among the cattle of Montour and Northumberland Counties, Pa., and the situation is so grave as to have resulted in conferences between the State Live-Stock Board and the U. S. Department of Agriculture. A number of farms have been placed under quarantine. It is believed that the disease was brought from South America. It is feared that it will spread, in spite of careful quarantine, to cattle on other farms and to human beings. Symptoms of the disease have already been observed in a number of children in one city. It is thought that pigeons flying from one farm to another carry the disease, and that human beings may be infected through the milk of suffering animals. It is hoped that the epidemic will be checked by destruction of all infected animals and disinfection of the premises occupied by them. The State and the Federal Government have joined in the expense of this undertaking.

Pure Food Law and Advertising.—Dr. Harvey Wiley, chief of the Bureau of Chemistry of the Department of Agriculture, spoke before the Sphinx Club, an association of advertising men, at a dinner on November 10, and assured them that if they published misleading statements about foods and drugs, even though the advertised article was labelled according to the law, they would sooner or later be prosecuted under the provisions of the pure food and drug law. The Court of Appeals of the District of Columbia has already decided that no trademark can demand protection if the owner of the trademark has sent out false information regarding the nature of his product. "How long do you suppose 'brain foods' will continue to be sold under that title?" Dr. Wiley asked. "You can't get a brain food that nourishes the brain any more than it does the big toe and just at the same time that it nourishes the big toe. Those 'brain foods' are going, and there will soon be no more of them."

New Surgeon-General.—Col. George H. Torney, now in charge of the hospital at the Presidio of San Francisco, was on November 13 appointed Surgeon-General of the Army, to succeed Surgeon-General Robert M. O'Reilly who will retire on January 14. Col. Torney is a native of Maryland, and is tenth on the list of colonels of the medical department. He was born in 1850, and was graduated from the University of Virginia in 1870. He entered the army as an assistant surgeon in 1875.

Dr. Thomas F. McParlan of New York has received from Pope Pius X the title of Knight of St. Gregory, in recognition of his services as visiting physician to St. Francis' Hospital and other institutions conducted by Sisters of the Roman Catholic Church. Dr. T. A. Emmet is the only other physician in New York who has been so honored. The title of Knight of St. Gregory entitles the holder to a place in the Pope's household.

Dr. John Gordon Wilson has been made professor of otology and head of the department in the Northwestern University Medical School, Chicago, having resigned as assistant professor of anatomy in the University of Chicago, which position he formerly held.

Dr. Smith Ely Jelliffe, formerly editor of the *Medical News* and later coeditor of the *New York Medical Journal*, has retired from the latter position, Dr. Frank P. Foster remaining, as before, editor-in-chief.

The Emmanuel Movement.—In response to invitations from New York clergymen, Dr. Worcester and Dr. McComb of Boston have arranged to give two courses of lectures in New York on the Emmanuel movement, one in the evening at Mendelssohn Hall, beginning November 19, and the other in the mornings at St. George's Church, beginning November 20. Dr. Isador H. Coriat will assist in the course and will lecture on Subconsciousness as a Normal and as an Abnormal Phenomenon, and on the Psychological Mechanism of Psychotherapeutics. The subjects of the other lectures range from a description of the movement to Methods of Psychotherapy, Functional Disorders of the Nervous System, Alcoholism, Its Causes and Its Cure, and Habit and Sleep.

Model Tenements.—It is announced that the enterprise of building and maintaining model tenements is shortly to be extended into Brooklyn. Mr. Henry Phipps, who has made this one of his many practical philanthropies, has purchased an entire block in that city, and improvement of the greater part will be begun at once. Two groups of Phipps model tenements have already been built in New York, one in East Thirty-first street, and the other in what is known as the San Juan Hill district, at Sixty-second street and Amsterdam avenue.

St. Agnes Hospital, Philadelphia.—Dr. E. Franklin Stahl, for many years one of the visiting physicians, has been appointed Medical Director of St. Agnes Hospital. Recently the entire staff of resident physicians was dismissed for insubordination.

Wills Eye Hospital, Philadelphia, is to be enlarged by the extension forward 20 feet of the main or clinic building.

New Tuberculosis Hospital.—The Thomas Hospital at Minneapolis, Minn., the first in the Northwest for the exclusive use of patients with tuberculosis, was dedicated on November 1. The hospital was built as a memorial at a cost of about $60,000.

The Home for the Aged, conducted by the Little Sisters of the Poor in the Bronx, New York, was dedicated, on November 14, by Archbishop Farley. The building will accommodate about 150, and is a fireproof structure.

Boston City Hospital.—Dr. George H. M. Rowe, for nearly thirty years superintendent of the Boston City Hospital, has been compelled to resign his office because of ill health. Dr. John H. McCollum, who has served as acting superintendent during Dr. Rowe's leave of absence, has been promoted to the vacancy. Dr. Rowe was graduated from the Harvard Medical School in 1869, and has spent the greater part of his professional life in the service of the city of Boston, having been assistant superintendent of the Boston Insane Hospital for some years before his appointment to the City Hospital. His successor, Dr. McCollum, is also a Harvard graduate of the same year. For a number of years he was physician to the Boston Board of Health, and in 1895 was appointed by the trustees of the City Hospital superintendent of the wards of the contagious department.

Hospital for the Ruptured and Crippled.—The annual report of the Board of Managers of the New York Society for the Relief of the Ruptured and Crippled shows that 40,272 patients had been treated at the hospital, at a total expense of $111,492.93. There was a considerable increase in the number of cases of infantile paralysis treated, the total for the year being 1,036. As a result there was a heavy drain on the brace shop and sewing room where appliances for the crippled are made, and the cost of running the out-patient department was larger than usual. The educational feature of the hospital is regarded as very important for the children. During the year a class in sewing and embroidery was added, and a class in gardening was conducted at the country home in Tarrytown. A deficit for the year of $29,711 is reported.

New Tuberculosis Dispensary.—The Montreal League for the Prevention and Treatment of Tuberculosis has been presented with a building which is situated in the center of the city to be used as a dispensary. The donor has also given the sum of $10,000 to the League as an endowment, on condition that a like sum is raised by it.

Charitable Gifts.—The North Adams (Mass.) Hospital receives, under the wills of the late Mr. and Mrs. Martin C. Jewett of that city, the income of a fund of $1,000 to be used in support of a children's ward, and several parcels of real estate together with some money to be used in the general work of the hospital.

Tuberculosis Exhibition.—The date of the opening of the tuberculosis exhibition at the American Museum of Natural History, New York, has been changed from November 20 to November 30. This has been done in order that the show may be more thoroughly advertized among all classes than was possible by the date first set. It is expected that Mayor McClellan will speak on the opening night and that Governor Hughes will address a later meeting.

Western Reserve University.—The H. K. Cushing Laboratory of Experimental Medicine at Western Reserve University, Cleveland, is to be dedicated on November 20. Dr. William H. Welch of Johns Hopkins University will deliver the address of the day.

The Tenth Congressional District (Georgia) Medical Society, at its annual meeting on November 5, elected the following officers for the coming year: *President*, Dr. R. L. Miller of Tennille; *Vice-president*, Dr. G. R. Maner of Warrenton. A resolution was passed designating Augusta as the permanent meeting place of the Society.

The Western District (Illinois) Medical Society met in Jacksonville on October 31. The following officers were elected for the ensuing year: *President*, Dr. J. W. Adams, Carrollton; *Vice-Presidents*, Dr. Rice, Quincy; Dr. David W. Reid, Jacksonville; *Secretary-Treasurer*, Dr. W. P. Duncan, Jacksonville; *Censors*, Drs. Christie and Nickerson, Quincy, and Dr. F. P. Norbury, Jacksonville.

In Memory of Dr. Carroll.—The late Dr. James Carroll was honored, on November 11, when a bronze tablet to his memory was unveiled in the main building of the University of Maryland. The address was delivered by Dr. William H. Welch of Johns Hopkins University.

Obituary Notes.—Dr. Davies Coxe of New York died in Dresden on November 7, aged 46 years. He had been in ill health for some time, but the immediate cause of death was an acute attack of pleurisy. Dr. Coxe was graduated from the University of Virginia in 1884, and later studied at the College of Physicians in New York. He served as interne at the Woman's Hospital in this city, and afterward practised here for fifteen years, making a specialty of gynecology.

Dr. Azel Ames of Wakefield, Mass., died November 14, at Danvers. He was born in Chelsea in 1845 and was graduated from the Harvard Medical School in the class of 1871. He was a noted sanitary engineer, and served with distinction in the Spanish-American war, and later in the Philippines. He was director of vaccination in Porto Rico in 1899 and United States Commissioner for the Department of Labor in the same island in the following year. He was sent from Porto Rico to Washington as Commissioner from the island in 1901.

Dr. Daniel Wixans Smith, for over fifty years a practitioner of Newark, N. J., died at his home in that city on November 10, after an illness of several months. Dr. Smith was born in 1833, and was graduated from the medical department of the University of New York in 1856. He was a member of the American Medical Association, the Essex County Medical Association, and the New Jersey State Medical Society.

Dr. Philip H. Sellew of Westfield, Conn., died at his home after a short illness, on November 7, aged 46 years. Dr. Sellew was a graduate of the Jefferson Medical College of Philadelphia in 1890. He had practised in Connecticut up to last spring, and was a member of the Connecticut State Medical Society and the Litchfield County Medical Society.

Dr. Henry Augustus Weymouth of Andover, N. H., probably the oldest practising physician in

that State, died at his home, on October 22, after a short illness. Dr. Weymouth was born in 1820, and was graduated from the Vermont Medical College, Woodstock, in 1843. He had practised in Andover continuously since his graduation.

Dr. John F. Burns of San José, Cal., died at his home on October 26, after a long illness, aged 50 years. He was graduated from Cooper Medical College, San Francisco, in 1883, and for several years was president of the Medical Society of Fresno County. He was also a member of the Medical Society of Santa Clara County, and was recently appointed Health Officer of San José.

Dr. William M. Strickler of Colorado Springs, Col., died at his brother's home in Denver on October 26, from the effects of an accidental overdose of morphine. Dr. Strickler was born in 1838, and was graduated from the Medical College of Virginia, Richmond, in 1869. Shortly after graduation he settled in Colorado Springs, where he served three terms as Mayor, and for two years as chairman of the finance committee of the city council. He was at one time president of the Colorado State Medical Society.

Dr. Alonzo Pettit of Elizabeth, N. J., died after a short illness, on November 14, aged 66 years. Dr. Pettit was graduated from the Buffalo Medical College in 1867, and had since practised in Elizabeth. He was one of the organizers of the Elizabeth General Hospital and a member of the visiting staff. He belonged to the American Medical Association and the New Jersey State Medical Society.

Dr. David K. Bechtel of Kulpsville, Pa., died at Philadelphia, on November 12, at the age of 63 years, as the result of burns accidentally received. He was graduated from the medical department of Howard University in the class of 1879.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BRITISH PHARMACOPŒIA—HARVEIAN SOCIETY—SECRETION OF URINE IN THE FETUS—HEREDITY AND PIEBALDS—NOTIFICATION IN IRELAND—THE PLEBISCITE OF THE ROYAL COLLEGE OF SURGEONS.

London, October 30, 1908.

The scope and object of the British Pharmacopœia was the subject of a paper in the Therapeutical Section, R. M. S., by Dr. Nestor Tirard, who pointed out that some criticisms were beside the mark, as they paid no regard to the limitations imposed by the Act of 1858, although these had been to some degree extended by the changes in medical practice. In 1898 modifications were made which were on the whole approved, and since then the addenda has been of service in India and the Colonies on account, chiefly, of climatic conditions. Dr. Tirard said further changes were necessary to promote uniformity between different countries and made reference to the international agreement entered into with this object. Already great progress had been made on points involving long researches. The pharmaceutical societies of Great Britain and of Ireland had been invited to confer with the committee of the General Council on the matter, and researches had been made by experts. Questions of additions, omissions, and standardization were referred to. The difficulties relating to the introduction of sera might involve State laboratories, which could give an official guarantee. Dr. Tirard hoped the new edition, when it appeared, would show that much had been done in spite of the impossibility of acting on all suggestions.

Dr. C. O. Hawthorne remarked that it was not for the Pharmacopœia to recommend particular drugs or combinations. Its sole duty was to determine standards of purity. That a drug was in use was its title to admission. Nor should the work be regarded as a text-book. It was as unnecessary as impossible for a student to commit its contents to memory.

Mr. H. W. Gadd referred to difficulties that had lately occurred in the law courts. It had been held that certain drugs were to be dispensed in pharmacopœial strength.

The Harveian Society on the 15th inst. resolved to admit to the membership those on the Dental Register holding a British dental diploma. A number of clinical cases were then shown—one by the president, Mr. D'Arcy Power, of recovery after a ruptured spleen caused by injury had been removed. Dr. Willcox showed a case of hemophilia in a man of 26 who had been under treatment for five years. Unless calcium and magnesium salts were administered from time to time, the coagulability of the blood fell below normal and bleeding came on. He also showed a case of hemoptysis in a boy whose brother had hemophilia, but this was considered to be tuberculous, of which there were some indications. A third case by Dr. Willcox was of adherent pericardium with double mitral disease. The patient had, a fortnight before being shown, a sudden attack of right hemiplegia with euphasia, but no unconsciousness. It was thought the symptoms were due to cerebral embolism.

As to the secretion of urine in the fetus, there was some discussion in the obstetrical section apropos of a case of malformation of the urethra causing dystocia, brought forward by Dr. J. Evan Spicer, illustrated by drawings and photos. This fetus had enormous dilatation and hypertrophy of the bladder with imperforate urethra. After summarizing the dissection and some remarks on other cases recorded, Dr. Spicer said the atresia does not affect the growth *in utero* nor render the life of the new-born infant impossible. It is dangerous only when there is large secretion by the fetal kidney, and that he held to be pathological. The kidney was not an excretory organ *in utero* unless a breakdown occurred in the mechanism by which the urethra discharges its functions through the circulation as provided for by the placenta. There might be some interruption during labor or just before, so that children are often born with some urine in the bladder. But in normal conditions the kidney remained inactive, as do other major organs, during fetal life.

The president, Dr. Herbert Spencer, was not inclined, without further consideration, to give up the older view that the fetus normally excreted urine into the liquor amnii. He had seen some half dozen cases of stillborn children with stenosis of the urethra, the urine causing distention above the obstruction and in one dystocia. When the kidneys were absent the liquor amnii was scanty. Other secretions did not all remain in abeyance. He had seen the uterus greatly distended when the outflow of mucus was obstructed.

Mr. Alban Doran referred to a recently reported case in which both kidneys were absent, the bladder empty, and very little liquor amnii. The suprarenals were hypertrophied. It was thought to support the theory that the liquor amnii was chiefly supplied by the fetus, but probably the evidence of a single case would not satisfy Dr. Spencer or other obstetricians.

Dr. W. S. A. Griffith said imperforate urethra was not necessarily followed by distention of the bladder, and he agreed with Dr. Spicer that interference with the secretion through the placenta was the cause of renal activity before birth. That the fetus could empty its bladder into the closed amniotic sac had never been proved and was very unlikely, although where great hypertrophy of the bladder existed it might be possible.

Mr. Bishop Harman related at the Ophthalmological Society a striking story of heredity—six generations of "piebalds." Seven members of the family were shown. The features were a white forelock, a white patch of skin spreading from this down the center of the forehead, and in some cases patches of white skin on the trunk and legs. The white forelocks were exactly in the median line. The ordinary hair was brown, ranging from light to very deep shades. The connections of the family had been ascertained for six generations and four are living. They comprise thirty-four childships and 138 individuals. Of the former nine showed the inheritance in direct descent. The anomaly, it was suggested, was of the nature of partial albinoism.

Compulsory notification of tuberculosis in Ireland is not passing through the House of Commons so easily as its advocates expected. On Wednesday, in the standing committee, Lord Balcarres agreed that the notification should be within seven days instead of forthwith, as first proposed in the bill. Sir William Collins urged the necessity of caution in applying a new law to a whole country and suggested that notification should only be required in cases likely to infect other people and not in mere trifling cases. This

being accepted by the Government, Lord Balcarres protested that no case could be trifling and that Sir W. Collins's amendment had knocked the scientific bottom out of the bill. Mr. Mooney quoted reports of the Registrar General to show that consumption is on the decrease in Ireland but on the increase in Scotland. Mr. Russell expressed surprise at such a statement and declared the facts were all the other way. A proposal that when a man is registered as tuberculous his family may have parish relief without any disqualification of his citizenship thereby was ruled out of order.

The ways of corporations are strange. When the Council of the College of Surgeons determined to take a plebiscite as to the admission of women, some optimistic reformers were jubilant. My advice, as the result of long experience of this body, was to wait. The plebiscite was taken, the vote was against the proposal by a large majority. The Council thereupon, as I have already told you, has resolved to admit women. Now people want to know what was the object of the plebiscite.

Yesterday a party of French medical men (of the Études Medicales Internationales) staying in London visited the Royal College of Surgeons and were shown over the several departments. A pamphlet giving them an account of the museum in their own language was presented to them. No one explained to them the recent plebiscite and it is currently reported that no one can state the motive of the Council in taking it.

TWENTY-FIRST FRENCH CONGRESS OF SURGERY.

(From Our Paris Correspondent.)

PARIS, October 15, 1908.

THE first session of the twenty-first French Congress of Surgery was held on October 1 under the presidency of Professor Forgue of Montpellier, who chose for his opening address "The Responsibility of the Surgeon." Professor Forgue believes that in view of the unjust attacks that have been made upon surgeons it is necessary to maintain professional dignity and to defend the honor of our profession against motiveless accusations. It is certain that in spite of all the guarantees of asepsis, all the safety of technique, all post-operative attention and care, there are still, from time to time, disasters which cannot be prevented or foreseen; the responsibility of the surgeon should, then, be limited. The fine discourse of the president, which was greeted with applause, was terminated by the exhortation not to mistake the duties and cares of the surgeon; he believed that the surgeon should know how to measure the value of his services, and his social importance, and that he should not pretend to assume more than his just and necessary responsibilities. The president then paid a tribute to the members of the French Association of Surgery who have passed away during the year—Hoffa of Berlin, Reboul of Nimes, Harrison of London, Filet of Lille, Auguste Reverdin of Geneva, and finally Ferrier of Paris, in whom French surgery lost one of the greatest minds and one of the most precise technicians by whom she had been honored. The president then declared open the twenty-first session of the French Association of Surgery.

The first question of the day was "The Surgery of the Ductus Choledochus and the Hepatic Duct." The two members who presented papers on this subject were Delagènière of Mans and Gosset of Paris. Delagènière considered all the normal surgery of the ductus choledochus and hepatic duct from the hilum of the liver to the duodenum; after having recalled the methods of access to the biliary ducts, the author considered operative technique, and spoke of the different operations for wound and rupture of the choledochus and the hepatic ducts, choledochotomy, hepaticotomy, and the supplementary maneuvers of these two operations (cholecystotomy, drainage of the biliary passages in the wound, peritonization, and epiploplasty of the subhepatic region); finally he described the consecutive care and the post-operative accidents. Delagènière has done twenty-one operations for calculus of the principal biliary passages, with twenty-one cures and six deaths; these deaths were in subjects attacked by angiocholitis. Of the twenty-one cured cases Delagènière has never observed the expulsion of forgotten calculi after the operation, nor later biliary fistulæ; he attributes this fact to the employment of his method of section of the biliary passages in severe cases, which are precisely those which are most exposed to the leaving of a calculus in the deformed canals.

Gosset of Paris divided his subject into four chapters, thus: (1) Operations for calculus of the duodenal portion of the choledochus. (2) Operations on the hepatic canal and the ductus choledochus for congenital or acquired strictures. (3) Operations on the hepatic duct and the ductus choledochus for tumors. (4) Immediate and remote results of operations on the principal biliary passages in cases of biliary lithiasis. In the first chapter Gosset said that the idea of infection of the biliary passages should hold a first position to-day in the treatment of lithiasis. The surgeon should propose for himself a double object; to remove the calculi and to combat the infection by appropriate drainage; thus has grown up hepatic drainage. He believes that every choledochotomy should terminate by hepatic drainage; in this case it is better not to suture the hepatic duct, but to place in contact with it a drain and then tampon the wound. The most frequent causes of death after operations on the ductus choledochus and the hepatic duct are these: Hemorrhage, generally due to a defective ligature of the cystic artery; infection; the persistence of infectious accidents, and cardiac and pulmonary complications. As post-operative complications are to be noted intestinal fistulæ, biliary fistulæ, and eventrations. As remote results it is interesting to know that there may be recurrences of lithiasis and calculi of new formation; by analyzing with care the results of the operation we may arrive at the knowledge that there are two operations after which there are found the most recurrences; these are cholecystostomy and choledochotomy with suture. After choledochotomy there are probably forgotten calculi that could not be evacuated secondarily; the conclusion to be drawn is that, whenever the circumstances permit, it is better to do cholecystectomy with drainage of the principal biliary passages.

After the reading of these papers interesting discussions arose, among which should be noticed that of Fontan of Toulon, who contends that we must preserve the gall-bladder when it is healthy, but must remove it at once when we are obliged to open it.

The second question in the order of the day was "The Surgical Treatment of Osseous Cavities of Pathological Origin." The authors on this question were Auguste Broca of Paris and Nove-Jusseraud of Lyons.

Broca in his paper remarked that he wished to study only osseous cavities of pathological origin, eliminating all the lesions of natural cavities in the osseous wall, that is to say sinuses of the surface of the bones. First he considered the physiological process of repair, then the surgical operations employed to cause pathological osseous cavities to disappear. He distinguished three great methods: (1) Suppression of one of the walls and direct cicatrization of the osseous surface preserved, which may be obtained either by tamponment or by cutaneous flaps. (2) The mobilization of one ossifiable osseous wall, which may be obtained in two different ways—by direct osteoplasty, applying against the bleeding osseous surface a flap of bony substance, or by indirect osteoplasty, applying a flap susceptible of ossification on its lower surface. (3) The filling of the cavity with a substance of foreign nature, either living or inert. For this obturation different substances are used, which may be classified in the following way: (a) fragments of living bone, which act as grafts, that is to say which we attempt to cause to live in their place; (b) inert, but absorbable substances, exciting by their presence the power to ossify in the ossifying tissue around them, and serving at the same time as a temporary support to the tissues, first the connective tissue, later the osseous tissue, which infiltrates them little by little by substitution and penetrates their pores. These foreign bodies are fragments of sponge, decalcified bone, plaster, naphthaline, gelatin, paraffin, mastic, etc. (c) Inert substances not absorbable obturate the cavity as a filling obturates the cavity of dental caries, and are destined to become encysted. Here, by its irritating action, the foreign body has the effect of increasing the activity of osteogenesis. Among these substances are amalgams of copper and lead, gutta percha, mastic, metallic alloys, etc. But foreign bodies have not been well tolerated except when they were aseptic; a foreign substance is eliminated if suppuration takes place; for this reason the last-named method is exceptionally employed.

Nove-Jusseraud divided the question into three parts—osteomyelitic cavities, tuberculous cavities, and neoplastic cavities. (1) Osteomyelitic cavities. Under this

name he classifies all the losses of substance having for their cause an acute infection of the bone; they are almost always the result of some operative interference. As the lesion has a natural tendency to repair, it is necessary above all to protect this process from interference. We must practise disinfection of the bone, and then occupy ourselves with the obliteration of the cavity, whether by the osteoplastic method or by filling it with a substance having the object of obturation of the osseous cavity by a foreign body, or finally, by cutaneous osteoplasty, which endeavors to cover up the cavity with an epidermic flap. (2) Tuberculous cavities, resulting from tuberculous lesions which do not form after the manner of osteomyelitic lesions; in fact, osseous tuberculosis is essentially destructive in such a way that repair of a tuberculous cavity is slow and difficult; two indications are to be fulfilled here: disinfection of the cavity and obliteration. Tuberculous cavities, by their small dimensions and the relative facility of their disinfection, lend themselves especially to the method of filling. (3) Neoplastic cavities in the great number of cases result from tumors of the bone of malignant nature, and necessitating operation; the history of these cavities is very short. The treatment of surgical cavities of pathological nature has been considerably facilitated of late; we must be satisfied if we are able to render the cure of these osseous cavities more rapid and sure, and thus increase the field of conservative surgery.

The third question in the order of the day was "The Surgical Treatment of Facial Neuralgia." The papers were read by Jaboulay of Lyons and Morestin of Paris.

Jaboulay said that we must first establish the precise diagnosis of the cause of the facial neuralgia, so as to make the treatment appropriate to the causal affection. We should not do the same operation for every case on account of the different maladies that neuralgia produce. The surgical treatment of facial neuralgia is not single, but multiple, and varies with the case; for true alterations of a peripheral neuron direct operations are applicable; *i.e.*, different forms of resection of the fifth pair of nerves for facial neuroses; for cases which are due to lesions of the central neurons operations are to be done that directly modify the nervous centers.

Morestin believes that a careful, precise, and complete examination will enable us to diagnosticate the causes of local neuralgias purely symptomatic, or to recognize pains that result from tabes, syphilis, and hysteria, and to vary our therapeutics in consequence, no intervention directed against the neuralgia being justifiable until it has acquired its autonomy, and cannot be modified by suppression of a local cause, or by medical means. Operations on the peripheral branches should be preceded by exploration by the aid of cocaine at different distances along the course of the nerve, to try to localize the seat of painful excitations. We should not make multiple sections. Extended resections, the tearing away minutely of terminal ramifications, the entire removal of the central portion as far back as possible, reinforce considerably the action of this method and give it a true curative value. Injections of alcohol constitute a palliative treatment, offering such advantages that it will often render unnecessary any other more serious operation. The more or less extended resection of the great cervical sympathetic has proved very efficacious, and constitutes a good resource against facial neuralgia. Operations on the sympathetic may be associated with procedures that involve the trigeminus. The extirpation of the Gasserian ganglion is now easily accomplished and may be done habitually: the gravity of the operation is lessened; its efficiency is certain, and we may say that total ablation corresponds to absolute cure; but the destruction of the large root of the trigeminus and the isolation of the ganglion is an operation of much efficiency, easier, less serious, and in consequence to be preferred.

HE PLASTERED HIS RIBS INTERNALLY.

To the Editor of the Medical Record:

Sir:—I enclose the following extract from the Sherbrooke (Eastern Townships, Canada) *Daily News*, dated September 29, 1908. This is certainly one of the most surprising violations of a physician's instructions that I have ever yet seen recorded:

"An old man named Trepannier, over 80 years of age, who had been suffering for some time from the effects of a fractured rib, died yesterday afternoon under peculiar circumstances. The physician attending him had given him a plaster to apply on his side to relieve the pain, and when he called early in the day yesterday could find no sign of it. Inquiries developed the suspicion that the patient, mistaking the use for which the plaster was intended, had swallowed portions of it, and the death of the patient ensued a few hours later."

Cookshire, Que. R. H. Phillimore, M.D.

Progress of Medical Science.

Total Extirpation of the Lower Pharynx for Epithelioma, with Permanent Esophagostomy; Remarks Upon the Surgical Treatment of Cancer.—The patient of M. H. Richardson was a woman of forty-seven years seen in 1902. Throat spasms prevented the swallowing of solid food. The larynx was free, but there was a sloughing tumor in the posterior pharyngeal wall. A fragment was examined and pronounced epithelioma. The area of implantation was so large that extirpation was impossible without complete destruction of the power of swallowing. The following operation was performed: An incision of six inches was made from the angle of the jaw downward along the anterior border of the sterno-mastoid muscle. At this time the patient began to breathe so badly that a tube was put into the trachea. The dissection was then carried down to the pharyngeal wall. This was difficult to get at because the enlarged thyroid gland extended almost entirely around the esophagus and up onto the pharyngeal wall. The pharynx was then opened. The tumor occupied the entire posterior wall and extended well around onto both sides. It also extended down into the upper part of the esophagus. The whole tumor was cut away, with a margin of from ¼ to ½ inch. This left but a very narrow strip of mucous membrane on the left side of the pharynx, about ¼ inch wide. Such a large area of mucous membrane was removed that there was nothing to be done but to bring the edge of the esophagus out and suture it into the wound. The bleeding points were tied with catgut and the denuded area of the pharyngeal wall was packed with gauze. Before the esophagus was sutured to the skin a chain of enlarged and hardened glands running into the mediastinum were dissected out. The lower and upper parts of the wound were closed with silkworm gut sutures. The patient was fed through a rubber tube left in the esophagus and made a good convalescence, and six years later was in good health and able to take an active part in domestic life. The author is disposed to take a hopeful view of the cancer situation, but adds that much as he would welcome an era when cancer would no longer be regarded as a surgical disease he feels that the time has not yet come when we can relax in the least our vigilance, nor has the time come when we can trust cancer in its operable stages to any method of attempted cure other than surgical excision. He has seen so many operable and favorable cases drift, under *x*-ray, toxins and other loudly-heralded cures, into inoperability and death that he is sure we must confine new methods, like the use of trypsin and amylopsin, to the inoperable cases. For the few authentic *x*-ray cures of cancer in its simple and superficial forms, like epitheliomata of the face, he has seen hundreds of patients who, under the dread of the knife and the encouragement of the *x*-ray, have drifted into hopeless inoperability.

New York Medical Journal, November 7, 1908.

Reflex Neuroses Arising from Ocular and Nasal Abnormalities.—S. L. Ziegler reviews the general development of this phase of clinical medicine. He notes four ocular factors as exciting causes of reflex neuroses: (1) ciliary spasm, or strain from unconnected ametropia; (2) accommodative effort; (3) muscular unbalance, and (4) painful ciliary scar or shrunken eyeball. Nasal factors are (1) pressive contact; (2) hyperesthesia, and (3) nasal obstruction. The various individual manifestations of reflex neuroses may be headache, migraine, localized muscular spasms, chorea, minor epilepsy, gastric disturbances and neurasthenia. Illustrative cases are given under each of these headings. The author says that in searching out the causes of trouble in any given case we should always bear in mind the following points: (1) The eye and the nose are undoubtedly most important factors in the etiology of reflex neuroses and should, therefore, be carefully examined and positively excluded before beginning a search for other causes; (2) ocular and nasal reflexes possess many manifestations in common, which should be carefully differentiated at the earliest possible moment; (3) eyestrain, whether from ametropia, subnormal accomodation, or muscular imbalance, should be carefully corrected in order to eliminate the eye as a causative factor; (4) an

atrophied eyeball, with contracting ciliary scar, should be enucleated; (5) pressure contact in the nose will always excite some reflex disturbance when any hyperesthetic area is impinged upon, and should, therefore, be eliminated; (6) every obstruction to free breathing should be removed; (7) recurrence of any reflex neurosis demands reexamination and renewed search for the original exciting cause.

The School Child.—J. W. Van Derslice mentions some of the causes which conspire against the proper development of the modern child, such as lack of harmony between parent and school, distracting social influences, poorly lighted school rooms and poorly printed books, unsanitary school houses, etc. The burden of the criticism of the public school is the over-crowding of the curriculum. Moreover, the present system groups all races, strata of society, conditions and customs of living, all varieties of taste, talent and capacities, and for this heterogeneous mass of material the educator is called on to formulate a system suited to the individual. This overcrowding of the curriculum is due to three causes: (1) every child must take care of all the work regardless of personal or individual creed; (2) whatever the last generation had must go into the curriculum of the present one; (3) domination by the colleges. In the public schools of the large cities there are from seventy to eighty per cent. of the pupils that are foreign born or the children of foreign-born parents. In quite a considerable proportion of these pupils the only real culture that they are apt to receive will be from the public schools, and as it is in the psychological period, that period in the development when there is an unfolding, that these studies are given, it is the period for the imbedding of real culture. Take the domestic science course, the immediate benefits of such a course in the poorer districts will be that there will be a demand for the better foodstuffs in the families coming under such influence. There can be no greater benefit accrue to the congested districts of the large cities than that the girls shall have a knowledge of foods, their values, modes of preparation, and the art of making tasty the commoner foods. The crying need of these districts is for better cooks, and if these girls of necessity must go from the school to the factory, to wifehood, where can they get a working knowledge of the duties of the housewife? So with the other culture studies as music, drawing, and literature, it would be a step backward to take away the taste of literature that these children receive. There should be a decided effort to inculcate in these children a taste for good literature; it is not that they do not read, but that their reading is ill advised, and a little painstaking effort might lead them along the better way.

Obstetrical Paralysis.—K. Osterhouse discusses the mechanics of the production of brachial birth palsy and presents a preliminary report on two cases. The paralysis may affect the upper arm alone, lower arm alone, or both. The main point of interest in the paper relates to the author's method of treatment, which is the familiar "bridging" process in nerve-gap cases. The details of the method can be best understood by giving the summary of one case. Patient was a girl of sixteen years, with left upper arm paralysis of moderate degree. There were contractures at the elbow joint, resulting in a mild degree of flexion, and the pectoralis major was markedly contracted. The arm could not be voluntarily abducted except to a very slight extent, and outward rotation and supination were almost entirely absent. Examination showed involvement of the fifth and sixth cervicals, but no induration or thickening could be made out on palpation, owing to fat. Marked atrophy of arm and shoulder, left arm being two inches shorter than right. Under ether anesthesia the plexus was exposed by the usual incision above the clavicle. The deep cervical fascia was found to be thickened and somewhat adherent to the plexus. Palpation showed several small indurated masses at the junction of the fifth and sixth cervical nerves, one mass extending a little distance into the fifth nerve above the junction. The deep cervical fascia was cleared away freely so as to expose the nerves, and the nerve sheaths were incised longitudinally from well above the junction to below it. The nerve junction and roots were then lifted clear of the sheaths on small padded grooved directors, and the fibres were freely dissociated, the dissociation being carried into the nerves well above and below. The suprascapular nerve was treated in the same manner. The nerves were then loosely wrapped in Cargile membrane, the wound closed in layers, and a plaster cast applied to approximate the head and shoulder. There was very little loss of blood, and the patient reacted well. The skin wound healed by first intention, and one month after operation the cast was removed and a strict course of electricity, massage, baking, and passive movements was instituted. The patient was instructed to use her arm as much as possible and attempt to exercise the paralyzed muscles. Some slight improvement in function was noted about four months after operation, and this steadily progressed. At the present time the patient can abduct the arm nearly to a right angle to the body, and flexion, outward rotation, and supination are markedly better. The atrophy and dwarfing of the extremity, which were considerable, appear about the same.

Journal of the American Medical Association, November 7, 1908.

Abdominal Hysterectomy.—A. E. Hertzler deprecates the tendency to quick operating in order to prevent shock. He says it is a great fallacy to believe that time is the only or even the chief element in the production of shock. A rough operation done in a short time may be much more productive of shock than a much slower one performed gently, with full attention to details. The use of mass ligatures and crushing forceps may be shock-producing long after the surgeon has ceased his work. He describes a method of abdominal hysterectomy which has developed in his hands in the course of years, and which aims at anatomic exactness rather than speed, and in which he tries to treat the pelvic stumps with the same consideration that is given to the stump of an amputated limb. For the details the reader is referred to the original article, which is fully illustrated, but the points specially observed are, as in the amputated limb, to remove that which is diseased, tie that which bleeds and nothing more, to preserve the best possible function, and to restore the natural covering of the parts as much as possible. Among the special points of the operation may be mentioned the tying of the veins, which is not shown in many of the cuts in standard textbooks, peritoneal closure with independent drainage below, the absence of clamps in the operation, and the suture of the peritoneum without causing pressure, by the use of delicate coaptation sutures. The disadvantages of the operation are that it is time consuming. In his hands it requires from forty-five minutes to an hour and a quarter (with twenty-five minutes as a minimum), but he has not seen shock worthy of note follow in any instance. With proper application and suitable material the isolated ligatures on the vessels are not likely to slip. The operation is not suitable, he admits, in acute infective processes and in suppurating fibroids. An accurate knowledge of anatomy on the part of the operator is essential, however, in all cases.

Nitrous Oxide Anesthesia.—W. D. Haggard describes nitrous ovide anesthesia and enumerates its advantages of quickness of action, comfort to the subject, almost immediate recovery, absence of lung complications, and improbability of later kidney, liver, and heart complications. It is especially to be preferred in patients suffering from disease of these organs and in those who have had uncomfortable experiences with other anesthetics. It should not be employed, however, for patients with dilated hearts or extremely bad hearts, whether from valvular or myocardial disease. It is not suitable for plethoric or alcoholic patients. Its zone of anesthesia is rather limited, though it can be employed for operations lasting half an hour or more. It is not always possible to secure the requisite skill for its administration nor to command the apparatus and the amount of gas required for a lengthy operation. Its cost, also, is considerable. Young children do not always take it well, and it should not be used in case of narrow or abnormal air passages, enlarged lymph nodes, goiters, or enlarged tonsils and adenoids. No fatalities are reported from the combined use of nitrous oxide and oxygen.

Local Anesthesia.—J. P. Mitchell holds that local anesthesia has a definite field of usefulness which can be increased by familiarity with modern methods and their use. Its dangers are always less than those of general narcosis. While some of the newer anesthetics may have the advantage in individual hands, eucain and cocain are the ones found most generally useful, and the danger of poisoning has been practically eliminated by the use of weak solutions in combination with adrenalin. Tablets for this purpose are in the market. Each of the several methods for application, viz., (1) surface application, (2) infiltration, (3) nerve blocking through endoneural and perineural injections, has its special applications, or they may be used in combination or combined with general anesthesia. Correct anatomical knowledge of nerve distribution and experience on the part of the operator are essential for the best results.

Blood Changes in Anesthesia.—W. W. Hamburger and F. E. Ewing reach the following conclusions: 1. In an analysis of the blood changes incident to nitrous oxide anesthesia, clinically and experimentally studied, they find that (*a*) The hemaglobin is not permanently reduced or anemia produced. (*b*) Hemolysis is not increased. (*c*) The changes in the readings of the hemoglobin and ery-

throcytes are transient and of no surgical significance. They are probably explained by capilliary stasis. The reduction of hemoglobin is not due to the anesthetic, but to the accompanying asphyxia. (*d*) The changes in coagulation time are not constant, but there is generally an increase of time required for clotting, most marked about the third day. 2. A series of experimental observations on ether anesthesia showed that. (*a*) The hemoglobin is slightly reduced, causing a slight anemia. (*b*) Hemolysis is not materially increased. (*c*) The changes in hemoglobin and erythrocytes are explainable on the basis of blood inspissation. (*d*) It causes a marked decrease in the coagulation time, most marked from the seventh to the tenth days. 3. In an analysis of the blood changes from chloroform anesthesia in animals, they find that: (*a*) The hemoglobin is reduced and anemia caused. (*b*) Hemolysis is increased. (*c*) There is a slight decrease in coagulation time, most marked in the seventh to the tenth days. 4. Comparing the three anesthetics from the standpoint of the blood changes, they conclude that nitrous oxide causes no permanent effects of any significance; that ether causes more harmful changes (slight anemia and marked decrease in coagulation time); that chloroform causes the most harmful results (hemolysis and production of distinct anemia).

Atrophy of the Iris.—Casey A. Wood reports a case of progressive and rather irregular disappearance of the iris tissues of the right eye in a healthy man, without other symptoms except increased tension in that eye. At present fully five-sixths of the iris tissue has disappeared, and the pupil has assumed the shape of an irregular triangle whose angles reach almost to the root of the iris, in which situations all the iridic layers have become absorbed. The absorbtion seems to have begun on the anterior surface and proceeded irregularly there, and the pigment layer has been absorbed chiefly, or only, at the pupillary edge. The patient had an injury to the superior maxillary bone sixteen years before. This was followed by antral disease, which is attributed, however, to an attack of influenza. There was no direct injury to the eyeball itself. Wood does not offer any explanation of the case, except that if it began early enough, septic absorption from purulent collections in the antrum and frontal sinus might be expected to exercise a toxic influence on the iris as a part of the uveal tract. The glaucomatous tension seems inadequate as a cause.

The Ear in Cardiovascular Disease.—The possibility of tinnitus aurium being a local symptom of general circulatory disturbances is suggested by L. F. Bishop, who gives his reasons for believing this to be the case. It is, in his opinion, the peripheral vasomotor regulation that is largely at fault in the production of this symptom, and he has been able in some instances to observe the tinnitus disappear with the improvement of the circulatory condition. While he has seen this in both high and low tension conditions, the most striking have been the low tension ones. He finds the literature on the subject very scanty, which he attributes to the fact that the critical study of the circulation as contrasted with the study of the heart alone has been too much neglected. The question of low arterial tension has been most slighted. Murmurs are produced not by a constriction as such, but by a relative constriction, and this can be brought about by dilatation causing the normal part of the vessel to act as a constriction. From this, he says, it is easy to understand why relaxed vessels produce a great deal of noise. He believes that: "1. There are certain cases of tinnitus aurium which are a local manifestation to general circulatory disorder. 2. This may have its foundation in arteriosclerosis, but the blood vessel disorder is often in a large measure functional. 3. It is found in connection with high blood pressure and also with low blood pressure, and while in both instances the symptom is relieved, the measures which regulate the circulation, the most striking results of treatment are to be obtained at the present time in instances of low arterial tension. 4. Observations of blood pressure to detect the gross departure from normal should be made by otologists; they can be made in a very few seconds by the author's simplified method."

The Lancet, October 31, 1908.

Rupture of the Left Auricle of the Heart.—A. W. Greig's patient was a Burman convict, male, 28 years of age, who, after a railroad journey and a walk of a mile, suddenly fell dead, having had no preliminary symptoms of any kind. Autopsy showed the pericardial sac full of blood. On the anterior superior aspect of the left auricular appendix there was discovered a rent, of triradiate shape, through which the tip of the little finger could be readily passed into the cavity of the left auricle, the wall of which was slightly puckered in the neighborhood, as if there had been a preexistent bulging during life. The heart was removed and the left auricle slit open at a distance from the tear, but although no undue force was used to effect this the rent was extended, the surrounding tissues being very friable. To the inner aspect of the auricular wall around the rent some recent blood-clot was adherent, but on removing this it was found that the deeper layers were partly decolorized and of firmer texture, showing that deposition of fibrin had occurred some time previous to death about the spot which eventually gave way. The deepest layers of the clot were either intimately adherent to, or had entirely replaced, the endothelial coat of the auricular wall, for on gently removing the former the muscular tissue was revealed. The rest of the left auricle, the remaining chambers of the heart, and the valves were, so far as could be seen, normal; the orifices of the coronary arteries were fully patent; there was no atheromatous change visible in the roots of the great vessels; nor was there hypertrophy or dilatation of the heart itself except in the immediate vicinity of the rupture. No gummatous deposit was found in the myocardium nor was there naked-eye evidence of subjacent fatty change. Nothing of significance was noted in the other organs, and the author is at a loss to account for the auricular lesion.

Scurvy Rickets Occurring in a Breast-fed Child.—T. H. Kellock reports the case of a female child 11 months old, who did well at the breast for nine months, but was then weaned and fed on diluted cow's milk and infant foods. In two months she had become listless and anemic, with diffuse tender swellings on the forearms and legs. There was nothing in the previous history suggesting syphilis, and no teeth had appeared. Some of the long bones were tender on manipulation. A diagnosis of scurvy rickets was made, and under the usual treatment for this affection the child appeared quite well. Sixteen months later the child's mother appeared with a younger child, aged ten weeks. The former appeared ill, anemic, and apparently suffering from want of food. She stated that while she was pregnant with this child her husband had been out of work and they had been very badly off, with the result that she had been short of food. She had, however, had plenty of milk in the breasts and the child had had nothing whatever but this. When nine weeks old a swelling appeared about the upper end of the right tibia, which was tender and painful, and the leg became, in the mother's words, "quite paralyzed." The child was sent to the author, as on its first visit to the hospital sarcoma of the tibia had been suspected. When seen the child seemed to be in fairly good conditon, and the only part affected was the upper end of the right tibia; here a doughy tender swelling of some size completely surrounded the bone and the child would make no effort to use the limb. The mother was directed to continue nursing the child, but to give her as well a little orange juice twice a day, at the same time she herself was ordered a mixture containing iron and sulphate of magnesium. At this time, too, it must be mentioned that her circumstances had somewhat improved and that she was getting at any rate sufficient food. The result of this treatment was immediate and rapid, as far as the child was concerned; the swelling on the tibia first became much less tender and in three weeks had almost completely disappeared.

Some Unusual Sequelæ of Convulsive Seizures in Childhood.—Histories of nine cases are given by F. J. Poynton. In Case 1 convulsions commenced in the ninth week. The child was marasmic, with an enlarged liver, and became idiotic by the eighteenth week. It was an hereditary syphilitic. In Case 2 there was an eclampsia suggesting idiopathic epilepsy, then improvement, and in two years an acute hepatic illness with meningeal symptoms. This case was also syphilitic. Case 3 was practically a duplicate of Case 2. Case 4 began in much the same way, but is still living. In Cases 5 and 6 there was a syphilitic history, but the symptoms were more of a paralytic character, and in Case 6 there were no convulsions. In Case 7 there was unconsciousness when the child was first seen. The left arm and leg were somewhat rigid, but the features of the case were slow rhythmical movements of the left arm and leg. In the upper extremity there were flexion and extension at the elbow and pronation and supination of the forearm. The left knee joint was slightly flexed, and there were on the slightest disturbance continual movements of flexion and extension involving the whole limb. The rhythmic movements gradually disappeared and the child recovered. Syphilitic history was wanting. Case 8 was similar in a general way to Case 7. So also Case 9. The two latter cases are on a fair way to recovery. The three latter cases suggested meningitis, but lumbar puncture was negative in two of them. Recognition of the rhythmical movements, which appear when consciousness is being regained, and particularly when the children begin to resent move-

ment, will make one at once cautious in diagnosing meningitis, and the occurrence of ocular palsies will also add to this caution. These cases again did not lose flesh in the same way that children do as a rule in meningitis.

British Medical Journal, October 31, 1908.

Home Treatment of Scarlet Fever.—R. Milne's paper is a plea for the use of a carbolized oil of ten per cent. strength, or eucalyptus oil, rubbed into the skin. He tells the nurses and parents, "rub the patient most carefully from the crown of the head to the soles of the feet," including the armpits and the roots of the hair. The rubbings are to be made morning and evening for the first four days, then once daily till the tenth day. The throat is to be swabbed with the carbolized oil every two hours for the first twenty-four hours. With this plan of treatment the author has never seen any nose, ear, or kidney disease. The severity of the attack is greatly modified. He claims that the treatment dispenses with the need of elaborate disinfection afterward, for the source of infection is destroyed (?). No carbolized sheets are hung in the doors of the sick room. Diet is restricted to soda water or equal parts of hot milk and water. Light diet is allowed in a few days and ordinary meals on the tenth day. As between carbolized and eucalyptus oils, the author has come to prefer the latter. He supports his proposition by the histories and courses of various institution and village outbreaks of the disease.

The Limitations of a Purin-free Diet.—A. Bryce presents the following conclusions: (1) Personal idiosyncrasy has much to do with the diverse results reported, and in my opinion this is ultimately bound up with the metabolic activity of the cells, and especially the ability of the cells of the mucous membrane to withstand the onslaught of irritants such as purin compounds. (2) Small quantities of purin are almost invariably well borne, and only in isolated cases are larger doses not tolerated. (3) The ability to tolerate purins is markedly influenced by disease—for example, neurasthenia, so called, and kidney ailments, where the integrity of the cells of the convoluted tubules is doubtful, yet a man in perfect health with a so-called gouty tendency may tolerate them badly because they act as irritants to the mucous membrane of the hepatic ducts, and produce hepatic insufficiency. According to the author, a purin-free diet in epilepsy offers the best chance of a cure. In some instances a little purin may be allowed. In headaches due to uric-acidemia tea and coffee should be cut off entirely at first, but may be used later if well diluted. Small quantities of caffeine are diuretic, and there results an increased elimination of nitrogenous elements, especially urea and the fatigue products generally. In asthma the general conditions are the same as with epilepsy. Relapses may succeed an initial improvement. The author's general experience is that while a purin-free diet is an admirable method of treatment in chronic disease, it is not suited as a dietary for ordinary purposes of nutrition in everyday life. The cases admirably illustrate the old adage that "every man is a law unto himself," and demonstrate the fact that most of them were extremely susceptible to the action of excess of purins in the diet, that when these were cut off completely freedom was obtained from their particular malady, but that when malnutrition arose their troubles returned with the old force. When they cautiously adopted a diet containing their old proteid forms of food, with a minimum of purins, then they regained their health and strength, and because they were capable of dealing with all the purins they ingested, kept free or comparatively free from their malady. It is not necessary to suggest that this was due to an excess of uric acid in the blood or tissues, but simply that for some reason or other, probably toxic, they were unable to deal with these particular foods.

Bee Stings and Rheumatism.—E. T. Burton has had a personal experience with the remedy named. His account of his experience is so graphic that it is reproduced verbatim: "I was attacked very suddenly on June 24 last with acute arthritis of my right hip, as suddenly succeeded by sciatica of the same side. A fortnight in bed was followed by a fortnight at Droitwich, with a daily bath at 104° for twenty minutes. A small measure of relief was obtained. My treatment consisted of a return to Droitwich, a daily douche of hot water to the offending hip, return to my lodgings, and reclining in more or less—chiefly more—pain for the rest of the time. I could not walk a quarter of a mile without two or three stops to relieve my agony, and Droitwich, always helpful before, did me very little good. Having been promised a supply of bees, I commenced, on October 17, the 'bee-sting cure.' I had seven or eight applied in the course of the sciatic nerve and round the hip-joint. When I awoke in the morning I was able not only to turn in bed, but to get out without hauling myself up in agony by the bedpost, and I walked across the floor without limp or pain for the first time in all but three months. I returned to bed at once, and had another half-dozen bees applied, subsequently dressing at 12:30 P. M. for dinner. The same night I had five or six more bees applied, and on October 19 the final installment of the same number. I walked well that day, and even ran about fifty yards without pain, and am now, on the evening of October 21, absolutely free from the slightest twinge. I may add that if I live for three months I shall be sixty-seven, and have been a rheumatic subject for twenty-five years. I intend, if during their hibernation I can procure them, to continue the application of the bees till I cease to react to the stings."

Berliner klinische Wochenschrift, October 26, 1908.

Serum Diagnosis of Syphilis.—Halberstaedter, Müller and Reiche have investigated the behavior of scarlet fever patients in reference to the appearance of a reaction similar to the supposedly specific reaction of Wassermann in syphilitics. Of ten patients examined five gave a distinct reaction expressed in inhibition of hemolysis, though seldom of such a marked nature as in the luetic cases. Syphilis was excluded in all the cases examined. Nine cases of measles, five of varicella and fourteen of whooping cough gave negative results. The authors tested seventy-eight other children, ten of whom were not suffering from syphilis or any other infection; all ten gave negative reactions. The remaining sixty-eight patients came with the clinical diagnosis of syphilis, and of these thirty gave a positive reaction and thirty-eight a negative one. Of the manifestly syphilitic cases 92 per cent. gave a positive reaction with the test. The reaction is, accordingly, valuable in corroborating clinical diagnosis and justifying the beginning of specific treatment.

Blood-pressure in Chronic Nephritis.—Engel says that the estimation of blood pressure by means of the finger is very untrustworthy; yet the importance of knowing the exact blood pressure is such that a sphygmomanometer ought to be possessed by every practising physician. Even the figures obtained with the instrument may be completely misleading if such factors as nervousness, excitement, etc., are not discounted. Thus an anxious patient showed a pressure of 170 mm., which, however, dropped to 130 after a reassuring prognosis. Of especial value is such an estimation in chronic nephritis, for high systolic blood pressure is a most frequent symptom of interstitial disease, while uncomplicated parenchymatous nephritis is usually accompanied by a normal blood pressure. The examination of the heart or of the urine may not always give a clue to the nature of the kidney lesion, and the sphygmomanometric data serve as a very important factor in the diagnosis and prognosis of renal disease. The gradual change of a purely parenchymatous disease into a mixed form is best evidenced by the behavior of the pressure curve if regular readings are taken for long periods of time. Diseases affecting the glomeruli in a marked manner are also accompanied by a raised blood pressure, and its estimation may be of value, therefore, in the course of scarlet fever, in cases of poisoning, etc. Uremic attacks are often preceded by sudden and marked increase of pressure. Both prognosis and treatment may accordingly be greatly simplified by the use of the sphygmomanometer in the course of chronic nephritis of any nature.

Insufficiency of the Spine and Scoliosis.—Schanz says that insufficiency of the vertebræ is a common condition characterized by tenderness of the vertebral spines and bodies; radiating pains are often complained of in this connection, and they may falsely lead to the diagnosis of gastric, thoracic, or pelvic disease. The condition is caused by the disproportion between the strength of the spine and the weight it supports, and often appears in mechanical disturbances of the spine. Thus scoliosis is very often accompanied by the symptoms of such insufficiency with marked manifestations of pain, contrary to the general opinion which considers that pain in scoliosis is infrequent. The disappearance of such pain in scoliosis shows that the compensatory changes in the skeletal and muscular system have made up for the deformity of the spine; progressive increase in pain is good evidence that the deformity is growing in degree. The presence of pain is of still further significance in the therapy of scoliosis; it serves as a contraindication to the usual amount of gymnastic treatment of the deformity, for further straining of the weak spine can only make things worse. The exercises should be much less strenuous than in cases not accompanied by pain.

Münchener medizinische Wochenschrift, Oct. 20 *and* 27, 1908.

Marmorek's Serum.—Strauss says that whenever tuberculosis is a local process and can be attacked by oper-

ative methods without interfering too seriously with the function of the parts affected, surgical treatment offers most chances of curing the patient. In other cases every measure that promises relief or cure should be tried, and Marmorek's serum has been successful enough to deserve further trial. Strauss has used it in thirty-eight cases, administering the remedy by the rectum or subcutaneously. It has proved to be completely harmless in every instance, and in a number of patients exercised a very favorable influence upon the course of the disease. The local phenomena were lessened in severity and the general condition of most patients likewise improved. Strauss concludes that the serum in question is a valuable aid in the treatment of surgical tuberculosis; in cases of general infection the influence of the serum does not seem to be very marked.

Eczema in Infants.—Mendelsson says that, according to Finkelstein, the eczema of infants is due to disturbed assimilation of the salts in milk; its treatment therefore is not local, but must consist of dietetic measures. The best diet is poor in salt but rich in proteid and fat, and is prepared by removing the salts of milk by washing the casein in water and then mixing it with diluted whey. Mendelsson obtained very good results with Finkelstein's diet, the eczematous conditions disappearing much more quickly and surely than with the older local treatment. The loss of weight noted on this diet should not stop its use, as it is caused by the rapid loss of water with the removal of salts in the tissues. The diet, however, should be tried only in such children who can bear fat well; such infants are usually large for their age, have a pasty skin and are prone to manifest not only eczema but other phenomena of "exudative diathesis." They stand the withdrawal of salt very well if it is not continued too long after the curative effect upon the eczema has been noted.

Treatment of Carbuncle.—Grasmann says the quickest and surest treatment of carbuncle consists in extirpation of the diseased area by a circular incision with smaller incisions radiating from it. Such incisions should in no case be carried through the actively inflamed portion of the lesion, but should be placed in the infiltrated skin surrounding it. The whole carbuncle should then be separated from the underlying fascia and the large wound packed with dry gauze. In other cases cross incisions through the carbuncle may be used, the four flaps thus made being lifted from the underlying tissue and supported by gauze packing; necrotic masses are to be removed with the knife or the scissors. After a few days, when the granulation tissue has well developed, the flaps are brought together by a couple of stitches, thus diminishing the size of the wound. The latter is completely closed within four to six weeks.

Functional Heart Disease.—Strubell says that the measuring of the blood-pressure is the first step in the diagnosis of functional heart disease. Increased blood-pressure may be labile in character, due to vasomotor phenomena, or constant, caused by arteriosclerotic changes. Even in the latter case, however, sudden rise in blood-pressure may be produced by sudden contraction of the sclerosed vessels. The warm bath is a good diagnostic procedure in these cases, for little fall of pressure is noted in angiosclerotic patients when placed in such a bath, while high pressure caused by vasomotor contraction falls considerably. The procedure may also be used therapeutically, long-continued warm baths with the consequent fall of blood-pressure proving very beneficial in cases of high pressure. Electrical stimulation during the bath serves for further diagnosis of the condition of the heart: normal individuals react with rise of general pressure and fall of pressure in the auricles; those with diseased hearts show fall of general blood pressure and rise in auricular pressure. The muscular system may also be used to relieve the splanchnic system and diminish the general blood-pressure; this effect is reached by light, passive exercise and not by active exercise, which should never be prescribed to patients with any heart trouble before the functional capacity of the heart has been thoroughly tested.

Treatment of Pelvic Abscesses.—Tillmanns says that pelvic abscesses may originate in the pelvis or gravitate in that direction; they may be diffuse or circumscribed, intraperitoneal or extraperitoneal. They may break into an organ or reach the surface and perforate the skin or the mucosa; most frequently they break into the rectum, after which spontaneous cure may take place. The primary abscesses may be caused by the injury or inflamamtion of any pelvic organ, pelvic bones, or joints, or the overlying soft parts; secondary abscesses are caused very often by appendicitis or by suppuration of the lymph nodes about the cecal region. In women the diseases of pregnancy and labor and especially gonorrhea are frequently responsible for the formation of abscesses; foreign bodies of various nature may also cause pelvic suppuration. The treatment consists in incision and drainage; the latter may be effectively done by way of vagina. Abscesses involving pelvic lymph nodes require large incisions and the removal of all nodes affected, after which drainage is usually necessary. Whenever possible pelvic abscesses ought to be opened extraperitoneally. If the abscess comunicates with a hollow organ it is sometimes best to sew the wall of the abscess to the external wound and by slow draining allow the communication to close up; later the external opening is allowed to be filled up by granulations. In tuberculosis of the public symphysis conservative treatment is not to be attempted, while if the sacroiliac joints are affected conservative treatment should be tried early in the case. Under no circumstances should minor operations such as curetting and injections of iodoform be tried, as they usually are completely unsuccessful.

Fulguration Treatment of Malignant Tumors.—Schultze considers in detail the apparatus required for the fulguration of tumors according to the method of Keating-Hart. He warns against the use of ether in anesthetizing the patient, for a single spark falling upon the ether mask may set in it flames; local anethesia is not sufficient, and chloroform is the only anesthetic to be considered. Schultze has tried the new treatment upon inoperable tumors only; before the fulguration, however, all macroscopically visible part of tumor was removed by the knife, so that the sparks were used in situations which the knife could not enter. No nervous shock and no bleeding was witnessed; indeed, fulguration acted as a powerful styptic. Experiments with animals showed that it was impossible to damage even exposed blood-vessels with the strongest sparks, and therefore such vessels were not considered a counterindication to the use of the sparks; no injury was caused in any case. Histologically, fulguration appeared to cause death of a thin superficial layer of tissue, carcinomatous as well as healthy cells being equally affected. Clinically, the secretion of the wounds was much increased and fine granulations quickly appeared; pain in the wounds was not very marked; the general condition was favorably influenced. However, the further course in all cases showed that no effect was exercised upon the malignity of the tumors treated; though the subjective symptoms were much improved in many instances, the disease continued to fatal termination as usual. The new method of treatment, therefore, is in no wise a "cure" for cancer; it is, however, a palliative against pain and against bleeding and offensive changes in the tumor tissue; in these respects, however, fulguration does not seem to be any more valuable than radium or even the use of caustics. The technique of using it is certainly much more complex than with these latter methods.

Dangers of the Ophthalmoreaction.—Schrumpf reports two personal cases in which the instillation of tuberculin for diagnostic purposes was followed by severe inflammatory symptoms with involvement of the cornea and the iris, as well as with unfavorable effects upon the general condition of the tuberculous patients. He names twenty-three other authors who have observed unpleasant or dangerous consequences of this reaction. He considers it improper to speak of the reaction in question as a completely harmless one, as is done by Calmette and his enthusiastic followers. The best mode of procedure is to inform the patient of the possibility of untoward symptoms, just as is done by the surgeons in the case of anesthetics. Another unpleasant feature of the reaction is the tendency of the local inflammation to reappear if tuberculin is used later for therapeutic purposes. Often, too, the reaction occurs in persons that show no symptoms or signs of tuberculosis; as its occurrence does not escape the patient's observation, it may have a very bad effect upon sensitive individuals.

Rosacea.—Shoemaker recommends the following ointment:

℞ Ol. eucalypt.
Creosoti (beechwood) .....āā ♏v.
Chloral hydrat.
Camphoræ .....āā gr. v.
Ungt. zinci oxidi
Ungt. aq. rosæ.....āā ʒss.
M. ft. ungt.
S.: Apply locally twice daily.

Book Reviews.

Traitement Chirurgical Actuel des Kystes Hydatiques du Foie et de Leurs Complications. Par le Dr. Albert Cauchoix, Ancien Interne Lauréat des Hôpitaux de Paris (Médaille d'Argent 1907); Prosecteur à la Faculté de Médecine. Paris: G. Steinheil, Editeur, 1908.

This book is a monograph devoted to the criticism of the prevailing methods of treating hydatid cysts of the liver and to the advocacy of an improved procedure. The author condemns "marsupialisation," enucleation, and total extirpation of cysts except in a few selected cases. He thinks that the reduction of the cavity of the cyst after evacuation of its contents and disinfection is the method best adapted for the majority of cases. A number of illustrative cases and a bibliography accompany the text.

Die Verletzung der Arteria Meningea Media. Von Dr. Custodis. Stabs- und Abteilungsarzt im I. Westpreussischen Feld-Artillerie, Regiment No. 35. Mit 2 Textfiguren. Berlin: Verlag von August Hirschwald, 1908.

This little book is devoted to one special problem of the surgery of the head, namely, to the injuries of the middle meningeal artery. The author considers very fully the pathology and the symptomatology of this accident and then describes the surgical treatment of it. An appendix gives a number of histories from the cases of the author and from the literature, the cases being classified according to the treatment adopted and the outcome. The book forms a useful monograph on the important injury it considers.

Lehrbuch der Muskel und Gelenkmechanik. Von Dr. H. Strasser, ö. o. Professor der Anatomie und Director des anatomischen Institut der Universität Bern. I. Band: Allgemeiner Teil. Mit 100 Textfiguren. Berlin: Verlag von Julius Springer, 1908.

Dr. Strasser thinks that the physician will possess a clearer understanding of the anatomy and physiology of the human body if he has studied the mechanical principles involved in the body considered as a machine. He therefore acquaints the reader with the elementary principles of mechanics and then considers the skeleton, the muscles and the joints as offering problems involving these principles. We do not share the author's opinion that the mechanics of the body as presented by him should become one of the subjects of study of a medical course, for the modern student of medicine is already overburdened with work. Dr. Strasser's book, however, ought to be of interest to anatomists and to physicians with love for mechanics; the latter, especially, will find enough material in the volume to indulge his love for mechanical problems and yet not take him away from the subject of his chosen profession.

Pulsating Exophthalmos. Its Etiology, Symptomatology, Pathogenesis, and Treatment. Being an Essay Based Upon an Analysis of Sixty-nine Case Histories of This Affection. By George E. de Schweinitz, M.D., Professor of Ophthalmology in the University of Pennsylvania, and Thomas B. Holloway, M.D., Instructor in Ophthalmology in the University of Pennsylvania. Philadelphia and London: W. B. Saunders Company, 1908.

This interesting subject is admirably treated in the volume before us. The object of the essay, which is one of 124 pages, is, in the language of the authors: "(1) To analyze those cases—69 in number—not previously recorded in the tabular statements already referred to; (2) to elaborate and compare the therapeutic measures, surgical and otherwise, which have been employed in their treatment; and (3) to endeavor to determine from these analyses those surgical procedures which seem likely to prove of the greatest advantage in the control of the symptoms of this disease." Sixty-seven pages of the text are devoted to an analysis of the cases considered. The remaining part of the volume is occupied by a tabulated report of 80 cases of pulsating exophthalmos. The essay should be read not only by all ophthalmologists, but by those who are interested in general surgery as well.

The Natural History of Cancer. With Special Reference to Its Causation and Prevention. By W. Roger Williams, Fellow of the Royal College of Surgeons. New York: William Wood & Co., 1908.

It was Dr. Williams' purpose in writing this book to apply the synthetic method to the study of cancer by leaving the many details of the subject and paying attention to the broad principles involved in the problem of malignant disease. After defining the terms "tumor" and "cancer," the author considers the geographical distribution and incidence of malignant disease; the increase of cancer in recent times; tumors of animal and vegetable worlds; the experimental study of cancer; the relation of the growth of malignant tumors to growth in general; the microbic theory of cancer; extrinsic etiological factors, such as inflammation, irritation, etc.; the influence of sex, of age, of heredity; the morphology and the clinical behavior of malignant tumors; cachexia; and finally, the various degenerative, inflammatory and retrogressive changes that may take place in tumors. He aims to show that no reliable indications are present now for elucidating the cure of cancer; its incidence, however, is clearly related to the alimentation of the human race, as shown by the distribution of the disease among the civilized nations and in the overfed classes of the population. The prevention of cancer or at least the diminution of its ravages lies, according to Dr. Williams, in the modification of the nutrition of the human race aimed at the diminution of the nourishment habitually taken. These findings are presented with such a wealth of illustrative examples, and such insight into the shortcomings of the laboratory study of malignant disease that the book becomes a storehouse of information on the subject considered, as well as an introduction to the study of the question from the novel standpoint developed by the author. It is a work *sui generis*, for there exists no similar study in any language, and its perusal is heartily recommended not only to physicians, but also to intelligent laymen interested in the cancer problem. The future alone can decide how correct are the views held by the author; at present, however, his work gives evidence of such erudition in the subject and such critical judgment as to command a respectful hearing from those even who are least apt to agree with his findings.

Estimation of the Renal Function in Urinary Surgery. By J. W. Thomson Walker, M.B., C.M. (Edin.), F.R.C.S., Hunterian Professor of Surgery and Pathology, Royal College of Surgeons of England (1907); Surgeon-in-Charge of Out-patients at the Northwest London Hospital and Hampstead General Hospital; Assistant Surgeon to St. Peter's Hospital. With 2 Colored and 7 Black-and-white Plates, 34 Figures in Text, and 32 Charts. London, Paris, New York, Toronto and Melbourne: Cassel & Company, 1908.

After giving several clinical histories illustrating the failure of renal function in consequence of operations and anesthesia, Dr. Walker considers the chemical examination of the urine, the study of the kidney as a filter by means of cryoscopy, the testing of the renal functions by means of injections of methylene blue, phloridzin, indigocarmine, etc. The second part of the book is devoted to the methods of studying the functions of one kidney alone, *x*-rays, cystoscopy, ureteral catheterisation, and the chemical tests for each kidney being fully described. The book contains numerous charts and pictures taken from actual cases and is throughout written from the standpoint of the practical surgeon who is called upon to test the functions of the kidneys before any operative interference. To such a worker the compilation of all the methods in one book ought to prove of great assistance, and this is what Dr. Walker's book really is. It is sure to find many readers among surgeons and physicians interested in the diagnosis and treatment of renal disease.

Pathological Technique. A Practical Manual for Workers in Pathological Histology and Bacteriology, Including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By Frank Burr Mallory, A.M., M.D., Associate Professor of Pathology, Harvard University Medical School; First Assistant Visiting Pathologist to the Boston City Hospital; Pathologist to the Children's Hospital; and James Homer Wright, A.M., M.D., S.D., Director of the Pathological Laboratory of the Massachusetts General Hospital; Assistant Professor of Pathology, Harvard University Medical School. Fourth Edition, Revised and Enlarged, with 152 Illustrations. Philadelphia and London: W. B. Saunders Company, 1908.

The new edition of this well-known manual needs hardly any comment from the reviewer. The additions to bacteriological methods consist of Dr. Zinsser's anaërobic method for plate-cultures, of three new methods for cultivation and recognition of typhoid bacilli, and of entirely new paragraphs on the organism of actinomycosis. The histological methods are enriched by the improvements in the technique of staining fibroglia, myoglia, and neuroglia fibers; by Wright's method of staining blood platelets and giant cells of the bone marrow; by a new stain for glycogen; by staining methods for *Spirochæta pallida;* and by the methods of preparing bacterial vaccines introduced by Sir A. E. Wright. The book remains an indispensable companion to everybody engaged in histological or bacteriological work.

Society Reports.

ILLINOIS STATE MEDICAL SOCIETY.

Fifty-Eighth Annual Meeting, Held at Peoria, May 19, 20, and 21, 1908.

The President, Dr. William L. Baum of Chicago, in the Chair.

An Address of Welcome was delivered by Hon. Thomas O'Connor, Mayor of Peoria, which was responded to by President Baum.

Psychopathology of Hysteria.—Dr. S. T. Robinson of Edwardsville reviewed the two ideas "generally held: (*a*) that of the entity or dominating soul of the plain man's belief, and (*b*) the coordination of the experimental psychologists. Mentioning some of the conclusions of psychic research investigators, the author argued that the late evidence justified the presumptive view that both elements entered into the personality. Thus he considered the controversy largly reconciled. There was, accordingly, a union which was both a great colonial empire, with many apparently independent centers, and an empire which was dominated by an indwelling soul. Next, he outlined the further division of this complex personality into the supraliminal and the subliminal spheres. These he discussed with special reference to the subliminal self and the threshold of consciousness. To these elements of the healthy mind he added those of potential memorability, whereby facts were assimilated and stored in the subliminal self; selection, whereby the necessities of the moment were satisfied, and, finally, the law of psychic cohesiveness, the psychic analogue of gravity in the physical world. Out of these psychological elements, when they became unhealthy, he deduced the four main factors which underlay hysteria: (1) Psychic poverty; (2) lack of cohesiveness; (3) morbid selection; (4) undue permeability, or instability of the threshold. First, the author reviewed the morbid subliminal life in a personality suffering from psychic poverty and lack of cohesiveness, which might let go of the life above, with, for instance, the production of anesthesias, and then he showed how the narrowed life above might be disastrously influenced from below with, for instance, evolution of the fixed idea. Suggestibility, absent-mindedness, alternation, and anesthesia, he mentioned as the chief stigmata, so lucidly described by Janet, and concluded that as hypnotic suggestion was to the subliminal life, so hysteria was to the ordinary consciousness. Genius and hysteria were set down as the two far-distant poles of human personality, the one produced by healthy cooperation of the subliminal and supraliminal faculties, while the other was due to the incoordinated uprush of subliminal impulse in a retracted field of supraliminal consciousness.

Arteriosclerosis.—Dr. Thomas J. Pitner of Jacksonville said that in considering this disease we were approaching the origin of many diseases. The study of this process throughout the body tended to broaden our views of the nature and causes of local diseases by showing how largely they were due to antecedent widespread arterial changes. Arteriosclerosis was a primary pathological process. There were no morbid anatomic changes preceding it. The principal element of the disease was the fibrous proliferation of the internal coat. The other coats were involved, but not so generally and constantly. The artery became thickened and hardened, with narrowing of the lumen and subsequent degeneration.

Dr. Ferd. Engelbrectson of Chicago referred to the deposit of salts in the development of the osseous system, and said, after the bones were started, what became of these salts. The system was not ready to eliminate them. They must be deposited somewhere, and he thought the nonelimination of these salts produced many conditions, including arteriosclerosis.

Dr. Wm. J. Butler of Chicago thought that cardiovascular diseases that were dependent on syphilis, whether it was aortitis or arteriosclerosis, or a myocarditis in conjunction with it, were benefited by the use of potassium iodide or calomel.

Dr. Robert B. Preble of Chicago referred to the uncertainty of prognosis in these cases. No matter what the manifestations might be, whether renal, cardiac, cerebrospinal, or gastrointestinal, the clinical picture was susceptible to sudden variations in character, and in advanced cases of arteriosclerosis, cerebral hemorrhage or thrombosis might suddenly develop. There might be some severe circulatory or gastrointestinal disturbance, thrombosis, or embolism, and hence the great liability of these patients to sudden death.

Dr. Joseph L. Miller of Chicago said that many of these cases were benefited by the use of iodides where the cause or causes were not of syphilitic origin.

Dr. C. D. Westcott of Chicago said the oculist not infrequently saw changes in the retinal vessels of these patients in the course of routine examinations for refraction. These changes were noted most commonly in middle life, in those who did not suspect any constitutional condition. When the oculist observed these changes in the retinal vessels, the patients should be referred to a good internist.

Diabetes.—Dr. James B. Herrick of Chicago discussed some of the points concerning the treatment of this disease, with special reference to the use of oatmeal diet. He emphasized the importance of differentiating the clinical types of diabetes, and spoke of the value of other factors than the mere estimation of the amount of sugar in the urine in determining the severity of a given case. Reference was made to the principle of tolerance of carbohydrates and the practical application of the same treatment. He spoke of the necessity for carbohydrates and their place in warding off impending coma. He detailed the oatmeal diet of von Noorden, described the technique of its administration, and its importance when properly used as a therapeutic agent.

Dr. Frank Billings of Chicago said that, until more was known about the cause of diabetes, the management of patients suffering with the disease must be along lines that were thought best.

Dr. George E. Baxter of Chicago asked as to the amount of exercise these patients were allowed during the oatmeal diet; whether they were kept at rest or allowed the normal amount of exercise.

Dr. Herrick, in closing, said that exercise, as a rule, did not harm a patient with diabetes. In fact, moderate exercise was rather beneficial, and in putting patients on this diet he had never restricted them as to exercise unless there was some special reason for it. The oatmeal diet was a valuable therapeutic agent, yet he was firmly convinced that it was also attended with danger. He did not wish to convey the impression that it cured diabetes. However, he had seen what he regarded as very favorable results in children. He mentioned a little girl of twelve, whose life was prolonged a year and a half by this treatment with only traces of sugar in the urine at any time.

Food Values in the Nutrition of Children.—Dr. Josephine Milligan of Jacksonville described the practical application of food values in every-day practice in the nutrition of children from the age of nine months to puberty. In chronic disease the nutrients and calories should be kept at the full standard or slightly above. In convalescents the nutrients and calories should be increased. A convalescent child might demand even as much as an adult. When as much study and attention had been put on the diet of children over nine months of age as had been expended on children under nine months, another great advance not only in life-saving for children would have been accomplished, but in better developed and healthier bodies and mind for the adult.

Drug Treatment of Cardiovascular Conditions.—Dr. Joseph L. Miller of Chicago emphasized the importance

of an accurate knowledge of the action of drugs. Reference was made to drug nihilism. The foundation of our knowledge of pharmacology was based on the action of drugs on normal animals, and he pointed out the fallacies in applying this to the treatment of diseased conditions, using such agents as vasoconstrictors, digitalis, strophanthus, caffeine, camphor, adrenalin. He pointed out the indications and dangers of using vasodilators, nitroglycerin, nitrites, amyl nitrite, etc.

Study of Diagnosis and Pathology Should Not Lessen Our Confidence in the Intelligent Use of Drugs.—Dr. Thomas W. Bath of Bloomington said that if he said anything concerning the routine drug treatment in those diseases that were not specifically influenced by drugs, he believed that many patients were over-drugged. Many patients were needlessly over-drugged by physicians who were somewhat too credulous to the claims of materia medica and drug circulars. Until the riddle had been solved with reference to those diseases which were still treated expectantly, physicians would best serve their patients not by giving placebos or suggestions, or Christian Science, but by taking a sensible view of the case and in offering nature a helping hand when she desired support.

Control of Hyperacidity by Diet and Drugs.—Dr. M. Milton Portis of Chicago detailed some experiments that were conducted on dogs with a Pawlow stomach. A great variety of foods were given, and in all cases it was found that vegetables excited the stomach to the least secretion. The time of secretion and the amount secreted were much reduced as compared with the feeding of meat, but the per cent. of HCl secreted could not be reduced. The total amount of secretion could be still further reduced by giving the vegetables in a finely divided state. The alkalies were found to reduce secretion, as had been observed, especially if given before meals. Morphine and hyoscin were found to have very little effect. Atropine and strontium bromide were found to have a marked effect in reducing the amount of secretion.

Baths and Exercises in the Treatment of Heart Disease.—Dr. Robert H. Babcock of Chicago emphasized the fact that the water should be merely warm or tepid for the initial baths, and weakly saline; also that as the patient's reaction permitted, the temperature should be lowered from time to time, until toward the end of the series a temperature of 85° F. could be obtained, by which time the waters were strongly charged with sodium chloride, 3 per cent. calcium chloride, 1 per cent., and made strongly effervescing. The weaker baths should be considered sedative and suited to weak, dilated hearts, while the colder, strongly saline and carbonated waters were stimulating. Since the natural Nauheim waters were strongly impregnated with calcium salts, Dr. Babcock never omitted the addition of calcium chloride. Since these baths were capable of harm as well as good, he believed they should be prescribed only after frequent careful examinations of the patient, and with due regard to the individual's reaction after and his sensations during each bath. This treatment was applicable chiefly to myocardial incompetence and valvular insufficiencies. These baths should be given cautiously in cases of stenosis and arteriosclerosis, and were of doubtful utility when chronic fibrous mediastinitis was present, and not at all in cases of aortic aneurysm or ectasia, for although the heart's contractions might be invigorated, the vascular lesion could not be improved and might be increased. This balneological treatment should be deferred in cases of pronounced dilatation with edema, until rest and other measures had improved cardiac power. Exercises were of two kinds, the so-called resistance exercises and medical gymnastics. The former consisted of extension and rotation of the extremities and trunk, performed against a measured degree of resistance offered by a trained assistant. Their beneficial effects in feeble dilated hearts were attributed to dilatation of the intramuscular arterioles, and consequent unloading of the heart's cavities. Patients with chronic myocarditis soon appreciated the benefit of exercise by a lessening of dyspnea and palpitation by increased strength and by reduction in abdominal girth. The author maintained close watch of the effects and in some cases combined medicinal therapy with the exercises. He concluded that (1) he was justified in recommending medical gymnastics as an important part of the management of myocardial incompetence when this was not too advanced. (2) They should be performed only with the aid of a trained assistant, who understood the object and kind of exercises to be given, and who would maintain close watch upon the pulse and respiration. (3) These medical gymnastics produced results similar to those of resistance exercises, and in suitable cases more quickly and powerfully. (4) Individuals with myocardial incompetence should not be allowed to substitute for these medical gymnastics so-called self-resisting movements at home. (5) The effect on the heart should be watched by a physician, who could judge of the degree of benefit obtained and how long the exercises should be taken.

The Use of the X-Ray by the General Practitioner.—Dr. George S. Edmondson of Clinton had used the *x*-ray in diagnosing dislocations. He had been highly pleased with this treatment in cases of lupus. One case of carcinoma of the cervix yielded nicely to the application of the *x*-ray by means of the Caldwell tube, but returned just as rapidly after the treatment had ceased. He had treated many cases of superfluous hair on the face, and in not one had he witnessed a failure to remove the hair. In the course of a few months the hairs invariably returned, but usually were not so hard to remove the second or third time. He had treated several cases of acne by means of the *x*-ray with satisfactory results.

Fracture of the Base of the Cranium, with Diastasis of the Left Temporoparietal Articulation; Complete Recovery.—Dr. George de Tarnowsky of Chicago reported a case of fracture of the base of the cranium, and summarized by saying that all head injuries should be prepared in a surgical way. All cases should be placed under the very keenest observation obtainable. Do not operate in cases of diffuse cerebral contusion. A progressive disintegration of cellular structures could not be restrained by a simple relief of pressure. Never operate hurriedly without having first observed the symptoms of the case and their trend, namely, increasing severity or manifest tendency to spontaneous recovery. Having diagnosed epidural hemorrhage, if coma should deepen, temperature decline, and pulse grow weaker, operate at once; if, with reaction, the clinical picture showed a tendency to remain stationary or to clear up, wait and watch. Not all blood clots needed surgical removal in order to effect a complete recovery.

Traumatism of the Brain.—Dr. J. W. McDonald of Aurora discussed fractures of the skull, their diagnosis, and treatment. He devoted considerable space to the consideration of intracranial lesions, such as hemorrhage, thrombosis of sinuses, contusions, lacerations, and their sequelæ. He likewise discussed meningeal and parenchymatous inflammations usually of a septic character. He reported a case which was interesting on account of the extent of the fracture, laceration of the artery, extent of the hemorrhage, and the speedy recovery.

Dr. Daniel N. Eisendrath of Chicago said there was a condition of laceration or contusion of the brain which must be separated completely in the diagnosis and prognosis from concussion and compression. There might be cases of contusion or laceration of the brain without any of the accompanying symptoms of head injury, such as were usually found in compression and concussion. These cases manifested themselves shortly after the injury without any of the symptoms of unconsciousness or any of the other focal symptoms except a focal disturbance, such as would be ordinarily due to pressure upon some cortical area

of the brain. Aphasia, or a condition known as paraphasia, was well illustrated in a case recently operated on by him, for other focal symptoms, such as hemiplegia or monoplegia.

Dr. T. J. Sullivan of Chicago said that in all injuries, where there was only a slight abrasion, no one was justified in allowing them to pass without thoroughly shaving, disinfecting, and closing the wound with some occlusive dressing. In many of these injuries, where there was an escape of fluid from the ear, and where other symptoms did not warrant immediate operative interference, thorough attention to the ear was essential. The ear should be thoroughly washed with soap and water for a considerable time, and after that with alcohol, and in children, for instance, where there was an escape of serum, it could be completely stopped, and an occlusive dressing applied by packing the ear with iodoform gauze, saturated with compound tincture of benzoin. This would prevent the escape of serum, make an antiseptic occlusive dressing, and cut off the port of entry of infection.

Dr. S. C. Stremmel of Macomb agreed with the last speaker, but could not agree with Dr. McDonald in using applications of ice in these cases, as it interfered with repair afterwards in cases of the milder injuries. In the more serious injuries it was different.

Dr. H. C. Fairbrother of East St. Louis said the picture complex of a fracture of the base of the skull was variable, and not the same in any two cases, depending on the site of fracture, the amount of hemorrhage, and the crushing force producing the fracture, so that there was no definite picture of symptoms pointing to certain fractures of the base of the skull, and the only certainty in arriving at a conclusion is by post-mortem examination in fatal cases.

Dr. McDonald, in closing, on his part, said that an ice-cap may be used when indicated only, and then not applied to the site of the fracture, as it would delay repair.

Dr. Tarnowsky, in closing, said he thought the diagnosis of fracture of the base and of diastasis of the temporoparietal articulation was positive in his case and not guesswork.

Injuries to the Diaphragm.—Dr. John Young Brown of St. Louis delivered an address on this subject, in which he emphasized the importance of early diagnosis and the prompt surgical treatment of these injuries.

Further Studies in the Treatment of Tuberculous Sinuses, Fistulous Tracts, and Abscess Cavities.—Dr. Emil G. Beck of Chicago said that in the ten cases presented before the Chicago Medical Society, January 15, the fistulæ had remained closed, and the two which at that time had a slight discharge had since closed. A longer series of cases treated since, with equally good results, had taught him some new points. First, the bismuth paste, if it was not discharged during the healing process, became encapsulated and finally absorbed. In cavities with rigid walls, the bismuth plug became first organized by connective tissue, and after absorption of the bismuth, fibrous tissue remained. When the walls of the abscess were resilient, such as the pleura, for instance, they would gradually collapse while the bismuth was undergoing absorption. This could be proven, first, by the taking of radiographs at certain periods; second, by physical examination of the patient; third, by microscopic examination of tissues. Bismuth subnitrate, although considered an insoluble substance, had been proven to be absorbed, when taken internally, or injected into fresh wounds. It was found by many observers in the urine, blood and milk, as well as in the organs thirty days after ingestion. Having proven the absorption of bismuth, the practical question arises, Is the absorption harmful? Little was heard of poisoning by bismuth, although nearly every practitioner prescribed it, and radiographers administered as much as forty grams of pure bismuth subnitrate in one bismuth meal, to obtain radiographs of the digestive tract, and none had observed any ill-effects from it. A few authentic cases of bismuth poisoning found in literature had put him on his guard, but in about two thousand injections he had not yet met with any symptoms of poisoning. Guinea pigs were injected with 1-20 of their body weight of bismuth paste, exhibiting no symptoms of poisoning. Arsenic-free bismuth might be considered harmless, but it was safer not to use more than 100 grams of the 33 per cent. bismuth-vaselin paste in the first injection. The bactericidal value of bismuth subnitrate had been underestimated. It had been determined by him that its presence in the living tissues invariably caused the gradual diminution and often a complete extermination of microorganisms in the secretions. The *Bacillus tuberculosis* shared the same fate. The discharge from the fistula likewise changed from a purulent or a seropurulent to the serous. The method was contraindicated wherever the plug might obstruct the secretion from vital organs, or in the cranial cavity, where pressure on the brain might cause serious damage. There was a promising field in the sinuses of the head. Five cases of resisting suppurative disease of the antrum of Highmore had been cured by Dr. Joseph C. Beck by this method. The most important advance made since January 15 was the prevention of tubercular sinuses. The method was as follows: A cold abscess following tuberculous disease should, under the most aseptic measures, be opened by an incision about one-quarter inch long, the pus evacuated, the cavity refilled at once with half the quantity of a ten per cent. bismuth-vaselin paste, and the opening not sealed. A sterile gauze dressing was placed over the incision and a five-yard sterile gauze bandage was snugly put on and securely pinned, so that the patient, usually a child, could not displace and infect it. Fresh dressings are to be applied daily under aseptic measures. Should the opening close and fluid reaccumulate, it should be reopened; the fluid, which was then more serous, squeezed out, but the cavity need not be refilled, as it would usually remain collapsed. Three cases so far treated in this way had demonstrated the practical value of the prophylactic method by bismuth paste injection.

The Treatment of Joint Tuberculosis.—Dr. Edward H. Ochsner of Chicago said that the treatment of joint tuberculosis naturally came under three headings—general hygiene, the treatment best suited for joints in general, and the special measures required for each individual joint. Under hygiene we must give special attention to fresh air and proper food. Under the second heading we must strive to relieve pain and to raise the resisting power of the patient. This could be best accomplished by absolute immobilization, subcutaneous injections of minute doses of Koch's new tuberculin under the control of the opsonic index, and the prevention of secondary infection. If secondary infection should occur, the sinus could usually be healed by the injection of bismuth paste. In immobilizing the joints there were two points to be observed: First, to immobilize it absolutely, and (2) to put the limb in such a position that the antagonistic muscles were in perfect equilibrium. If this was accomplished, the muscle spasm would soon subside, the pain would be relieved, and a long step taken towards a cure of the affection.

Fetal Death in Utero.—Dr. C. G. Smith of Red Bud read a paper on this subject, in which he drew the following conclusions: (1) The fetus becomes to all intents and purposes a foreign body in the uterus as soon as it ceases to be viable. (2) It is not good practice to permit a fetus to remain in a woman longer than fifteen or twenty days after it has perished. Procrastination here may become equally as harmful as meddlesome early interference. (3) The removal of a dead fetus by careful surgical procedure, without the use of emmenagogues or ecobolics, when carried out along the lines of strict surgical cleanliness, can not work harm to the woman. (4) It appears that the advanced age of the parturient woman, in some cases, reduces the general vitality of those forces which are

concerned in the work of developing the product of conception, and this reduction of vitality may become the prime factor of intrauterine death.

Ectopic Gestation.—Dr. Arthur B. Eustace of Chicago reported a case of ectopic gestation which presented some interesting features, and drew the following conclusions: (1) The probabilities are that an intrauterine pregnancy in this case did not exist and that the gangrenous condition of the appendix was secondary to a suppurative process in the right Fallopian tube. (2) That a positive diagnosis of the conditions within the abdomen could not be made. (3) The surgical technique primarily used, *i.e.* vaginal celiotomy, was contraindicated, as it was impossible to use the proper surgical therapy necessary to correct the intraabdominal condition by the vaginal route. If later a laparotomy had not been performed, the condition of the vermiform appendix and the right Fallopian tube might never have been recognized, unless found at autopsy, whereas his patient made a complete recovery.

Treatment of General Peritonitis Complicating Appendicitis.—Dr. Daniel N. Eisendrath of Chicago reviewed briefly the principal points in the pathology and diagnosis of this complication of appendicitis. Although it was formerly regarded as a much dreaded condition, it was now felt that the surgeon could control the outcome in the majority of cases if they were seen during the first twenty-four to seventy-two hours. The reasons for this improvement were a rapid technique in removing the source, *i.e.* the appendix, a minimum amount of manipulation of the intestines with no irrigation, the use of the Fowler position, and the continuous administration per rectum of normal saline solution.

President's Address.—President Baum, in this address, suggested a State Commissioner of Health and a Board of Medical Examiners in lieu of the present State Board of Health, saying that these two separate offices had worked well in other States. This matter would be referred to the Legislative Committee, who would be instructed to prepare a bill covering the recommendation and present it to the State Legislature.

Some Observations on Ophthalmia Neonatorum.—Dr. Willis O. Nance of Chicago related some personal observations on the management of purulent conjunctivitis in the newly-born. He emphasized the value of Credé's method of prophylaxis, and pleaded for its more general adoption in private practice. The idea that ophthalmia neonatorum and gonorrheal ophthalmia were always one and the same did not hold good in the light of modern thought and investigation. Seventy per cent. of the author's cases were gonorrhea; the pneumococcus was responsible in ten per cent., and the staphylococcus, diplobacillus, and *Bacillus coli* were found in the remainder. Silver nitrate was the remedy *par excellence*, and no other preparation could take its place. Irrigations with permanganate of potassium, 1-15,000, by fountain syringe, using from one to two quarts three times a day, had proven particularly efficacious. When the lids were swollen, canthotomy was indicated. Warm applications were preferable to cold; the former, by stimulating circulation, enabled the leucocytes to wage a better fight against the pathogenic germs of the disease. Corneal complications were responsible for loss of sight. If haziness or ulcer developed, it was usually an indication that the treatment was illy chosen, or that it was being ineffectually carried out. If the disease was recognized early, and intelligent treatment was instituted promptly, there need be little fear of an unfavorable outcome of the disease. The worst stage of the disease should be when the case was first seen.

Diagnostics in Spinal Surgery.—Dr. Julius Grinker of Chicago said that a correct history of the past illnesses and injuries was absolutely necessary because of the frequent connection of past trauma with the development of surgical diseases of the spinal cord. Attention should also be paid to the order in which symptoms developed, and whether the onset was slow or sudden. The objective examination would concern itself with disorders of (*a*) motility, (*b*) reflexes, and (*c*) sensation. The determination of the exact level of the disease and what structures in the cord were involved would occupy the greater portion of time. Finally, the relation of the objective cord findings with past and present history and possible findings in other parts of the body would often enable the surgeon and physician to make not only a localizing but also a pathological diagnosis. Modern spinal surgery depended entirely on modern methods which were based upon the recent painstaking labors of laboratory and clinical neurologists.

Traumatic Lesions of the Cord.—Dr. R. C. Borland of Rockford followed with a paper on this subject, in which he favored immediate operation on apparent crushing injuries of the spinal cord involving the entire extent of the cord.

The Ophthalmoscope.—Dr. Cecil M. Jack of Decatur drew attention to this instrument as an aid in diagnosis in general practice and said its use had not received the importance it deserved.

The Sanatorium; Its Influence and Value.—Dr. J. W. Pettit of Ottawa said the sanatorium must be considered from a business standpoint and conducted on business principles. Just in proportion as physicians departed from business methods in the conduct of these institutions just to that extent was their usefulness impaired and failure invited. It was not possible, except on the most extravagant scale, to provide for even a majority of these sufferers; therefore it was the duty of those most prominently identified with their care not only to devise inexpensive methods, but to firmly oppose the present tendency to extravagance and lavish display which characterized all of our leading sanatoria.

The Tuberculosis Dispensary.—Dr. Ethan A. Gray of Chicago said the dispensary was, in the smaller cities exactly as it was in the larger, a most economical and efficient means of treating the moderately advanced indigent consumptive. Its influence was, in his opinion, quite as broad, if not broader than the sanatorium, by reason of the larger number of patients reached. Especially was this true where house conditions permitted of the ideal home treatment.

How Shall We Apply the New Antituberculosis Law?—Dr. E. J. Brown of Decatur said that if in each county the local medical society as a body would take up this matter and obtain through the referendum a carrying out of the provisions of this act in their respective communities, many hundreds of cases could be successfully treated, further infection of other people could be prevented, and millions of dollars saved to their families and the State thereby.

Frontal Sinus Surgery.—Dr. A. E. Prince of Springfield exhibited two typical cases, one a frontal sinus obliteration after the Killian method, in which the anterior wall of the frontal sinus was removed, and the other after the Jansen method, in which the floor of the frontal sinus was removed, thus eliminating the deformity. Dr. Prince spoke of three things which had heretofore retarded the progress of frontal sinus surgery, namely (1), danger to life. This was obviated by the use of radiographs, which indicated the lateral and antero-posterior diameter dimensions of the sinus. (2) Doubtful cure. This was corrected by thorough curettement and perfect drainage, the thoroughness of which had been emphasized and popularized by Prof. Killian, who removed the anterior portion of the os planum and the diseased cells of the ethmoid. He also removed the anterior wall of the sphenoid when necessary. (3) He emphasized the fact that the Killian operation, although excellent as regarded a cure, was not desirable for the American people, who placed a great deal of stress on personal appearance. This objection had been met by a modification of the Jansen operation, which was

especially advocated by Dr. Arnold Knapp of New York. Dr. Prince exhibited a further modification which was illustrated by one of the cases exhibited, showing no deformity. In this operation an incision was made along the eyebrow, but did not extend down the side of the nose. He presented a new rongeur forceps, which enabled him to remove the floor of the sinus, the anterior ethmoid cells, and to make a free communication into the nose through a comparatively small incision, which made the operation entirely devoid of deformity.

The following papers were also read: "Self-Cure by Advertised Medicine; or, Does It Pay to Have a Doctor?" by Dr. Chas. L. Mix, of Chicago; "Serum Diagnosis of Syphilis," by Dr. Wm. J. Butler, of Chicago; "Five Hundred Consecutive Cases of Alcoholism," by Dr. J. F. Hultgen, of Chicago; "Placenta Prævia," by Dr. F. D. Hollenbeck, of Chicago; "An Interesting Case in Diagnosis Confirmed by Surgical Operation," by Dr. C. B. Horrell, of Galesburg; "Diagnosis and Treatment of Acute Tenosynovitis of the Hand," by Dr. Allen B. Kanavel, of Chicago; "The Significance of Inflammation and Its Treatment," by Dr. S. C. Stremmel, of Macomb; "Psychic Aberrations Associated with the Diseased Prostate Gland," by Dr. J. F. Percy, of Galesburg; "Obstetrical Work by the Country Doctor," by Dr. C. B. Brown, of Sycamore; "Extrauterine Pregnancy and Hematocele," by Dr. A. Belcham Keyes, of Chicago; "Plea for More Active Cooperation with the Local Secretary," by Dr. C. Hubart Lovewell, of Chicago; "Fracture of the Patella," by Dr. A. P. Heineck, of Chicago.

Officers.—The following officers were elected: *President*, Dr. J. W. Pettit, of Ottawa; *First Vice-President*, Dr. J. L. Wiggins, of East St. Louis; *Second Vice-President*, Dr. E. M. Eckhard, of Peoria; *Secretary*, Dr. E. W. Weis, of Ottawa, reelected; *Treasurer*, Dr. E. J. Brown, of Decatur, reelected.

Quincy was selected as the place for holding the next annual meeting; time, third Tuesday in May, 1909.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 23, 1908.

DR. WILLIAM S. STONE IN THE CHAIR.

Report of Two Cases of Fecal Fistula, One Abdominal, the Other Ileovaginal; Operation; Cure.—Dr. CHARLES F. ADAMS reported these cases:

CASE I.—This case had been referred to him on July 23, 1907, by Dr. F. M. Burke of Brooklyn. She was forty-six years of age, had been married at the age of seventeen, and had seven children, the last fourteen years ago. She was well-nourished, and her general condition was good. She had had a feeling of bearing down for nearly a year, but no pain. For six months she had had a bloody discharge on intercourse. Examination showed the uterus high up in the pelvis, and barely reached by the examining finger. The cervix was completely involved in a cancerous growth, and the vaginal walls partially folded in over the growth. There was a serosanguinolent discharge with characteristic odor, and the cervix bled at the touch of the finger. The patient was told that the growth would probably return if removed, but she decided to risk an operation, and was admitted to the hospital on July 29, 1907. The following day she was operated upon. Dr. Adams had at first intended to do a partial vaginal hysterectomy, but the uterus was so high in the pelvis, and the vaginal walls so voluminous, with a narrow vaginal outlet, that he decided to go in from above. The uterus and appendages were removed, which was very difficult, as a large part of the operation had to be done by the sense of touch. The incision was closed in layers, plain catgut for the peritoneum, and chromic No. 2 for the fascia, and a subcuticular suture for the skin. Considerable shock followed the operation, but she experienced absolutely no pain after coming out of ether. The pulse kept about 120, and the temperature from 100° to 103° for four days, when the dressing was removed, and a foul seropurulent discharge was observed coming from the lower part of the wound. On the following day there was a separation of the lips of the incision down to the fascia with necrotic edges. The next day the whole line of incision had given way. The upper portion of the wound was covered by the omentum, but the lower part showed peristalsis taking place. For several succeeding days the wound was carefully dressed. On the sixteenth day, a tiny fecal fistula appeared in the most prominent loop of the small intestine. It was hoped that, as the fistula was so small, it might close up of itself, but he was disappointed. One morning he touched the opening with a stick of pure nitrate of silver, and the following day he found the opening the size of a goose quill, and the patient flooded with fecal discharge, the skin about the opening being badly excoriated. He operated upon her a second time, just one month after the first operation, and found the intestines bunched up in a mass in the incision, and densely adherent. In separating them, he made several more holes, which he sewed up. The original fistula was freed by removing a wedge-shaped piece from the free border by which he was able to get healthy tissue to unite without interfering with the mesenteric attachment. In closing the wound, he used through-and-through sutures of catgut, interrupted with knots coming inside the gut and Lembert sutures of catgut over this. The abdominal wound was partly closed with catgut, making use of a three through-and-through suture of silver wire and tension sutures, and not closing the wound tightly at the lower extremity for the purpose of giving drainage. There was a slight leakage of fecal matter on the third and fourth days, after which the patient made a good recovery. She was at present in good health, although there was considerable thickening in the vault of the vagina.

CASE II.—This was a case of illeovaginal fistula, operated upon in St. Mary's Hospital, Jamaica, on August 20, 1906. The patient was thirty-three years of age, and had one living child. In October, 1905, she had had a criminal abortion performed, and had peritonitis; she was confined to her bed until the following June. During this time a fecal fistula developed, establishing a communication between the small intestine and the vagina. She claimed that it appeared directly after the attempt at abortion. There had been a profuse discharge of fluid feces. Her weight fell from 154 to 94 pounds. Under the anesthetic examination showed a fistulous opening in the right vaginal fornix, which allowed a probe to pass for several inches; with the finger in the rectum, it was demonstrated that it did not communicate with that organ. With the exception of some thickening to the right of the uterus around the site of the fistula, the uterus and appendages seemed to be normal. The abdomen was opened in the median line. A loop of the intestine was found firmly bound down in the cul-de-sac extending from the median line to the right. This was freed with difficulty, and found to be the real seat of the fistula. About fourteen centimeters of intestine were resected, and the ends brought together with a Murphy button. The fistulous opening in the vagina was enlarged, and gauze drainage introduced. The patient made an uneventful recovery, the button coming away on the twelfth day.

Dr. ABRAM BROTHERS said he was interested in the question of when one should operate for the various forms of fistula. He had seen fistulas occurring after operation heal spontaneously. His cases had uniformly healed of their own accord. Some of these fistulas had followed operations for appendicitis, and some had followed operations on the adnexa, etc.

Dr. ADAMS said he thought that where the large intes-

tine was involved one could not get good results by any other than operative measures.

Dr. Brothers believed Dr. Adams was correct, when the sigmoid, rectum, or other portions of large intestines were involved.

A Case of Strangulated Dissecting Hernia, Simulating Peritubal Suppuration; Exsection; Recovery.—Dr. Arnold Sturmdorf related the history of this case. He said that "dissecting" properitoneal, or intestinal hernia, as it was called, was uncommon, especially in the female. The form known as the parainguinal was presented by the case related. The hernial canal ran parallel to the inguinal canal without any anatomical relation to the inguinal rings proper. The hernial sac, with its strangulated contents, was fixed within the layers of the abdominal parietes. The cases reported in literature like the present case were usually not detected until strangulation was present, so that it was difficult to detect exact conditions. The term parietal was applied to those cases in which the sac existed between the layers of the abdominal wall, either in the loose connective tissue existing between the peritoneum and the fascia transversalis, or between the internal and external oblique. The sac might spread in several directions, sustaining constrictions by fascial and muscular bands producing the bilocular or multilocular forms of this hernia. Of 115 cases collected by Gobell, 111 were in males and four in females. The occurrence of these hernias was attributed to a congenital diverticulum of the peritoneum escaping through abnormal ostia, resulting from embriological imperfections in the abdominal parietes. The case in question was a Russian, thirty-four years of age, married eight years, had had six children and two miscarriages. Her family and previous history was negative. Her present trouble dated back one year, and was supposed to have followed a currettage after the last miscarriage. The symptoms were attacks of pain with intervals of pain and fullness of the right side on a transverse line inwards, and about one inch from the anterior superior spinous process, some constipation, and leucorrhea. She had been treated for "womb trouble" in the outdoor department of Mt. Sinai Hospital. Five days before admission to the speaker's service she was seized with an attack of pain more severe than any hitherto experienced, which was accompanied by uncontrollable vomiting and constipation. The vomiting was not fecal, but the constipation was complete. The temperature was 100.8°, and the pulse 120. The general condition was good. One inch to the inner side of the right anterior superior iliac spine an infiltrating, resisting mass seemed to invade the abdominal parietes, covering an area of about four fingers' breadth and extending downward toward the right adnexa, which presented evidences of an old infection. The uterus was fairly mobile, and the left adnexa normal. The urine showed increased indican, the blood a leucocytic count of 23,400, with 94 per cent. polynuclears. These points seemed to suggest an old suppurative process with intestinal obstruction, due to adhesions or inflammatory bands. An incision was made directly over the prominent point of the mass. Dissection through the infiltrated muscles down to the transversalis fascia revealed a hernial sac with six inches of gangrenous ilium, constricted by an abnormal opening in the fascia, the hernia lying between the fascia and the peritoneum. The normal condition of the inguinal rings and canal was easily demonstrable. Exsection of the involved gut with its mesentery, followed by anastomosis, resulted in complete relief of all symptoms and the entire recovery of the patient.

Pregnancy Toxemia, Dead Fetus, Cicatricial Cervix, Vaginal Cesarean Section.—Dr. LeRoy Broun related the history of Mrs. H., aged thirty-seven, mother of several children, who consulted him on March 22, stating that she had not menstruated since September 19, and that she had only felt life on one occasion. Examination revealed the presence of a large fibroid in the fundus of the uterus, associated with pregnancy. The fetal heart was 150. Her temperature was normal and urine contained no albumin. The scant amniotic fluid brought the fetal parts into strong relief, simulating the presence of other fibroids. The head seemed to press firmly against the cul-de-sac. The possibility of this being a fibroid was admitted. The following day the physician was sent for on account of vomiting, though her condition was apparently good. Her pulse was 110, and she passed a good amount of urine. Her family objected to her going to the hospital, but finally, on March 30, she was brought to the Woman's Hospital, where Dr. Broun saw her, and found her without any radial pulse. Three ounces of urine, heavy with albumin and casts, were withdrawn. Her condition precluded any anesthetic. The cervix, which was hard and sclerotic, was dilated sufficiently to admit a finger. A bougie and bag were introduced. The patient was bled ten ounces, and a pint of salt solution was put under each breast every two hours; rectal irrigation with hot saline solution was kept constantly running. Within the next twelve hours she passed three drams of urine, and at the end of twelve hours her pulse became perceptible at the wrist. The uterus was then emptied by a vaginal cesarean section, the entire operation taking fifteen minutes. The saline injections and rectal irrigation was continued, but the kidneys ceased to act, and the patient died eighteen hours after the operation. No autopsy could be obtained, but Dr. Broun believed there were degenerative liver changes associated with some kidney lesion; otherwise, he could not explain the vomiting, which continued for four days, and the failure of the kidneys to respond after emptying the uterus. He presented the fetus, which had a marked spinal deformity. He presented the case for the purpose of accentuating the value of vaginal cesarean section in cases requiring rapid emptying of the uterus, when the existence of a sclerotic cervix rendered instrumental dilatation a dangerous operation. The existence of an unyielding cervix was risky in the extreme, being almost certain to be attended by deep tears to the base of the broad ligament, even extending to the lower segment of the uterus, followed by profuse hemorrhage. Vaginal cesarean section was practically devoid of danger in skillful hands, and could be performed in fifteen to thirty minutes.

Drainage After Rupture of Recent Ovarian Abscess.—Dr. LeRoy Broun reported this case, a woman, twenty years of age, married, who had aborted two weeks previous to entering the hospital. Since aborting there had been a vaginal discharge and tenderness over the lower abdomen. There was a tuboovarian mass on the left side, which was removed. The condition was one of salpingitis with a small ovarian abscess. The abscess was ruptured during removal, but the intestines were not soiled. On account of the recent occurrence of the infection, a pelvic gauze drain was introduced, isolating the site of the operation. The patient made the usual recovery, with the exception of a staphylococcus infection of the abdominal wound. He reported this case to bring out the fact that a certain class of cases should be drained. Tuboovarian abscesses of long standing were uniformly sterile, and operations for these need not be followed by drainage. In such cases, drainage was necessary only to stop oozing from a large raw surface, or in order to render certain necrotic areas in the site of the old abscess extraperitoneal. In the class of patients to which the case reported belonged, the bacteriological activity remained for some time after the subsidence of the acute condition of the uterus, and in such cases he had had the best results by introducing drainage.

Dr. Abram Brothers said that he thought every case of vaginal cesarean section should be placed on record. He wished to report a case operated upon about three months ago for conditions almost parallel to those of the case reported by Dr. Broun. The patient was a primipara, seven months pregnant. She was known to have albumin

in her urine one week before operation. She was placed in the best dietetic and hygienic surroundings in order to overcome the toxemia. She was seized with her first convulsion with a urinary secretion of forty ounces. Two more convulsions followed within a short time, and with no signs of labor coming on and a rigid cervix, he decided that a cesarean section was justified. As the patient was in no condition to be removed to a hospital, he performed the operation at her home. The convulsions ceased, and she went on to complete recovery except for a small vesicovaginal fistula, which he proposed to close in the near future.

Dr. Samuel W. Bandler said that he had had the opportunity of performing three vaginal cesarean sections, and the results in all three cases had been most gratifying and without injury to the mother.

Dr. Arnold Sturmdorf said he had had one sad experience with toxemia of pregnancy. His patient was a doctor, who was anxious to have offspring. The urine was examined regularly, and absolutely nothing was found. At 12 o'clock he was summoned, and found Dr. Dorman doing post-mortem cesarean section, trying to bring a living child into the world. At autopsy there were found the characteristic changes in the kidneys. There were no cardiac lesions. As to the question of pelvic drainage, he said that in acute conditions in the presence of temperature or of acute infection they should drain. Once the acute stage had subsided, it made no difference whether they drained or not. In subacute or chronic stages of suppuration the pus would seek the path of least resistance, and the introduction of gauze drainage might block the pus.

Dr. William S. Stone said that in acute fulminating cases, whether you emptied the uterus or not, the result would be the same. Such cases were analogous to cases of putrefaction from retained gestation products, with chills, rise of temperature, and the patient going on to complete convalescence.

Demonstration of a Manikin of the Pelvis.—Dr. Dougall Bissell presented this manikin, in order to demonstrate the operation for retrodisplacements about the round and broad ligaments. The after-treatment of these cases had not received sufficient attention. If the bladder was allowed to collect ten or fifteen ounces of urine it would force the uterus back further than one would imagine. This he demonstrated with the manikin. The bladder should be emptied more frequently after these operations than was often done.

Uninterrupted Tubal Pregnancy.—Dr. Hermann J. Boldt reported this case. Mrs. H., thirty-four years of age, mother of one child, was operated on September 9, 1904, for ruptured tubal gestation, complicated by peritonitis. The ruptured part of the tube was tied off, and the remnant with the ovary left. The right Fallopian tube was found to be in a condition of catarrhal inflammation, but was left *in situ*. The patient remained in excellent health until March 25, when she had gone four days over her period, and wished to know whether she was pregnant, as she had made arrangements to go to Europe in a few weeks. Examination showed the uterus to be slightly enlarged. To the right of the uterus a tubal swelling was felt, which was slightly sensitive to the touch. The diagnosis was made of either an early intrauterine pregnancy with an acute salpingitis, or a tubal gestation with the usual accompanying changes in the uterus. There being no etiological factor for the sudden acute inflammation of the tube, he leaned to the diagnosis of tubal pregnancy. Three days later there seemed to be no change, except that the swelling was more sensitive. A day later she began to stain. On April 1, the swelling was more sensitive and larger, and, despite the fact that the woman had no subjective symptoms, he felt sure of his diagnosis, and decided to operate. The tube was exsected and the ovary attached into the cornu. The remnant of the other tube was also exsected and the ovary attached to the cornu. The large appendix, which was inflamed, was also removed.

Progressing Tubal Abortion.—Dr. Hermann J. Boldt reported this case. This patient had had her last child five months ago, and was operated on April 13. She complained of irregular bleeding and severe cramplike pain in the lower abdomen. She also had pain in the lower rectum. A mass three inches in diameter was found to the left of the uterus. The uterus was slightly softer than normal, but not appreciably larger. The patient was supposed to have aborted, and had been curretted, and the mass was thought to be of inflammatory nature. On opening the abdomen, the fimbriated end of the tube was found to be occluded by adhesions with the omentum and intestines surrounding the tube, all of which were firmly adherent. The ovary being seriously affected, it was removed with the tube. Both patients were out of bed three days after the operation.

The Development and Malformation of the Female Genitalia.—Dr. Henry P. DeForest read this paper. He said that there was no treatise in existence in which the origin and development of the genital apparatus in the female was discussed, and at the same time the ultimate outcome of the variations in the normal development as they occurred in the adult was exemplified. He had tried to coordinate the two subjects and to show the comparison of the development and the malformation of the female genitalia. The three structures concerned in the formation of the sexual organs of both male and female, the Wolffian body and its duct, the Müllerian ducts, and the genital gland, existed in every embryo at an early stage of fetal life. As development progressed, the Müllerian ducts were principally concerned in the formation of the female sexual organs, while the rôle played by the Wolffian bodies was of little importance. In the male the Wolffian bodies played a principal part in sexual development, and the ducts of Müller were not entirely obliterated and the uterus masculinus might be of sufficient size to show a distinct uterine formation. The genital gland developed in the first instance into the ovary and in the second into the testicle. There was a tendency at the present time to maintain that sex was predestined from the very ovum itself, and while this theory was not firmly substantiated, it might also be true within the ovum cell. Variation might exist from the very onset of embryonic life. The fact remained, however, that from time to time individuals developed, presenting in one person well marked characteristics of both sexes, although, as a rule, one sex predominated. By reason of the wide variation of forms that had been observed, a more or less elaborate system of classification had been defined. He had used the one adopted by Van Cott. The general condition was known as hermaphrodisnus. There were two varieties, true and false. In the true the female generative organs were present; in the false either a male or female genital canal and either male or female genitalia. There were three forms of the true varieties: 1. Bilateral, ovaries and testicles on both sides. 2. On one side an ovary and on the other a testicle. 3. Unilateral, on one side ovaries and on the other testicles. In the majority of the cases of the true variety functionally active male and female organs were not present. Either the ovaries or testicles were stunted. There were two forms of pseudohermaphrodism, male and female. The male pseudohermaphrodism fell into three subdivisions: A. Complete: Testicles present, also tubes, uterus, vagina, and female external parts. B. External: Testes and male genital canal with female internal parts. C. Internal: Persistence of Müllerian ducts, rudimentary vagina, uterus, and tubes; testes and male external parts. The female pseudohermaphrodism (with ovaries) fell into three divisions: A. Complete: Ovaries, persistent Wolffian bodies and all male external genitals. External: Ovaries, internal female genital canal, external male organs. C. Internal: Ovaries, external female

genitals, persistent Wolffian duct. The majority of the false varieties of hermaphrodism belonged to the male sex. Dr. DeForest then related the following case. The individual was 24 years of age. The family history could not be obtained. The person had been reared as a woman, had menstruated regularly, and in both appearance and manner of life was regarded as a young woman of rather prepossessing appearance. She had no growth of hair upon the face or elsewhere, except on the pubic and axillary regions. She lived in a boarding house where was also a man of fifty and his daughter of eighteen. She lived with this man as his wife in a surreptitious manner, became pregnant, and was delivered of a child. In the meantime the daughter of the man became very friendly with her, and the masculine side of her nature asserted itself, and, overcoming the scruples of the girl, they lived together as man and wife. The daughter became pregnant and in turn was also delivered of a child. No further history of this unusual case could be obtained. A photograph was exhibited, showing the upper part of the body to be that of a well developed woman, the hair long, the contour of the face, though somewhat masculine in type, suggested a woman rather than a man. The breast were large and well developed. The lower part of the body was distinctly masculine in type, the pelvis and hips narrow and the external genitals, upon superficial inspection, were those of a man. The penis was well developed and both testicles were present and of large size. Another photograph showed that upon raising the penis and supporting the two halves of the divided scrotum, the vagina was exposed. The condition and arrangement of the internal organs could only be conjectured, but, in view of the fact that menstruation and impregnation took place, there was no doubt that a uterus existed and that one or both ovaries were present and functionating.

Dr. Samuel W. Bandler, Dr. Abram Brothers, Dr. H. V. Vineberg and Dr. LeRoy Broun discussed the paper.

Dr. DeForest closed the discussion.

SIXTH INTERNATIONAL CONGRESS ON TUBERCULOSIS.

Held in Washington, D. C., September 21 to October 12, 1908.

(Special Report to the Medical Record.)

SECTION ON PATHOLOGY AND BACTERIOLOGY.

Fourth Day—Thursday, October 1.

The Problem of Immunity in Tuberculosis.—Dr. Edward R. Baldwin, Saranac Lake, in a brief review traced the beginning of preventive inoculation experiments from the time of the discovery of the bacillus by Koch. The Americans were among the earliest to achieve a degree of success, especially Trudeau and de Schweinitz. Results on the whole were discouraging. The soluble extractives of tubercle bacilli having failed to immunize animals, Koch introduced the emulsions of new tuberculins which were partially successful. The discovery of differences in virulence between typical human and bovine types of bacilli by Theobald Smith gave an impetus to investigations of protective inoculations in cattle. To overcome the objections due to the use of living human bacilli and to apply the principle of immunization to human beings was the next step. Hope of this achievement was held out by von Behring in 1905, but nothing definite had been made public since then to indicate that this hope was justified. Other investigators had since worked with encouraging success—Pearson and Galliland, Calmette and Guerin, Heymanns and Klimmer. The situation now was not hopeful for the establishment of a long-continued immunity. Repeated protective treatment must be considered necessary from the present outlook and by means of an agent equally innocuous to cattle and mankind. The problem of passive immunity was still a distant goal which should not be forgotten; on this rested the hope of an efficient therapy.

Immunization Against Tuberculosis.—Dr. A. Calmette and C. Guerin, Lille, had published some time ago articles showing that it was possible to produce in cattle, goats, and guinea pigs a marked resistance to artificial tuberculous infection by way of the digestive tract. The resistance was obtained by feeding the animals emulsions of bovine tubercle bacilli. In cattle a single ingestion usually sufficed to produce an infection so slight that after reacting to tuberculin for one, two, or three months the animals ceased to react and became capable of resisting repeated doses of tubercle bacilli which infected the control animals. They possessed a special resistance against fresh tuberculous infections, a resistance which was in every respect comparable to that which Koch first observed in tuberculous guinea pigs that had received an injection of a fresh dose of virus. There could be no doubt that tuberculous animals and healthy animals prepared by previous large doses of tuberculin possessed incomparably greater resistance than animals which were new to the inoculation.

Experiments in Immunization Against Tuberculosis.—Dr. J. Bartel, Vienna, said the behavior of tubercle bacilli that had entered the body through natural channels indicated a protective action on the part of the cells of organs, especially of lymphocytes, against the infection. In vitro it was possible, with the aid of various organs, especially of a lymphocytic nature, to render living tubercle bacilli virulent by confining them for some time within the organs at a temperature of 38 degrees. This was true of human as well as of bovine bacilli. In the course of attempts to produce immunity on this principle, animals had been successfully immunized against an infection which proved fatal to the control animals

A Contribution to the Study of Tuberculous Immunity.—Drs. Jules Courmont and A. Lesieur, Lyons, made this contribution. The reinoculation of tuberculosis at another point on the body of an animal which was already tuberculous might give a positive or a negative result. They had tested this question on the guinea pig, using virulent cultures of bovine bacilli with the transcutaneous method. Favorable conditions found in the slowness of the process, the insignificance or absence of local lesions, and the magnitude of the caseous glands. The results were clearly defined when two successive inoculations were made at intervals of two weeks. The reinoculation was negative; no local lesion was produced; the glands did not become tuberculous and were never caseous. It was proven that a lesion in process of evolution prevented the evolution of a second inoculation.

Immunity Production by Inoculation of Increasing Numbers of Bacteria, Beginning with One Living Organism; Its Therapeutic Application.—Drs. G. B. Webb, W. W. Williams, Colorado Springs, and Prof. M. A. Barber, Kansas, referred to the importance of using living virus, as attempts to produce lasting immunity against tuberculosis by the inoculations of dead bacilli or their products had not proved satisfactory. A relative degree of acquired immunity to tuberculosis was suggested by the fact that probably 60 per cent. of all autopsies on man showed healed lesions. Organisms were selected from hanging drops, according to the technique of M. A. Barber, and inoculations made subcutaneously. Experiments made with mice, with anthrax bacilli; initial dose, one thread (about three organisms), gradually increased to 500 threads without causing evidence of disease. Immunity was thus produced. Guinea pigs with tubercle bacilli; initial dose, one bacillus, gradually increased to over 10,000, without symptoms of tuberculosis. Evidence of immunity. Rabbits, with tubercle bacilli; results on feeding with tubercle bacilli similar to other experiments.

Tuberculins and the Measure of Their Activity.—Prof. A. Calmette, Lille, in this contribution called attention to the fact that efforts had been made by means of various processes to obtain a purer and more active tuberculin. Koch's old tuberculin contained a large quantity of

foreign substances capable of producing a temporary rise of temperature when injected in nontuberculous subjects. These various attempts to obtain a new substance showed a great desire on the part of pathologists to obtain a product which would possess all the advantages of Koch's old tuberculin without producing the disturbing effects of the impurities. Prof. Calmette had finally prepared for therapeutic use a particularly active and relatively pure tuberculin which could be introduced intravenously into the body of a healthy animal in large doses without producing elevation of temperature, which was impossible with any of the other tuberculins. It was very well borne by tuberculous patients, and physicians experimenting with it in hospitals and sanatoriums had obtained excellent results, He did not claim that it cured tuberculosis, but evidently delayed the progress of the disease and endowed the organism with resistance to the infection.

The Treatment of Pulmonary Tuberculosis with Tuberculinum Purum.—Dr. J. Gabrilovitch, Halila, Finland, presented this paper. The tuberculin contained in full measure the active principles of Koch's old tuberculin. It was prepared from cultures of tubercle bacilli of the human variety, but was so altered by use of chemical agents that when used subcutaneously it no longer produced a general reaction, and could therefore be used in large and rapidly increasing doses, both in children and adults. It had been employed by the author in a sanatorium, as well as in private practice, and with good results. It could be used in cases of acute or subacute tuberculosis.

The Chemistry of the Tubercle Bacillus.—Dr. Victor C. Vaughan, Ann Arbor. The tubercle bacillus was grown in large quantity, and, after having been freed from fats, waxes, and other substances, soluble in alcohol and ether, was split up by an alcoholic solution of alkali into its poisonous and non-poisonous portions. The portion which was poisonous killed animals within a few months when given in doses of 75 to 100 mg. The non-poisonous portion sensitized animals to the tubercle bacillus but was without poisonous action. The non-poisonous portion had been used, and was being used, in the treatment of tuberculosis in man, but as yet it was too early to state whether it was better for this purpose than the old tuberculin.

On the Action of Soaps Upon the Vitality and Immunizing Property of Bacillus Tuberculosis.—Dr. Hidego Noguchi, New York, presented this paper. The experiments were to test the action of soaps on *Bacillus tuberculosis*. Oleate soaps possessed the power of modifying virulent tubercle bacilli so that when subsequently inoculated into guinea pigs they either failed utterly to cause lesions of tuberculosis or the lesions were much slighter in degree. Guinea pigs which failed on inoculation with oleate treated bacilli to develop tuberculous lesions acquired as a result of the inoculation a degree of immunity to virulent cultures of *Bacillus tuberculosis*. Oleate soaps possessed distinct bactericidal properties for bacillus tuberculosis. Addition of the soaps to otherwise favorable culture media prevented the growth of *Bacillus tuberculosis* even when the quantity was small. Solutions of the soaps brought in contact with emulsified bacilli diminished their ability to grow in cultures.

The Part of Enzymes in Tuberculous Lesions.—Dr. E. L. Opie, New York, had studied the enzymes of tuberculous tissue in animals inoculated in the pleural cavity with tubercle bacilli. The enzyme peculiar to polynuclear leucocytes was present shortly after inoculation, but quickly diminished in activity. A second enzyme which digested proteid in weak acid was present in abundance until caseation occurred, but subsequently disappeared. The serum of the exudate which accumulated within the chest lost the power possessed by the serum of the blood to inhibit this and similar enzymes. The enzymes which acted in acid were doubtless present in the epithelioid cells of the tubercle, and were similar to those of the large mononuclear cells of an inflammatory exudate which the epithelioid cells resembled. Autolysis caused by the enzymes no longer held in check might explain the occurrence of caseation in tissue containing products of tubercle bacillus and poorly vascularized.

Histochemical and Cytological Study of Tuberculous Sputum.—Drs. Fernand Benzancon and S. I. de Jong, Paris. The authors were unable to find any characteristic sign of a tuberculous nature of the pulmonary lesions, but discovered differences in the microscopic appearances of sputa, according to the variety and course of the lesion. In the ordinary form of chronic pulmonary tuberculosis the pulmonary endothelial cells were abundant and at first well preserved; often they were macrophagic. Elements often described as lymphocytes in tuberculous sputum were in reality fragments of densely packed polynuclear leucocytes, young pulmonary endothelial cells, or bronchial cells. During the period of cavity formation the degenerative features predominated. The investigations showed that prognostic information might be gained from this study of tuberculous sputum.

Studies on the Calcium Metabolism in Tuberculosis.—Dr. A. C. Croftan, Chicago, had conducted experiments to show that the deutero-albumose, almost universally present in tuberculous foci, sputum, cultures and media, and in the blood and urine of tuberculous subjects and tuberculized animals, when rendered calcium free possessed marked fever producing power in tuberculous animals and human beings, and that this power was lost when the albumose was again combined with calcium. The combination with calcium might, therefore, be considered as a protective antipyretic process in tuberculosis, and might aid in explaining the peculiar phenomenon of increased urinary calcium excretion, and suggested certain therapeutic possibilities which were strengthened by the observation that workers in lime salts seemed to possess a certain immunity against tuberculous infection.

Fifth Day—Friday, October 2.

Some Considerations Concerning Lesions of Tuberculosis.—Dr. W. T. Councilman, Boston, said the character of the tubercular lesion might be modified by the variety of bacillus and the number of bacilli. These differences were brought out by experiments on the lower animals. Animals not susceptible to a small number might be infected by a larger number. There was greater susceptibility of certain organs and local susceptibility due to injury or nutritional changes. Exudation entered more largely into the tubercle of the child than into that of the adult. As to the mode of infection, it undoubtedly took place both by the respiratory and alimentary tracts, as well as by the skin and genital tract. He demonstrated the histology of the tubercle, showing that the most predominant cells were the epithelioid and giant cells. The endothelioid cells migrated from the blood-vessels and were present in the tissue as wandering cells.

The Frequency of Healed Tuberculosis of the Mesenteric Glands, with Particular Reference to the Relationship to Hyaline Deposit in These Glands and the Healing of Tuberculous Lesions.—Dr. A. S. Warthin, Ann Arbor, in the course of ten years' study of the hemolymph nodes, had been struck by the constant presence of hyaline changes or deposits. These were usually spoken of as evidence of retrograde change, and no special value attached to them. He believed that they represented in all cases old healed lesions, and that the nature of the lesion in the majority or all cases was tuberculous. In all the cases of tuberculosis he examined he found transition changes between the lesion and these hyaline deposits. He believed that the intestinal portal of infection was as common and as important, if not more so, than the pulmonary.

Dr. Wm. H. Welch, Baltimore, said that these lesions had, of course, been long recognized, but the suggestion that they were tuberculous was rather new and extremely interesting.

Dr. W. T. Councilman, Boston, thought that though

tuberculosis could lead to these hyaline changes, they could also be produced from a number of other infectious diseases.

Prof. Harbitz, Christiania, agreed with Dr. Warthin that in most cases the hyaline deposits were due to tuberculous infection.

A Fibrotuberculoma of the Pleura.—Dr. Rist, Paris, reported a case of fibrotuberculoma of the pleura weighing ten pounds, occurring in the left pleura of a woman, taking the place of a completely atrophied lung. It was free in the cavity, being attached to the chest wall by a pedicle. Microscopical sections were shown.

Analysis of One Thousand Consecutive Autopsies in Montreal, with Reference to the Incidence of Tuberculosis in the Different Organs.—Drs. J. G. Adami and John McCrea, Montreal, presented this analysis of a thousand cases, showing tuberculosis past or present in 41.7 per cent., or 417 cases.

Anatomical Characteristics of Tuberculous Infections and Their Relation to Tuberculin Reactions.—Prof. S. Arloing, Lyons, showed that the lesions which accompanied tuberculous infection did not always represent tubercles visible to the naked eye. The lesions were sometimes extremely slight and visible only in histological sections. There were some cases in which the bacilli spread in the organism without leaving any trace of their passage. It might be revealed by experimental methods of diagnosis, especially tuberculin and the serum-agglutination test. These tests revealed the existence of infection rather than the presence of appreciable lesions.

The Pneumonic Process in Pulmonary Tuberculosis.—Prof. Raymond Tripier, Lyons, said in the lungs the morbid process in every kind of tuberculous formation was pneumonic, and it was observed that there was a simultaneous tendency to diffuse bronchopneumonia and lobular, sometimes pseudo-lobar, and exceptionally lobar inflammations which, if the condition became chronic, resulted in hyperplastic and sclerotic changes. If these productive phenomena which necessitated an increase of the circulation were frequently seen in pulmonary tuberculosis in spite of the debilitated state of the organism, it was because the caseous, necrotic lesions which were produced by the obliteration of numerous blood-vessels were necessarily accompanied by compensatory vascular dilatation in other portions. The diffuse pneumonic process was followed by diffuse sclerosis, and if hepatization took place it was never gray, but red, and its persistence produced hyperplastic pneumonia and the fibroid changes, which were to be regarded as cicatricial.

The Pathology of Tuberculous Peritonitis.—Dr. Walter Altschul, Prague, said that, although tuberculous peritonitis was quite frequent, as indicated by the fact that he found 299 cases among 10,322 autopsy reports, the recent pathological literature contained practically nothing about the etiology. Among 299 cases he found that 156, or 52 per cent., were women, and of these only 52 showed tuberculosis of the genital organs. By exclusion, the conclusion was arrived at that the infection traveled by way of the lymph channels, the path of infection being from the peribronchial lymph glands through the perforating lymphatics of the diaphragm into the peritoneal cavity, chiefly to the retroperitoneal glands, which were almost always involved in tuberculous peritonitis. That the infection actually did travel by this path was shown by those cases which presented tuberculous lesions only in the retroperitoneal and peribronchial glands.

Periostitis and Adipositis Tuberculosa Toxica Multiplex.—Dr. O. Amrein, Arosa, Switzerland. This was a report of a not yet described form of tuberculous disease, "multiple periostitis and adipositis." The chief characteristics of the disease were diffuse, hard, painful swellings (infiltrations) under the adipose tissue beneath the skin, without being abscesses, combined with infiltration of the periosteum, caused by the toxins of the tubercle bacilli.

Philadelphia County Medical Society.

At a stated meeting held September 23 a symposium was held on "The Division of the Fee." Dr. John H. Gibbon discussed the question from the surgeon's standpoint. He took the ground that such a practice is indefensible, being morally and ethically wrong to all the parties concerned. Both the attending physician and the consultant are entitled to adequate compensation, and the former, when requested, should designate the latter, by reason of his superior skill and knowledge and not on account of the size of a possible commission or division of fee. Dr. S. Solis-Cohen discussed the question from the point of view of the internist. He took the ground that there could be no difference between surgeon and internist as to the indefensibility of the practice. The injunction against procedures of that kind was issued many years ago in the words "Thou shalt not steal." In case of consultation the attending physician should receive from the patient a fee commensurate with the time required, the distance traveled, and the special skill contributed. Dr. M. Howard Fussell expressed the general practitioner's opinion of the evil. He was in entire accord with the views that had been expressed, and could conceive of no condition in which the payment of a commission by the consultant to the attending physician or a division of fees between the two would be justifiable. He felt that often the consultant should impress the patient with the value of the services rendered by the attending physician in arriving at an early and correct diagnosis and soliciting consultation with a view to effective treatment.

College of Physicians of Philadelphia.

At a stated meeting held November 4, Dr. Edward J. Wood of Wilmington, N. C., read by invitation a paper entitled "Studies of the Etiology, Pathology, and Symptomatology of Pellagra, with Reference to Its Endemic Occurrence." He referred to the distribution of the disease and to its recent recognition in the southern part of the United States, where a considerable number of cases have been observed. Here the disease occurs in all grades of society and it appears in two forms, acute and chronic. The former is almost invariably fatal, while the latter exhibits periodicity of recurrence, especially in the spring. Often there are constitutional symptoms, an anorexia, stomatitis, diarrhea, emaciation, together with paresthesial spastic-paralytic phenomena, as well as maniacal excitement, and hallucinations and delusions. A characteristic feature of the disorder is the cutaneous exanthem, which is rarely if ever absent. It appears on the hands, the feet, the face, the back of the neck, and at times in other situations. Often it takes the form of an erythema, while sometimes resembling sunburn. At other times it exhibits a weeping surface and it may be covered by crusts and be the seat of suppuration. Its striking feature is its almost exact symmetry in situation and in form. The disease is commonly attributed to the ingestion of Indian corn supposedly diseased, but it has been observed in persons not exposed to infection from this source, and in those using maize of the highest quality. Bacteria have been found in such corn and likewise in the blood of victims of the disease. No form of successful treatment is known. Drs. George E. de Schweinitz and T. B. Holloway presented a communication entitled "The Operative Treatment of Papilloedema (choked disc), with Special Reference to Decompressive Trephining." They pointed out the improvement in vision when this was impaired, and its preservation if impaired, effected by the relief of intracranial pressure in cases of brain tumor and allied conditions, and they made a plea for early operative intervention under such circumstances if the best results were to be obtained.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Indiana State Board of Medical Examiners.

May, 1908.

ANATOMY.

1. Give the structures of the gall-bladder and its surgical landmarks.
2. Give the origin and insertion of each of the following muscles of abdomen: Obliquus externus, obliquus internus, transversalis.
3. Name each bony prominence of the elbow and give its relations to the joint.
4. Name the blood-vessels and nerves divided in an amputation of the forearm at the union of the lower and middle third.
5. Name the blood-vessels that constitute the portal venous system, and the organs from which each conveys the blood.
6. Give the periods for the eruption of the temporary teeth.
7. Give the branches of the subclavian artery and thyroid axis.
8. Locate an incision for ligation of external carotid, and state what structures are encountered.
9. What muscles effect the displacement of the fragments in an oblique fracture from above, downward and backward, of the femur immediately above the condyles, and how?
10. Make a drawing showing the nine regions of the abdominal cavity with the name and contents of each.

PHYSIOLOGY.

1. Mention the chief heat-producing tissues of the body in the order of their capacity, and state why these structures evolve more heat than others.
2. Give your opinion of alcohol as a food, and state your reasons and authority for such opinion.
3. Define absorption, secretion, and excretion, and state through which anatomical structures each occurs with greatest activity.
4. What is the mechanical effect upon the circulation of the blood of inspiration, normal expiration, and violent expiration?
5. What portion of the vascular system is most susceptible or responsive to the vasomotor nervous influence, and why?
6. In what particular does the condition of the brain in coma differ from its condition in sleep?
7. Explain briefly the difference between emulsification and saponification of oil and fats in the process of digestion.

MATERIA MEDICA AND THERAPEUTICS.

1. Give derivation, physiological action, and indications for the therapeutic application of ergot.
2. Name three medicinal agents which increase diaphoresis.
3. Name an antagonist to the physiological action of jaborandi.
4. Name three medicinal agents which are emetic in their action, and dose of each.
5. Give physiological action, dose, and therapeutic indication for tr. of gelsemium.
6. Name (*a*) a hydragogue cathartic and (*b*) a cholagogue cathartic, and dose of each.
7. Name some therapeutic indications for mercury.
8. What effect has benzoin on urine? Name two preparations of the agent with dose of each.
9. Give derivation, therapeutic indications, and dose of apomorphine.
10. Write a prescription for acute articular rheumatism.

CHEMISTRY.

1. Give antidote in case of poisoning by (*a*) arsenic, (*b*) corrosive sublimate, and (*c*) carbolic acid.
2. Give specific gravity of healthy urine and give test for (*a*) bile, (*b*) sugar, and (*c*) albumin.
3. What is potassium iodide and how prepared?
4. Name the bile salts.
5. Name the fluids of the body that are normally of acid reaction.

PATHOLOGY AND BACTERIOLOGY.

1. How would you determine whether a dog had rabies or not?
2. Give technique of determination of rabies in the dog.
3. Give technique of determination of an epithelioma.
4. What is the difference between a benign and malignant growth?
5. What is meant by a metastatic growth?
6. Give morphology and method of culture of the diphtheria bacillus.
7. Give morphology and method of culture of the tubercle bacillus.
8. Give complete technique of determining a case of diphtheria.
9. How would you stain the tubercle bacillus?
10. What is meant by (*a*) pathology and (*b*) bacteriology?

PHYSICAL DIAGNOSIS.

1. Give technique of diagnostic puncture and the evidence derived therefrom.
2. Define ataxia. How is ataxia of the upper extremities tested? How is ataxia of the lower extremities tested?
3. Give discrimination between organic and functional murmurs.
4. Give technique of cardiac percussion.
5. What is the normal pulse rate? What is the increase for each degree of temperature above normal?

INTERNAL MEDICINE.

1. Give common cause, prevention, and treatment of summer diarrheas of infancy and childhood.
2. In auscultation of healthy lung, what sound is heard, and what is it called?
3. Name some diagnostic symptoms of secondary syphilis.
4. Name the cardinal symptoms of exophthalmic goiter.
5. Give differential diagnosis between renal colic and hepatic colic.
6. Name some of the causes of endocarditis.
7. What conditions predispose to cerebral hemorrhage?
8. Differentiate between cerebral vomiting and gastric vomiting.
9. By what routes and media does the exciting cause of typhoid fever gain entrance to the human organism? How may it be prevented?
10. Name some points of diagnostic value in chronic interstitial nephritis.

OBSTETRICS.

1. State the cause of (*a*) deficient power of the uterine muscle, and (*b*) excessive power of the uterine muscle. Give proper management of each.
2. Define caput succedaneum, and give etiology.
3. Name four important signs of pregnancy at the third month.
4. Differentiate between pregnancy and fibroid of the uterus.
5. Under what conditions would you perform podalic version? Give technique of operation.
6. What changes occur in the circulation at birth?
7. Give the causes of cystocele and rectocele, and state the treatment which should be employed.
8. When should ergot be employed in obstetric practice? What are its contraindications?
9. Name the symptoms of puerperal sepsis. How would you prevent it?
10. What are the premonitory symptoms of puerperal convulsions? What treatment would you employ to prevent puerperal convulsions?

GYNECOLOGY.

1. Define the (*a*) dorsal posture, (*b*) left lateral-prone posture, and (*c*) knee-chest posture.
2. Give causes, diagnosis, and treatment of endocervicitis.
3. Give diagnosis and treatment of ectopic gestation.
4. Give causes, pathology, diagnosis, and treatment of salpingitis.
5. Give preparation of patient for an ordinary plastic operation.
6. Give causes and symptoms of urethrocele. Give differential diagnosis.

SURGERY.

1. Give diagnostic points of fracture of base of skull.
2. Give diagnosis and treatment of appendicitis.
3. Describe a compound fracture and give treatment.
4. Give diagnosis and treatment of gallstones.
5. How many kinds of hernia are there?
6. Through what channels is carcinoma disseminated?
7. What indications are to be followed to promote primary union of a wound?
8. Give signs, symptoms, and treatment of fracture of the clavicle.
9. Give indications for trephining in fracture of the skull.
10. Name five causes of swelling in inguinal region.

PEDIATRICS.

1. Give sequelæ that most frequently follow eruptive fevers occurring in childhood, and state cause and prognosis for same.
2. Give diagnosis, cause, and treatment for cholera infantum.

NEUROLOGY.

1. Give symptoms of cerebral compression.
2. Give definition of dementia and state the more important forms.
3. What are the diagnostic symptoms of multiple sclerosis?

LARYNGOLOGY AND RHINOLOGY.

1. Give treatment of nasal polypi.
2. Give etiology and treatment of hypertrophy of the tonsil.

OPHTHALMOLOGY AND OTOLOGY.

1. Give causes, diagnosis, and treatment of chronic glaucoma.
2. Give symptoms, diagnosis, and treatment of gonorrheal conjunctivitis.
3. Give etiology, symptoms, and treatment of acute inflammation of the middle ear.

ETIOLOGY AND HYGIENE.

1. Give cause and hygienic treatment of diphtheria.
2. What is most essential from a sanitary standpoint in plumbing a bath-room?
3. What method would you use in filtering a city water supply?
4. How would you place a water-closet in relation to a farmhouse?
5. Write an article not exceeding seventy-five words on the practical value of the operation of the Pure Food and Drug Act.

MEDICAL JURISPRUDENCE.

1. Give signs of death by morphine.
2. Define (*a*) delusion, (*b*) illusion, and (*c*) hallucination.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

INDIANA STATE BOARD OF MEDICAL EXAMINERS.

May, 1908.

ANATOMY.

3. The bony prominences at the elbow are: (1) the external condyle of the humerus, (2) the internal condyle of the humerus, and (3) the olecranon process of the ulna. If the forearm is extended, the internal condyle of the humerus, the tip of the olecranon, and the external condyle will all be found on the same transverse line. In extreme extension the tip of the olecranon is slightly above the level of the condyles. If the forearm is flexed to a right angle, the tip of the olecranon is immediately below the condyles.

4. In an amputation of the forearm at the union of the lower and middle thirds there will be divided: (1) *Arteries:* radial, ulnar, anterior and posterior interosseous. (2) *Veins:* radials, ulnars, interosseous, median, anterior and posterior ulnars. (3) *Nerves:* median, radial, ulnar, anterior and posterior interosseous, musculocutaneous and internal cutaneous.

5. The blood-vessels that constitute the portal venous system, are: The (1) *superior mesenteric vein*, which conveys the blood from the small intestines, the cecum, and ascending and transverse colon; (2) *splenic vein* which conveys the blood from the spleen; (3) *inferior mesenteric vein*, which conveys the blood from the descending colon, sigmoid flexure and rectum; (4) *gastric vein*, which conveys the blood from the stomach.

8. The line of incision for ligation of the external carotid artery is the upper part of a line drawn from the sternoclavicular articulation to a point midway between the angle of the jaw and the tip of the mastoid process. The portion above the level of the upper border of the thyroid cartilage represents the line of the external carotid. The *structures encountered* are: The skin; superficial fascia with the external jugular vein and the great auricular nerve; the platysma myoides, and the deep fascia; the anterior border of the sternomastoid; the hypoglossal nerve; facial, lingual, and superior thyroid veins.

9. In oblique fracture of the femur, immediately above the condyles: The lower fragment is tilted backward by the gastrocnemius and plantaris. The upper fragment is drawn inward by the pectineus and adductors; and forward by the psoas and iliacus.

PHYSIOLOGY.

1. The chief heat-producing tissues of the body, are: (1) The muscles, during contraction (including the heart); (2) the secreting glands, especially the liver; (3) the brain, during mental activity.

2. "The exact value of alcohol as a food, broadly considered, is uncertain. Recent experiments, carefully made on man, however, clearly show that when moderate amounts of alcohol are ingested, the alcohol is burned up in the body—*i.e.* oxidized like any non-nitrogenous food. The potential energy of the alcohol is transformed into kinetic energy, and consequently alcohol is to be considered as having some food value. It may, therefore, be classified with the non-nitrogenous foods. Further, as a non-nitrogenous food, alcohol may replace an isodynamic amount of fat or carbohydrate in the diet without change in the balance of income and outgo. Alcohol serves to protect body protein and fat from oxidation; *i.e.* like a typical non-proteid food it diminishes the oxidation of tissue proteid by being itself oxidized. These facts, however, do not imply that alcohol is necessarily a desirable food or that it is physiologically economical. It is to be remembered that, prior to its oxidation in the body, alcohol may produce deleterious effects of various kinds, more than counterbalancing any gain which may result from its oxidation. It may likewise give rise to changes, either directly or indirectly, in the various metabolic processes of the body, which must of necessity influence more or less its value as a food. Alcohol has a direct and an indirect influence upon the secretion of gastric juice. In this direction it acts as a stimulant. It likewise stimulates the secretion of saliva."—(Chittenden in *Reference Handbook of the Medical Sciences.*)

3. *Absorption* is the process by which the products of digestion are taken up into the general circulation. It occurs with greatest activity in the villi of the small intestine.

Secretion is the process by which certain organs (glands and membranes) separate from the blood certain constituents which are further elaborated and serve some further office in the economy. It occurs with the greatest activity in the liver (unless the urine is considered as a secretion).

Excretion is a similar process by which there are removed from the blood waste materials, and products of no further use to the body, and which if retained would be injurious. It occurs with greatest activity in the lungs and kidneys.

4. *Inspiration* causes the blood pressure to rise, and the heart to beat faster, but each beat is shallower.

Expiration causes the blood pressure to fall and the heart to beat slower, but the beats are deeper and more dicrotic.

5. *The portion of the vascular system most susceptible to the vasomotor nervous influence:* The arterioles or small arteries.

The reason: Because they contain relatively the greatest amount of muscular tissue.

6. In *sleep*, the brain is anemic; whereas in *coma*, the cerebral vessels are congested with venous blood.

7. Under the influence of the steapsin of the pancreatic juice, neutral fats combine with water; the result is a splitting up into glycerin and a free fatty acid.

In *saponification* a similar reaction occurs, but the resulting products are glycerin and a soap.

Emulsification is a physical rather than a chemical process; the fat is broken up into minute globules which are in a state of more or less permanent suspension. Soap solutions make the most permanent emulsions.

MATERIA MEDICA AND THERAPEUTICS.

1. ERGOT. *Derivation:* The selerotium of the claviceps purpurea.

Physiological action: Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

Indications for the therapeutic application: To promote uterine contractions during third stage of labor; fibroids, menorrhagia, post-partum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

2. *Three medicinal agents which increase diaphoresis:* (1) Alcohol; (2) Dover's powder; (3) pilocarpus.

3. *An antagonist to the physiological action of jaborandi:* Atropine.

4. *Three emetics:* (1) Apomorphine hydrochloride; dose, gr. 1/10 hypodermically. (2) Copper sulphate; dose, gr. iv to vj in water. (3) Zinc sulphate; dose, gr. x to xv in water.

5. TINCTURE OF GELSEMIUM. *Physiological action:* Circulatory, respiratory, and nervous depressant.

Dose: 8 minims.

Therapeutic Indications: Headache, migraine, asthma, whooping cough, nervous cough, spasmodic dysmenorrhea, torticollis, and other conditions depending upon localized muscular spasm.

6. (*a*) A hydragogue cathartic: Elaterin, dose gr. 1/20 to 1/12. (*b*) A cholagogue cathartic: Podophyllum, dose gr. viij to xij.

8. Benzoin increases the acidity of the urine. Sodium benzoate; dose, gr. xv. Benzoic acid; dose, gr. vij.

9. *Apomorphine* is derived from morphine (by the abstraction of one molecule of water).

Therapeutic indications: To cause prompt vomiting, and as an expectorant (in bronchitis and pneumonia).

Dose of apomorphine hydrochloride: gr. 1/30 as an expectorant; and gr. 1/10 as an emetic.

10. *For acute articular rheumatism:*

℞.

Sodii salicylatis ʒijss
Fluidextracti glycyrrhizæ.
Tincturæ aurantii aa ʒijss.
Aquæ chloroformi q.s. ad. ʒviij. Misce.

Signa: Take two tablespoonfuls every four hours.

CHEMISTRY.

1. The antidote to: (*a*) *arsenic,* is freshly prepared ferric hydroxide; (*b*) *corrosive sublimate,* is white of egg in moderate quantity, followed by an emetic; (*c*) *carbolic acid,* is sodium sulphate, or alcohol.

2. The specific gravity of healthy urine is about 1015 to 1025.

(*a*) *Test for bile:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

(*b*) *Test for sugar:* The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

Fehling's test: Place in a test-tube a few c.c of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(*c*) *Test for albumin:* The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

3. Potassium iodide is a transparent, or milk-white, crystalline, solid; odorless, with a sharp salty taste. It is very soluble in water. It is prepared by saturating a solution of potassium hydroxide with iodine, then evaporating, and calcining the resulting mixture of iodide and iodate with charcoal:

$$6KHO + 3I_2 = KIO_3 + 3H_2O + 5KI$$

4. The bile salts are: Sodium glycocholate and sodium taurocholate.

5. The fluids of the body that are normally of acid reaction, are: The urine, gastric juice, and sometimes sweat.

PATHOLOGY AND BACTERIOLOGY.

4. *Benign tumors* are encapsulated, do not tend to infiltrate the surrounding tissues, do not give rise to metastatic growths, do not tend to recur after removal, do not produce cachexia, and do not have a fatal tendency (except from their location).

Malignant tumors are not encapsulated, tend to infiltrate the surrounding tissues, give rise to metastatic growths, have a tendency to recur after removal, give a cachexia, have a fatal tendency.

5. *A metastatic growth* is one that is set up in a part of the body not directly continuous with the original growth.

9. The material must be recent, and, if sputum should be free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

PHYSICAL DIAGNOSIS.

2. *Ataxia* may be defined as lack of co-ordination in muscular movements, so that the performance of certain acts becomes difficult or impossible.

To test ataxia of the upper extremities: The patient, with his eyes closed or bandaged, is asked to touch the tip of his nose or the lobe of his ear, first with one index finger, then with the other; or the tip of one finger with the tip of some other indicated finger. Or the patient may be asked to thread a needle. If these things are done successfully the co-ordination is good, and there is no ataxia.

To test ataxia of the lower extremities: If the patient can walk, he may be asked to walk along a straight line, such as the crack between two boards of the floor, or along the border of the carpet. If he cannot walk, he should have his eyes covered, and be requested to touch the inner malleolus of one foot with the great toe of the other foot. Or the patient may be asked to stand with his heels together and his eyes closed and to notice whether he stands fairly steadily or sways about considerably. In the latter event there is ataxia.

3. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

5. The normal pulse rate in the adult is about seventy to seventy-five a minute. For each degree of temperature above the normal, the pulse rate is usually increased about eight or ten beats.

INTERNAL MEDICINE.

2. In auscultation of healthy lung the inspiratory sound is heard, and also a sound during the first part of expiration. It is called vesicular breathing.

3. *Some diagnostic symptoms of secondary syphilis:* Sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching, by being of a coppery or raw ham color, by being painless, by polymorphism (macules, papules, pustules, etc., being present at the same time), and by being roughly symmetrical. In this stage may also appear; iritis, periostitis, and alopecia.

4. *The cardinal symptoms of exophthalmic goiter* are: (1) Tachycardia, (2) goiter, (3) exophthalmos, and (4) tremor.

5. In *renal colic:* The pain is in the region of the affected kidney, it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In *hepatic colic:* The pain is in the region of the liver, it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

6. *Some of the causes of endocarditis,* are: Acute articular rheumatism, chorea, tonsillitis, scarlet fever, pneumonia, cancer, gout, diabetes mellitus, Bright's disease, septicemia, gonorrhea.

7. *The conditions which predispose to cerebral hemorrhage* are: Advanced age, rheumatism, gout, syphilis, alcoholic excesses, Bright's disease, prolonged muscular exertion, chronic lead poisoning, severe physical or mental excitement.

8. *Cerebral vomiting* is projectile in character, and is accompanied by little or no nausea, is continuous even after stomach is emptied; there is no salivation, no tenderness over liver or stomach.

Gastric vomiting relieves the previous nausea, and re-

turns on ingestion of food; salivation is present, also tenderness over liver and stomach.

9. Typhoid fever gains entrance to the human body by the mouth, chiefly through water, ice, milk, or other foods.

The entrance of typhoid fever into the human organism may be prevented by boiling all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food; flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed, after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

10. Some points of diagnostic value in chronic interstitial nephritis, are: Increased arterial tension, urine increased in quantity and of low specific gravity, a few hyaline casts may be present, albumin is either absent or present in very small amount; hypertrophy of the left ventricle, later on of the whole heart; a systolic murmur; uremia; retinitis, choked disc; anorexia, nausea, vomiting, diarrhea, cramps, numbness, dyspnea.

OBSTETRICS.

1. (*a*) *Deficient power of the uterine muscle* may be caused by: "Overdistention of the uterus from plural pregnancy or polyhydramnios; distention of the bladder or rectum; obliquities and displacements of the uterus; thinning of the uterine walls resulting from frequent and quickly repeated labors, or from degeneration of the uterine tissues; precocious or advanced age; general debility or feebleness of the woman from previous diseases, enervating habits, heat of climate, or of season, or the air of a superheated room; exhaustion of the woman from hemorrhage or from lack of sleep or food. Uterine action is sometimes inefficient from uremia, and when there is morbid adhesion between the fetal membranes and uterine wall. Mental emotions: fear, grief, surprise, anxiety, disappointment, and the presence of offensive persons or things will produce it. These last may depend upon idiosyncrasy or unaccountable personal antipathies."—(King's *Manual of Obstetrics.*)

(*b*) *Excessive power of the uterine muscle* may be caused by: Abnormally large pelvis, small fetus, unusual relaxation of the maternal soft parts, nervous excitability or peculiar temperament of the woman.

2. *Caput succedaneum* is a swelling on the presenting part of the fetus, which is developed during birth. It is due to edema of that part of the fetus (the presenting part), which is not compressed by the maternal structure during uterine contraction.

3. *Four important signs of pregnancy at the third month:* Softening of the cervix; purplish hue of the vagina; amenorrhea, and the enlargement, pigmentation, hardening, and possible secretion in the mammary glands.

4. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

5. The *indications for podalic version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother; and (7) in any case where speedy delivery is imperative.

6. *The changes occurring in the circulation at birth,* are: The hypogastric arteries become obliterated, the foramen ovale closes, the Eustachian valve atrophies, the ductus arteriosus and ductus venosus become impervious and shrivel up.

8. Ergot should be employed in obstetric practice to promote uterine contractions after the third stage of labor. It is contraindicated if the birth canal is not free and the os uteri is not dilated.

GYNECOLOGY.

3. Ectopic gestation. *Diagnosis:* "When extrauterine pregnancy exists there are: (1) the general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text-Book of Obstetrics.*)

Treatment consists in the removal of the product of conception by a laparotomy, as soon as the diagnosis is made.

6. Urethrocele. *Causes:* Traumatism during labor and stricture or tumor in urethra.

Symptoms: Frequent and painful micturition; partial incontinence of urine; retention of urine in the urethrocele, later becoming alkaline and undergoing decomposition. The bulging in the anterior vaginal wall can be seen and touched, and a sound passed into the urethra can be felt through the urethrocele.

Differential Diagnosis:

URETHROCELE.	SUBURETHRAL ABSCESS.	VAGINAL TUMOR.
Indistinct bulging.	Prominent tumor.	Prominent tumor.
Disappears on pressure.	Only partially disappears, and pus may be squeezed out into urethra.	Does not disappear on pressure.
Tumor elastic and compressible, not tender on pressure.	Tumor fluctuating and prominent, very painful on pressure.	Tumor firm.
No pain on walking or coitus.	Very painful	
Only the vaginal and urethral wall between the examining finger and a sound in the urethra.	The thickness of the intervening structure is increased by the presence of the abscess.	The thickness of the intervening structure is increased by the tumor.

(Compiled from Ashton's *Gynecology.*)

SURGERY.

5. *Varieties of Hernia:* Hernia may be classified:

I. *Anatomically:*

1. Inguinal.
   - Oblique
     - Acquired
     - Congenital
     - Infantile or encysted
   - Direct
     - External
     - Internal
   - Interstitial
     - Intraparietal
     - Interparietal
     - Extraparietal

   [Incomplete, or Bubonocele.]
2. Femoral.
3. Umbilical.
   - Congenital
   - Of infants
   - Of adults
4. Ventral. 5. Lumbar. 6. Obturator. 7. Diaphragmatic. 8. Pudendal, etc.

II. *Clinically:* Reducible irreducible, obstructed or incarcerated, inflamed, and strangulated.

6. Carcinoma is desseminated chiefly through the lymphatics; less frequently by the circulation; and occasionally by mechanical transportation in the movements of the body.

10. *Five causes of swelling in the inguinal region:* Inguinal hernia, iliac abscess, lymphadenoma, retained testicle, and hydrocele of the spermatic cord.

NEUROLOGY.

1. *The symptoms of cerebral compression,* are: Headache, vertigo, vomiting, mental dullness, sometimes paralysis, contracted pupils, coma, and cyanosis.

2. *Dementia* is a general enfeeblement of all the mental powers.

The more important forms of dementia, are: Primary, secondary, acute, chronic, senile, paretic, alcoholic, and syphilitic.

3. *The diagnostic symptoms of multiple sclerosis,* are: Nystagmus, scanning speech, intention tremor, exaggerated patellar reflex, ankle clonus, ataxia, vertigo, unsteady gait.

MEDICAL JURISPRUDENCE.

1. There are no characteristic signs of death by morphine. The only lesions are those that may usually be observed after death from asphyxia. The blood is dark and fluid; the brain, meninges, and lungs may be congested; the bladder is usually full of urine.

2. A *delusion* is a belief in something which has no real existence, but is purely imaginary; and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion.* If the whistling of the wind is mistaken for a voice telling a person to do a certain thing—that would be an *illusion.* If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination.*

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Jan. 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 1
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Jan. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March 9
Delaware	J. H. Wilson, Dover	Dover	Dec. 8
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Jan. 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	
Georgia	E. R. Anthony, Griffin	Atlanta	May —
Idaho	W. F. Howard, Pocatello	Boise	April 6
Illinois	J. A. Egan, Springfield	Chicago	Jan. —
Indiana	W. T. Gott, Indianapolis	Indianapolis	May 25
Iowa	Louis A. Thomas, Des Moines	Des Moines	Dec. 8
Kansas	D. P. Cook, Clay Center	Kansas City	Feb. 9
Kentucky*	J. N. McCormick, Bowling Green	Louisville	April 27
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 20
Maine	Wm. J. Maybury, Saco	Portland	March 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 8
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 9
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 8
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Jan. 5
Mississippi	S. H. McLean, Jackson	Jackson	May 11
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	Nov. 23
Montana*	Wm. C. Riddell, Helena	Helena	April 6
Nebraska	E. J. C. Sward, Oakland	Lincoln	Feb. 2
Nevada	S. L. Lee, Carson City	Carson City	May 3
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	Dec. 30
New Jersey	J. W. Bennett, Long Branch	Trenton	June 15
New Mexico	J. A. Massie, Santa Fe	Santa Fe	Jan. 11
New York	C.F.Wheelock, Univ.of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Feb. 2
N. Carolina*	B. K. Hays, Oxford	Asheville	June 9
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	Jan. 5
Ohio	Geo. H. Matson, Columbus	Columbus	Dec. 8
Oklahoma*	F. P. Davis, Enid	Muskogee	
Oregon	B. E. Miller, Portland	Portland	Jan. 5
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	Dec. 1
Rhode Island	G. T. Swarts, Providence	Providence	Jan. 7
S. Carolina	H. H. Wyman, Aiken	Columbia	June 8
S. Dakota	H. E. McNutt, Aberdeen	Sioux Falls	Jan. 13
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville	May —
Texas	M. E. Daniel, Honey Grove	Dallas	
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	Jan. 4
Vermont	W. Scott Nay, Underhill	Montpelier	Jan. 12
Virginia	R. S. Martin, Stuart	Lynchburg	Dec. 16
Washington*	K. Turner, Seattle	Spokane	Jan. 5
W. Virginia	H. A. Barbee, Point Pleasant	Huntington	April 13
Wisconsin	J. V. Stevens, Jefferson	Milwaukee	Jan. 12
Wyoming	S. B. Miller, Laramie	Laramie	

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Louisiana.—In accordance with a recent amendment to the medical practice act, providing for reciprocity, Louisiana now reciprocates with the following States: Colorado, Connecticut, Delaware, District of Columbia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Dakota, Ohio, South Carolina, Texas, Utah, Vermont, Virginia, Wisconsin.

Pennsylvania.—Three hundred and ninety-five candidates took the June examination in this State, and three hundred and sixty-two passed satisfactorily. This leaves 8.37 per cent. of failures. The general average of failures at the June examination has been between 13 and 14 per cent.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 14, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	479	173
Diphtheria	337	23
Measles	180	3
Scarlet Fever	215	7
Smallpox	—	—
Varicella	96	—
Typhoid Fever	78	15
Whooping Cough	18	2
Cerebrospinal Meningitis	6	2
Malarial Fever	—	—
Totals	1409	225

Scoliosis and Nutrition in Adolescents.—Professor Hutinel believes that scoliosis is a general condition rather than a local one, and is a form of delayed rickets. It is to be found most frequently in girls between the ages of 8 and 16 and less frequently in boys. If we look at these young people we find that the lower part of the body and legs are well developed, but the chest and arms are narrow and meager. There are circulatory troubles, flushing and paling of the face, and cold, clammy hands. The digestion, liver action, and kidney action are all poor. Cyclic albuminuria is frequent. Diarrhea, constipation, and chronic appendicitis are common. Headache, hysteria, neurasthenia, and incapacity for work are all found The condition is often hereditary, and this factor, combined with malassimilation, bad feeding, and insufficient oxygenation, result in a condition similar to rickets. Treatment demands rest, sleep, good feeding, no severe exercise, massage, hydrotherapy, and plenty of fresh air.—*Annales de Médecine et de Chirurgie Infantiles.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the week ending November 13, 1908:

THE DIFFERENTIATION OF OUTBREAKS OF TYPHOID FEVER DUE TO INFECTION BY WATER, MILK, FLIES AND CONTACTS.*

By JOHN F. ANDERSON, M.D.,

PASSED ASSISTANT SURGEON AND ASSISTANT DIRECTOR HYGIENIC LABORATORY, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE, WASHINGTON, D. C.

WHEN I received the invitation from our Honorable President, Dr. Lewis, to read before this association a paper on the differentiation of typhoid fever outbreaks due to infected water, milk, etc., I fully realized my limitations in dealing with the subject. However, I thought that a few observations I had made while investigating in my official capacity several epidemics of typhoid fever might be of some interest and, perhaps, profit to you.

It is a serious reflection upon the people of the United States that, according to the census report for 1900, there were 35,379 deaths in the United States that year from typhoid fever—a preventable disease. This loss of life, according to Whipple's calculation, represented a money loss to the community of $212,000,000 for that year alone.

The average typhoid death rate in cities of the United States is about 35 per 100,000. Whipple states that in the cities about 40 per cent. of the typhoid fever is due to water, 25 per cent. to milk, 30 per cent. to contagion—including fly-transmission, and only about 5 per cent. to all other causes. The Board of Officers of the Public Health and Marine-Hospital Service investigating typhoid fever in the District of Columbia found in 1906 that of the cases studied by them about 11 per cent. were definitely attributable to milk infection, about 7 per cent. to infection by contact: in 1907 they definitely attributed about 9 per cent. to milk and about 19 per cent. to contact. The cases attributed to infection in milk were those occurring in the course of definite outbreaks among the customers of certain dairymen and in the number were not included cases probably due, but not definitely traceable, to milk infection.

In the study of an outbreak of typhoid fever it is of vital importance, first of all, to determine whether the disease is really typhoid fever. For this purpose, in addition to the usual bedside methods two other procedures may and should be employed in all doubtful cases. I refer to the Widal reaction and to blood cultures. The blood culture is of more value than the Widal test, in that cultures can be obtained in the first days of the disease. For the examination of the blood we have found the bile enrichment method, followed by plating on Endo medium, the most satisfactory. By this method cultures taken in the first week of the disease will give positive results in 90 to 100 per cent. of the cases.

Having determined that the disease prevailing with undue frequency is typhoid fever it is necessary that each case be studied in detail from an epidemiological standpoint. In places which require the reporting of typhoid fever the study is much easier than in those where it is not done. The essential data can only be obtained by competent persons visiting the patients and obtaining all possible information from the patient, nurse, and family and by an inspection of the premises.

A blank form containing all the points about which information is wished facilitates the collection of data. These data should consist of the name of the patient, age, color, etc., date of onset of the disease, residence, occupation, water used wholly or occasionally, milk and other uncooked food, relation to persons sick with typhoid fever or who have recovered from the disease lately or remotely, whether servants have recently been changed, and a general survey of the premises paying especial attention to privies, flies, screens, etc. The blank form used by the Board of Officers of the Public Health and Marine-Hospital Service in Washington, D. C., is one of the most complete I have seen.

It is well to have a map of the city and, as the data for each case are collected, to indicate the location on the map by sticking in a large pin. A glance at this map will readily show if the cases are confined to any particular locality; if so, it might indicate some local condition responsible for the infection, such as an infected well or conveyance by flies, etc.

It may be found that an unusual number of cases are occurring on the route of a certain dairy. If this be the case, the dairy should be visited and the handling of the milk followed from the cow to the consumer. Special inquiry should be made in regard to the possibility of the milk having become infected in any way. If the cases are generally distributed and the epidemic began with explosive onset attention may be focused on the water supply, and this should be studied from all standpoints.

All data collected should be at once tabulated and carefully studied as to the bearing of the various probable sources of infection.

I shall now take up in detail the special characteristics of outbreaks of typhoid fever due to infected water and milk, and to transmission by flies, etc., and cite a typical example of each.

CHARACTERISTICS OF OUTBREAKS DUE TO WATER.

The striking characteristics of outbreaks of typhoid fever due to water are:

1. General distribution of cases throughout the area supplied by a particular water. The incidence of cases is independent of social conditions, occupation and age, except that very young children as a rule are not affected in equal proportion to other ages, due to the difference, perhaps, in susceptibility and to taking less water.

2. Explosive onset of the outbreak. When a water supply previously good becomes suddenly infected, as in the case of Plymouth, or Butler, Pa., the outbreak begins with great suddenness and violence. There is a sudden and great increase in the number of cases reported; this increase may continue until the sources of infection of the water are removed or the water supply changed. If the former be the case there is a more gradual decline in the number of cases than when the supply is suddenly replaced by a pure one, in which case the decrease is sudden and marked. Secondary cases from contacts may keep the number above normal for a time.

When there is a continuance of the source of the infection, as in the case of the Lowell and Lawrence outbreaks of 1890 and 1892, the onset is not usually so explosive in character and the decline is more gradual. In Pittsburg, where there is a continual infection of the water supply, the disease is more prevalent in the fall and winter, which may be due in part to other causes than the water.

When a water supply, such as a river, is subject to continual infection the increase in the number of cases in late summer and fall may be attributed to the fact that, as the number of cases increase which supply infection for the stream, the amount of infection is correspondingly increased.

3. Seasonal prevalence; spring or late winter. Outbreaks of typhoid due to infection of a water supply previously good usually occur in the late winter or spring. This is due, as in the case of the Plymouth and New Haven epidemics, to the fact that infected discharges are thrown on the frozen ground and when thaws or floods come the infection is suddenly washed into the stream.

When a supply becomes infected by the failure of the purification methods used or by a change in the supply the outbreak is, of course, independent of season.

4. Comparative freedom from the disease of persons not using the suspected water. When there is more than one water supply or where persons use pure bottled waters or boil the water the comparative freedom of such persons from the disease is striking. This was well shown in the Butler epidemic, where a large part of the first ward of the city received their water from deep driven wells. In this ward, with an equal population to the other four wards, there were only about one-half as many cases.

5. Inspection of the water shed shows evident sources of infection. An inspection of the water shed may show that it is being continuously infected by discharges of typhoid fever cases. In some cases, as at Butler and other places, the discharges may actually have been allowed to go directly into the stream from privies overhanging it.

6. The outbreaks may have begun or ended following a change of the water supply. When a previously good water is replaced for any good reason by an unknown water or a suspected water is replaced by one of undoubted purity the consequent beginning or discontinuance, as the case may be, of an outbreak of typhoid would properly be laid to water.

7. Bacteriological and chemical examination reveals evidences of pollution. While it is practically hopeless to expect to find the typhoid bacillus in water, still the finding of *B. coli* in small amounts of water and chemical evidences of pollution are additional evidence against the water.

8. Exclusion of all other probable causes. This means the exclusion of milk, food, contact, fly transmission, and other possible sources of infection.

The Butler epidemic was a typical outbreak due to infection of the water supply and a brief account of it is given.

The Butler Epidemic.—I had the opportunity of investigating the epidemic of typhoid fever in Butler, Pa., in the fall and early winter of 1904. Through the kindness of Dr. W. R. Batt, of the State Board of Health, I was able to see many of the cases and to study the causes that led up to the outbreak.

Butler had a population of 16,000 to 18,000. It derived its water supply from three sources: (1) Deep and shallow wells, (2) water from the Connoquenessing Creek, which was collected by an impounding reservoir and then filtered by a mechanical filter, and (3) water supplied by a company from five driven wells. The water supplied from this last named source was delivered only in what is known as the first ward.

On August 28 the impounding dam was carried away and from that time until November 15 water was taken directly from the creek through the

emergency intake. From August 28 to October 20 the water was probably, at times, supplied to the city unfiltered. On account of some repairs to the plant the water from October 20 to November 2 was pumped directly from the emergency intake in the creek without filtration to the reservoir and supplied to the city.

The investigation for the State Board of Health* by Dr. Batt of the water shed drained by the Connoquenessing Creek showed that there had been 17 cases of typhoid fever on the shed during September and October. Two of the cases were within 1,500 feet of the intake at the pumping station and the farthest removed was seven miles. Four cases occurred within 450 feet of the reservoir, being located on a slope draining directly into the reservoir. Practically no disinfection of the discharges had been practised.

From October 1 to January 29 there were 1,348 cases of typhoid fever, 71 being in persons residing out of the city. The cases by months were as follows: October, 47; November, 976; December, 222; January, 32; making 1,277 which, with the 71 outside cases, made a total of 1,348, with 111 deaths.

The first ward, which has previously been referred to as receiving its water largely from driven wells, while the largest in population, had only a little more than half as many cases as any of the other four wards.

The conclusions of Dr. Batt sum up the situation so thoroughly that I quote the following:

"The conclusions to be drawn from a review of the facts as they have been found to exist are that, following the destruction of the Boydstown dam on August 28, water for distribution to the people of Butler was taken from the Connoquenessing Creek through an emergency intake at the pumping station; an examination of the waters of this creek showed that it maintains a fairly constant evidence of pollution, and that at various periods the operation of the filter plant designed to remove such pollution was partially or entirely suspended, and that as a result of this polluted water being used for domestic purposes, 1,348 persons who so used it were stricken with typhoid fever between October 1, 1903, and January 29, 1904, with 111 fatalities."

OUTBREAKS DUE TO MILK.

On investigating an outbreak of typhoid fever the following points would indicate very strongly that the infection was being introduced through the milk:

1. Sudden outbreak of an unusual number of cases followed by a rapid decline. The outbreak is frequently sudden in its onset; a large number of cases occurring on a certain milk route within a few days. If the infection be introduced only once, as by flies, there is a sudden rise followed by a sudden decline in the number of cases. If there is a continuance of the infection, as from a bacillus-carrier, the onset may be more gradual and the decline will be delayed.

In dairies which do not practise sterilization of bottles the milk may become infected through bottles delivered at houses where there are cases of typhoid fever; these infected bottles are returned to the dairy, refilled, and delivered to other customers. Where the milk becomes infected by washing the cans with infected water, as in the Palo Alto outbreak, the number of cases is usually much greater than when infected in other ways. After the usual incubation period secondary cases from contacts begin to appear.

2. The appearance of an unusual number of cases among the customers of a certain dairy. The appearance of an unusual number of cases without a general increase elsewhere on the route of a dairy should at once direct especial attention to that milk.

Of course, typhoid fever due to infection from other sources may occur among persons supplied by a particular dairy, but they will not be found to be chiefly consumers of the milk. It is often very striking how the customers of a dairy whose milk is infected may be picked out by the unusual proportion of cases on that milk route. Very frequently cases may be traced in persons not directly supplied by the suspected dairy, but who have taken this milk at the home of some friend or at a restaurant. An increase in the number of cases on a certain route associated with a decrease generally throughout the city is particularly suggestive of milk infection.

3. Unusual incidence of cases among users of milk. It will be found that there is an unusual prevalence of typhoid fever among the users of milk; the non-consumers escape or develop as secondary cases. As women and children generally use more milk than men an unusual prevalence of the disease among them is a common feature of milk-borne outbreaks. Those families on the suspected route who make a practice of pasteurizing their milk escape, except from infection as secondary cases.

The following table, taken from Whipple, shows the relative percentage of cases of typhoid fever in different ages in the Stamford (milk) and the New Haven (water) epidemics and brings out the unusual prevalence of the disease among children in milk outbreaks:

Place	Ages in Years				
	0 to 5	6 to 15	16 to 30	31 to 45	Over 45
Stamford	16.95%	18.19%	32.90%	14.76%	4.15%
New Haven	8.10%	36.73%	40.63%	10.43%	3.18%

4. More cases among the well-to-do than among the poor. In a milk outbreak there are usually more cases among the well-off, due to the fact that they are more able to buy milk and use it in larger quantities than the poor, while in fly-borne outbreaks the poor and those living under insanitary conditions are more often attacked.

5. The finding of the typhoid bacillus in the suspected milk. This is practically hopeless, as the milk rarely comes under suspicion for at least three weeks after having become infected. In addition, the technical difficulties are so great that it is an almost hopeless procedure, though the isolation of the organism should be attempted. If successful, it is absolutely conclusive.

I shall cite, as an example of a milk outbreak, one in Savannah, Ga., which I had the opportunity of studying in the early summer of 1907.

Outbreak of Typhoid Fever in Savannah, Ga., Due to Infected Milk.—This outbreak, which I had the opportunity of studying, was undoubtedly due to infection in the milk supplied by one of the largest dairies in the city.

The city has an unusually pure water supply, it being derived from a system of deep artesian wells. From the 1st of January, 1907, to May 1 there had only been 19 cases of typhoid fever reported to the health officer, two of these being imported cases. Preliminary investigations showed that an unusual

*Epidemic of typhoid fever in Butler, Pa. Twentieth Annual Report, State Board of Health, 1904.

number of cases were occurring among the customers of a certain dairy. This dairy did a wholesale as well as a retail business. The milk sold wholesale was delivered in cans to dealers, who retailed it out to their customers.

On March 5 there was a death from typhoid fever in a family who lived over one of the milk depots. There does not seem to have been any decided increase in the number of cases of typhoid fever reported until the last two weeks of April, when there were six cases reported. From May 1 to 15 there were 17 cases, and from the 16th to the 31st 78 cases were reported.

The cans in which the milk was delivered to the depots were returned to the dairy and, without any sterilization, were used to deliver milk to the same or some other dealer. Various members of the family in which the case of fever occurred assisted in the sale of milk in the bakery as well as in the care of the patient.

The following table shows in bi-weekly periods from January 1 to June 1 the number of cases of typhoid fever reported and the milk used before being taken sick:

Semi-Monthly Periods	Dairy														Condensed Milk.	No Milk Used.	Imported Cases.	Contact Cases.	Total.
1907	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O				
Jan. 1–15.	.				1			.											1
Jan. 16–31.	.	.			.	1		.											1
Feb. 1–14.	2						1	.							1				4
Feb. 15–28.	.	1	.	.	.			.											1
Mar 1–15.	1							.											1
Mar. 16–31.	.	.			.		1								2				3
Apr. 1–15.	.	.			.	.	.	.	1								1		2
Apr. 16–31.	2	1			.	.	1		1								1	.	6
May 1–15.	9	.	.	1	.	.	1	.		1							4	1	17
May 16 31.	54	.	1	1	.		4				1	2	1	2	1		5	5	1	78
Total...	68	2	1	2	1	1	8	1	1	1	1	2	1	2	1	3	5	11	2	114

Of the 114 cases shown in the table 68 had used milk from the suspected dairy (dairy A). Deducting from the total of 114 cases those who used only condensed milk, those who used no milk, imported cases, and cases clearly attributed to contact; 75 per cent. of the remainder were persons who had used milk from dairy A.

CHARACTERISTICS OF OUTBREAKS DUE TO CONTAGION AND TRANSMISSION BY FLIES.

For purposes of convenience I shall discuss the characteristics of outbreaks of typhoid fever due to contagion and transmission by flies at the same time. The great part played by flies in the transmission of typhoid fever was first emphasized in the masterly Report on the Origin and Spread of Typhoid Fever in United States Military Camps during the Spanish War, by Reed, Vaughan, and Shakespeare. They concluded that "flies were undoubtedly the most active agents in the spread of typhoid fever. Flies alternately visited and fed on the infected fecal matter and the food in the mess tents. More than once it happened when lime had been scattered over the fecal matter in the pits, flies with their feet covered with lime were seen walking over the food. Typhoid fever was much less frequent among members of messes who had their mess tents screened than it was among those who took no such precautions. Typhoid fever gradually died out in the fall of 1898 in the camps at Knoxville and Meade with the disappearance of the fly, and this occurred at a time of year when in civil practice typhoid fever is generally on the increase. * * * The first pits at Knoxville contained, before the first 24 hours had passed after the arrival of the troops, fecal matter infected with the typhoid bacillus. Flies swarmed everywhere. Instead of abating, the disease increased. The soldiers were using the same water used exclusively by the inhabitants of West Knoxville, and among the latter there was not at that time a case of typhoid fever. Certainly the disease was not disseminated through the drinking water."

Alice Hamilton* investigated in 1902 an outbreak of typhoid fever in the nineteenth ward of the city of Chicago. This ward, which only contained about one-thirty-sixth of the total population of the city, had between one-sixth and one-seventh of all the deaths from typhoid fever. It seemed to her that, while the water was undoubtedly the causative factor in the epidemic throughout the city, there must be some local cause for its undue prevalence in the nineteenth ward. The sanitary arrangements in this ward were found to be very bad and on those streets with the worst sanitary arrangements there were the largest number of deaths from typhoid fever, irrespective of the poverty of the inhabitants.

Flies caught in two undrained privies, on the fences of two yards, on the walls of two houses, and in the room of a typhoid patient, were used to inoculate 18 tubes; from five of these tubes the typhoid bacillus was isolated. In this outbreak the chain of evidence implicating the fly in the spread of the disease was certainly convincing and almost complete.

The outbreak in the city of Winnipeg, in August, 1904, investigated by Dr. E. O. Jordan, which was confined almost entirely to the poorer part of the city, was attributed to transmission by flies and contacts.

Outbreaks due to direct contact are seen especially in institutions where there are typhoid fever cases and in houses where the family and friends visit and assist in the care of the patient. In these cases the infection is conveyed either directly by the future patient or indirectly by the nurse to food consumed by others.

Typhoid-carriers such as the one reported by Soper in the person of a cook, who was responsible for at least 28 cases of typhoid fever in families in whose employ she had been, are instances in which the infection is conveyed by a third person.

The bacilli have been found in practically all of the excretions of typhoid fever cases and it is only by the most scrupulous care on the part of the attendant that infection can be avoided for himself and others.

The chief characteristics, then, of outbreaks of typhoid fever due to transmission by flies and by contact are their local character, their appearance in places where the sanitary conditions are poor or where they are neglected, occurring during the fly season in the case of fly-transmission, and among those most closely associated with the patient.

OUTBREAKS DUE TO INFECTION BY VARIOUS OTHER MEANS.

There have been reported in the literature many interesting outbreaks of typhoid fever due to conveyance of the infection by oysters and other shellfish, fruits, vegetables, ice cream, watercress, celery, ice, etc.

Investigating an epidemic of typhoid fever in Lexington, Va., in November, 1903, I was able

**Journal American Medical Association*, Vol. 40, 1902, p. 576.

to trace a number of cases which were most probably due to infected ice. The water used for the manufacture of ice was obtained from a spring which was open to contamination by drainage from the privies of houses in which were cases of typhoid fever. I isolated the typhoid bacillus—proved to be such by cultural and agglutination reactions—from the water storage tank in the ice factory.

ROCKY MOUNTAIN SPOTTED FEVER.

WITH REPORT OF A CASE.*

By ALF. A. ROBINSON, M.D.,

OGDEN, UTAH.

WITHIN the last decade Rocky Mountain spotted fever has become a nosological entity. Investigations under the directions of the Montana State Board of Health, the U. S. Public Health and Marine Hospital Service, and the American Medical Association have thrown much light upon this heretofore obscure disease.

Because of the name "tick fever" by which it is known, one should not think of any connection existing between this and African tick fever or Texas cattle fever which are transmitted by the bites of ticks, although the etiological factor was at one time thought to be closely allied to the *Piroplasma bigeminum* (Smith and Kilborne) of the latter disease. Neither should it be confused with typhus or cerebrospinal fevers because it is referred to as "spotted fever." This confusion of nomenclature will be avoided by designating the disease as Rocky Mountain spotted fever, which name has been adopted by Stiles and Ricketts.

Rocky Mountain spotted fever is an acute infectious, endemic disease, transmitted by the bite of a tick; characterized by (1) severe pains in the back, muscles, and joints; (2) a papular or petechial eruption, appearing first about the ankles, wrists, and forehead and extending later, though to a less marked degree of intensity, over the entire body and (3) an irregular fever, terminating by lysis in from two to seven weeks.

The history of this disease may be divided into two epochs: (1) from 1847 to 1902; (2) from 1902 to the present time.

The first period consists principally of vague rumors and indefinite reports of a disease which may or may not have been Rocky Mountain spotted fever. Only a few symptoms were recorded by the early writers. There were meagre surmises as to its nosology and etiology, but no accurate investigations were made. During this period the disease was referred to as "mountain fever," "bull fever," "typhomalarial fever of the Rocky Mountains," "black fever," "blue disease," and "spotted fever."

In 1902, under the direction of the Montana State Board of Health, there were begun investigations as to the true nature of the disease. Hypothetical surmises then gave way to scientific researches and Rocky Mountain spotted fever, as a distinct and definite problem, was studied with proper and befitting accuracy. Since that time it has borne the names "tick fever," "Rocky Mountain spotted fever," "piroplasmosis hominis," and "intermittent tick fever."

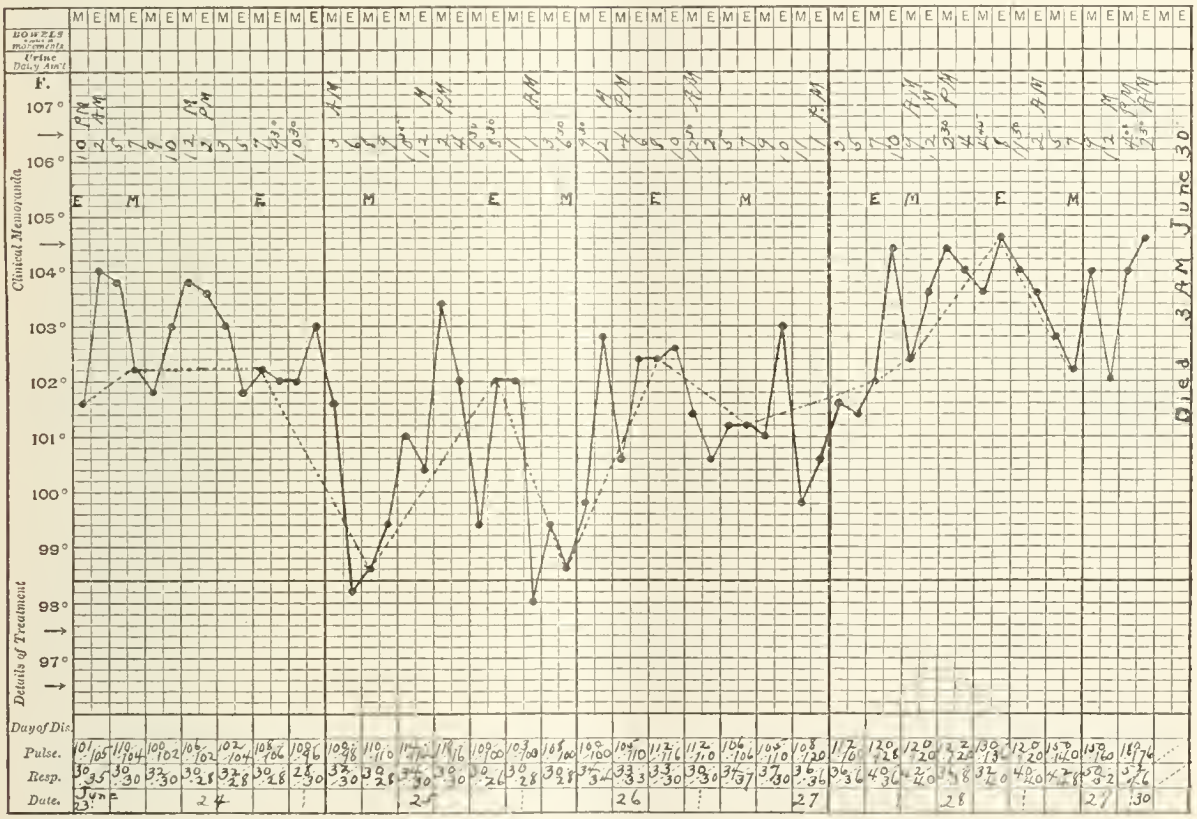

CHART 1.—Common type of temperature (Wilson and Chowning). The dotted line represents the curve of the usual morning and evening observations; the continuous line shows the intermediate variations.

Information of its occurrence among the Indians is rather unsatisfactory. Buckley was unable to obtain any convincing evidence that they suffered from "spotted fever."

The Mormons, en route to Utah in 1847, may have encountered this disease. No accurate description is given, but the conditions under which they traveled, the season of the year, and the country through which they passed, render it highly probable that these pioneers suffered from Rocky Mountain spotted fever.

*Prize Essay, Francis W. Shain Prize, Jefferson Medical College, 1908.

C. E. Boyle, while traveling to the Pacific coast in 1851, met a disease which he called "Rocky Mountain fever," or "bull fever." It appeared at

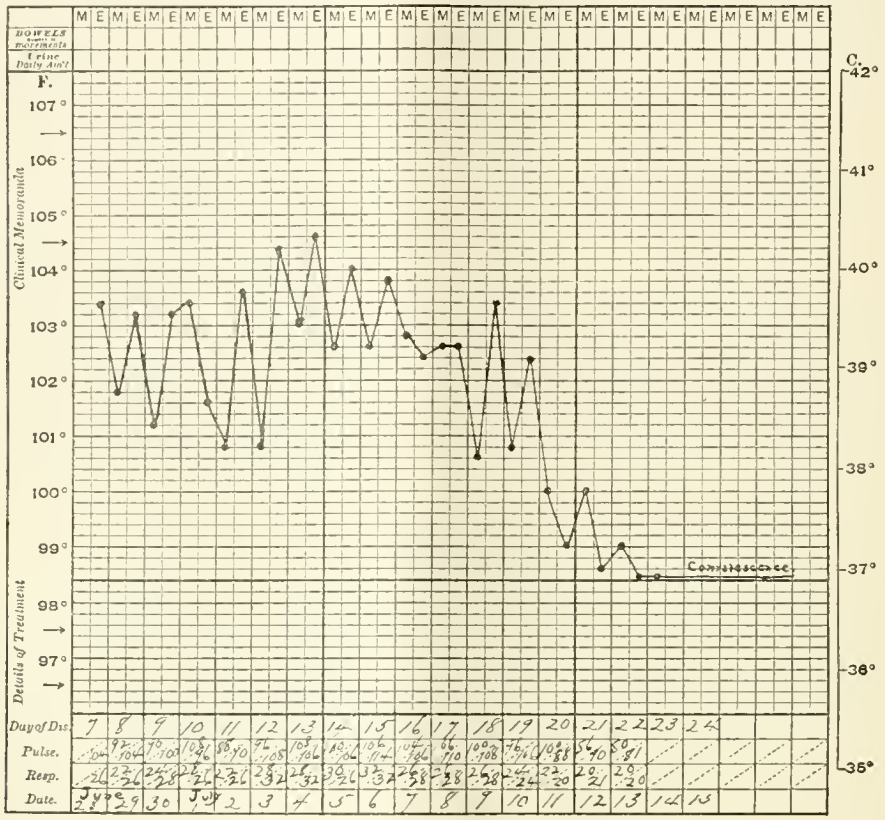

Chart 2.—The curve of defervescence (Stiles).

South Pass, Wyoming, among the members of his company. His description is vague, however, and inconclusive.

Lyons, Colorado, met a disease "called mountain fever by pioneer brethren," but these cases were proven to be malaria. The fort was afterwards re-

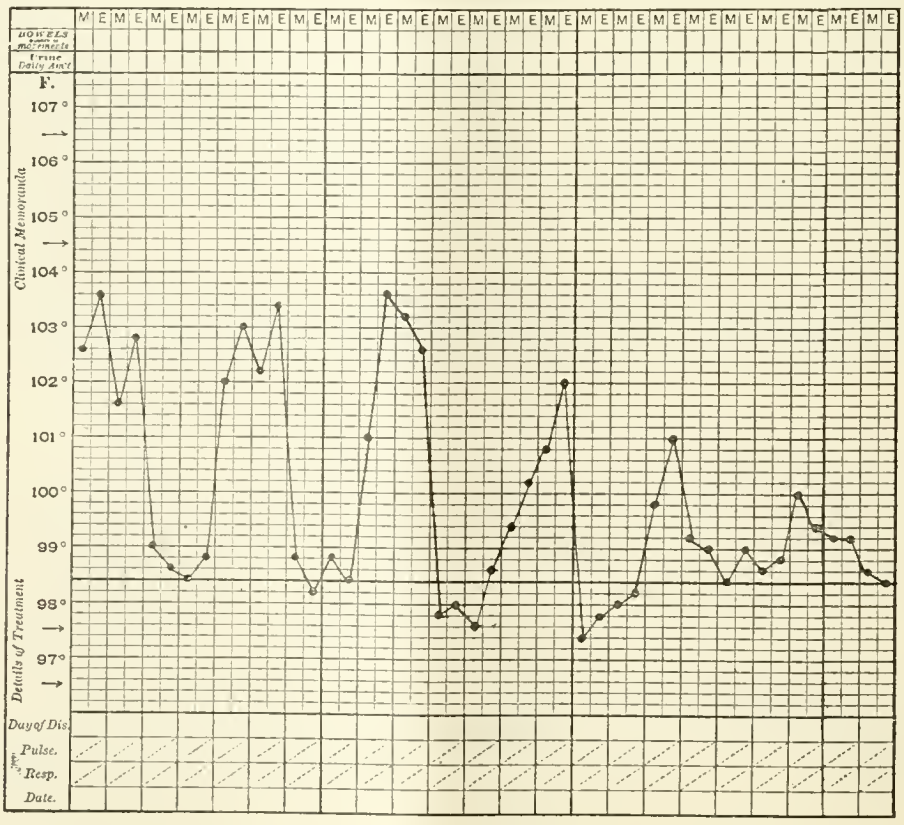

Chart 3.—The intermittent type (Kieffer).

At the same place, four years later, W. T. Ewing saw twenty-five cases of a unique disease. Of these, two were fatal. He thought it most simulated malaria but knew of no assignable cause other than altitude.

Waggoner, of the U. S. Army, while at Ft. moved on account of its unsanitary location.

In 1868 Curtin saw four cases at Cheyenne. Two of the men were prospectors and the other two had

been living in tents, thus exposing them to the bite of ticks. He believed the disease to be "one of the already classified varieties," described an eruption, and pointed out the fact that well known diseases were diagnosed as Rocky Mountain fever.

In 1875, Patski, of the U. S. Army, of Ft. Steele, Wyoming, referred to "mountain fever" as occurring among wood choppers along streams. He attributed it to malarial infection, and claimed successful treatment with quinine. These patients were in Rocky Mountain spotted fever and not malarial districts and were likely subjects to become hosts for ticks.

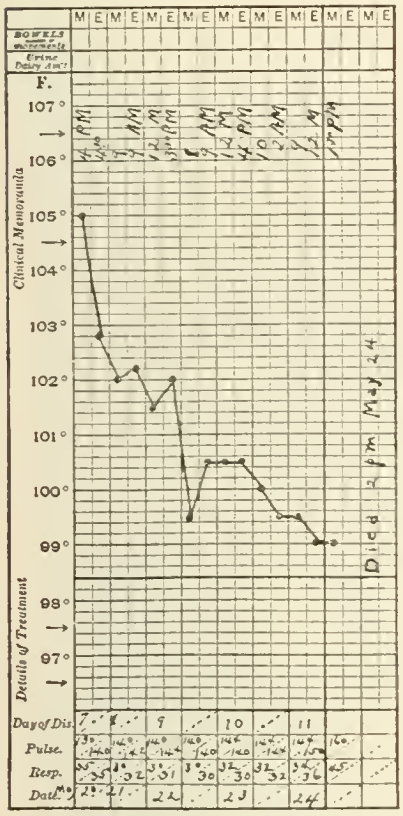

Chart 4.—The preagonal decline (Wilson and Chowning).

In the same year Jaquette, of the U. S. Army, of Ft. Boise, Idaho, wrote of . . . . . occasional case of fever, either remittent or intermittent, commonly called in this country 'mountain,' or 'typhomalarial fever.' This prevails more especially among the citizens who are occupied in mining or on farms in the valley along the river." This corresponds well with Maxey's geographical distribution in Idaho.

Also in 1875 Town, of the U. S. Army, of Ft. Shaw, Montana, made a brief reference to what may have been this disease.

"Mountain fever" was discussed by Williamson and Benedict at a meeting of the Salt Lake Medical Society on March 18, 1877.

Smart, of the U. S. Army, published an article in 1878 in which he says: "Now the question comes, is it a fever *sui generis* or are we to give it recognition as typhoid, typhomalarial, or malarial remittent fever?" He repeated a number of cases met with by Gray, at Ft. Fetterman, Wyoming. Gray found that quinine had no effect to prevent or control the daily return of high fever.

In 1880, Hoff, of the U. S. Army, wrote: "From time to time there have appeared in American medical periodicals articles under the caption 'Mountain Fever,' giving description of a febrile disease of somewhat peculiar character, which apparently is indigenous to the country vaguely demonstrating the Rocky Mountain region. Owing, doubtless, to the spareness of population, the rarity of the disease, and, not least, the fact that the pioneers of our profession in this extreme Western country are, as a rule, workers, not recorders, the literature of the subject is extremely meagre."

In 1896, Wood, of the U. S. Army, submitted to the Surgeon-General descriptions of the disease from eight Idaho physicians and was the first to refer to it as "spotted fever."

In 1898, Woodruff, of the U. S. Army, wrote on "The Form of Typhoid Fever called Mountain Fever." This reference was made to typhus levissimus and not to Rocky Mountain spotted fever. The Widal reaction was obtained in his cases.

In 1899, Maxey, of Boise, Idaho, read a paper before the Oregon State Medical Society, in which he expressed his opinion that "spotted fever" is an independent, specific disease. His description is much more lucid than any antedating.

McCollough and Gwinn each presented a paper on "Spotted Fever" before the Montana State Medical Society in May, 1902. They state that the disease has prevailed in the Bitter Root valley from the earliest history of settlement by white inhabitants. Gwinn reported two autopsies.

In 1902 the disease was investigated for the Montana State Board of Health by Wilson and Chowning of the University of Minnesota. They advanced the tick theory of transmission, described parasites within the red blood cells, and suggested the burrowing squirrel (*Citellus columbianus*) as representing the original host of the disease (cf. Etiology).

Anderson, of the Public Health and M. H. Service, visited Montana in 1903 and made a study of the disease. He confirmed the blood findings of Wilson and Chowning and referred to the malady as "tick fever."

Wilson and Chowning continued their work in 1904 and published new observations. They named the blood parasite *Pyroplasma hominis* (and later *Piroplasma hominis*) as the cause of the disease.

Stiles, Chief of the Division of Zoology, of the Hygienic Laboratory, visited Montana in 1904 and made a study of Rocky Mountain spotted fever. He failed to confirm the observations of Wilson and Chowning, and Anderson, as to the presence of a piroplasma in the blood.

In 1905, R. W. Smith, of Seattle, Washington, reported the study of one case, in which he observed the intracorpuscular body described by Wilson and Chowning.

Nine cases were studied by Kieffer, of the U. S. Army, at Ft. Russel, Wyoming. Careful laboratory investigations gave unsatisfactory results. He referred to the disease as "intermittent tick fever."

In 1906, a grant was made by the American Medical Association through the Committee on Scientific Research for the study of Rocky Mountain spotted fever, and working in part under this grant, Ricketts of the University of Chicago made bacteriological and hematological studies, of which the former gave negative results, and has continued his

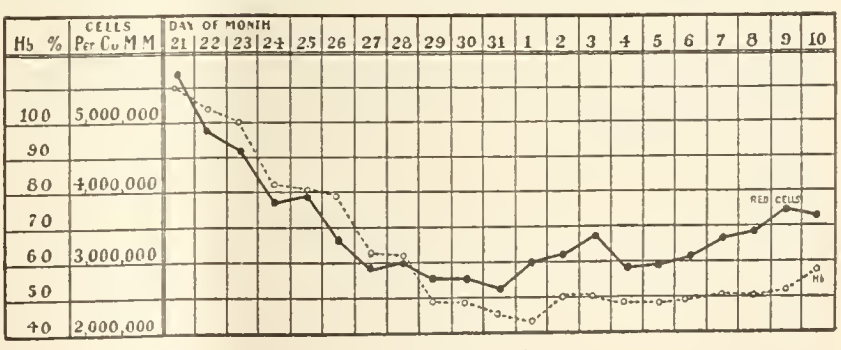

Chart 5.—Blood Chart (Kieffer).

investigations of the infectious agent by means of animal inoculations. He has demonstrated that the disease can be transmitted to the monkey and guinea-pig by the bite of a tick.

Etiology.—Rocky Mountain spotted fever has a distinct geographical distribution and occurs only in the spring and early summer months. Some years there occur a greater number of cases than others. Maxey states that there were few cases in Idaho in 1907, but he can assign no cause for it. The intensity of the disease also varies from year to year.

Two types are met with: a rare one in which no eruption developes, which is usually a mild form; another, characterized by a distinct rash, in which the symptoms are more marked.

Geographical Distribution.—The disease has been reported from Montana, Idaho, Wyoming, Nevada, Oregon, Washington, Utah, and Colorado.

The most constant locality in which this fever prevails in Montana is the Bitter Root valley. Wilson and Chowning state that on the western side of the Bitter Root valley, in an area of four to ten miles wide and fifty miles long the disease is most prevalent. McCollough says the disease has been found to occur in Phillipsburg, Clinton, Camas Prairie, Rock Creek, up the Blackfoot, Rattle Snake valley and far up the Lo Lo as well as in the Bitter Root valley. Gates reports a number of cases near Bridger.

Ed. E. Maxey, Secretary of the Idaho State Board of Health, outlines the distribution in that State as follows: "The geographical distribution in this State, as I know it, is about as follows: The valleys of the Weiser, the Payette, the Boise, and the Wood rivers; I might say the disease has been reported along the entire north-bank watershed of the Snake River. I know of no cases having been reported from the territory south of the Snake River. I do not know if they have the disease in the north end of the State or not, but think not. A few cases have been reported from southwestern Idaho, but these cases, I think, were on streams flowing south into Salt Lake. In other words, it has been our experience here in Idaho, that the disease is found only on watersheds which face or flow toward the south."

Gates reports cases from Thermopolis, Meyersville and Shoshone River in Wyoming. Kieffer says: "The region in which the men from this post have become infected is that section embraced in the headwaters of the three small streams which go to make up Crow Creek." Probable cases are reported from South Pass, Ft. Fetterman, Ft. Steele, and Cheyenne.

The disease is reported in the Quinn River valley; Paradise valley; near Winnemucca; at Ft. McDermitt, and from Reno in Nevada.

Geary reports a case from Burns, Oregon. R. E. Lee Steiner, at present of Salem, tells me of twenty-three cases he attended in the vicinity of Lakeview. John G. Patterson, of Merrill, had one near that place.

R. W. Smith of Seattle reports a case from Moses Lakes, Douglass county, Washington.

I am informed by Noyes of American Fork of three cases occurring in Cedar valley, Utah. One patient was a sheepherder and resided at Fairfield, while the other two, a farmer and his daughter, lived at Cedarfort. Wheritt has had several cases at Heber City. Laymen tell me of having contracted "mountain fever" while hauling wood from a district designated as "Tickville," which is about fifteen miles north of the villages Fairfield and Cedarfort. From the abundance of ticks in this locality the district gets its name. R. J. Smith reports a case, but his patient had been visiting in Idaho.

Braden of Carbondale, Colorado, reports four cases from that locality. He refers to one seen by LeRosignol and Hotopp near Rifle.

Rocky Mountain spotted fever is a disease of the spring months. Cases have, however, been seen as early as February and as late as July. It usually makes its appearance in March and reaches its maximum in May, after which time it declines. This is illustrated in the following table of 114 cases: March, 6 cases; April, 19; May, 43; June, 31; July, 5. In spring, but exact month uncertain, 10 cases.

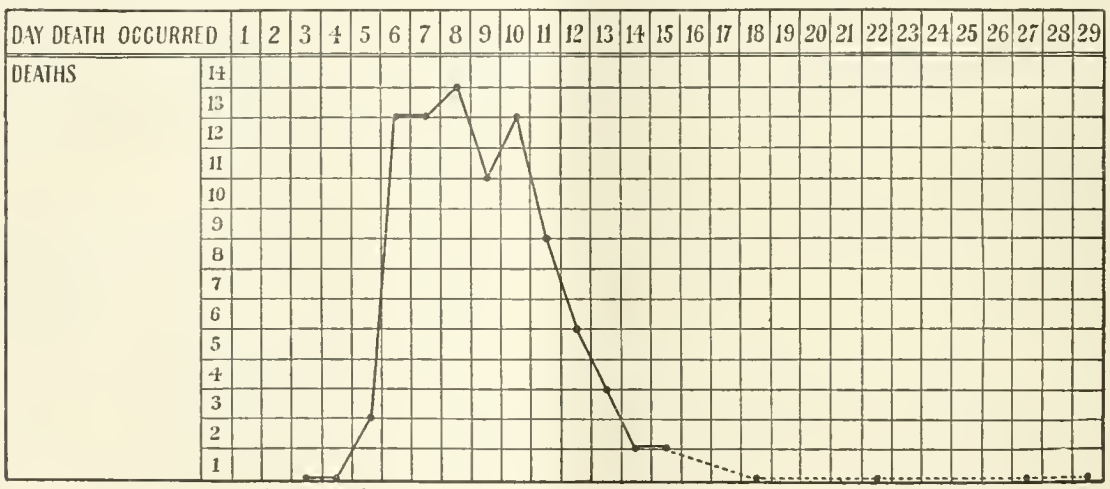

Chart 6.—Showing the days in which death occurred in 96 cases.

Age seems to play no rôle. Anderson gives the ages of greatest liability to infection as from fifteen to fifty, and reports eighteen months as the youngest and seventy-four years as the oldest ages recorded. Of 121 cases, 76 were males and 45 females. Maxey states that it is much more frequent in men on account of their exposed occupations.

A summary of cases reported shows that those whose occupations take them into the hills, along streams and through brush, are the ones most frequently infected. Among sheepherders, cattlemen, engineers, prospectors, ranchers, and lumbermen the disease is principally found. The female patients are commonly housewives living on farms and the children are principally those of the rancher.

Wilson and Chowning made studies of the blood of patients suffering from Rocky Mountain spotted fever and in their results published, described ovoid, intracorpuscular bodies possessing ameboid movement. This organism they named *Piroplasma*

hominis, which they said is similar to the malaria parasite and to *Piroplasma bigeminum* (Smith and Kilborne, 1893) found in Texas cattle fever.

Anderson's findings were in harmony with those of Wilson and Chowning. He describes these organisms as follows: "In the fresh blood a few cells were found to contain parasites. Three forms were seen. The most common was a single ovoid body, refractile, situated within the cell, usually near its edge. When the slide is warmed this body possesses the power of projecting quite rapidly pseudopodia and a slight change of position. This form, which is apparently an early or young form, is about 1.5 to 2 micra in length, and 0.5 to 1 micron in width at its widest part. It closely resembles the earliest intracorpuscular parasites of estivoautumnal malaria. Another form, not so common, was larger, being about 2 to 2.5 by 1 to 1.5 micra, larger at one end and showing in the larger end a dark granular spot; this was also ameboid. The third form was not arranged in pairs, distinctly pyriform, with the smaller end approaching, and in two cases a fine thread uniting the small ends was seen. Motion was not observed in this form, but the spot mentioned in the second form was seen."

Cobb, Westbrook, and R. W. Smith agree with the findings of Wilson and Chowning. Chowning now believes that "the organism present in the blood is a streptothrix or some closely related fungoid organism."

In four hundred hours of microscopic study of fresh and stained blood of typical cases, Stiles and Ashburn were unable to find this parasite. Maxey, Simon, and Cole found no piroplasma in the blood of cases in Idaho. Maxey took blood smears to Prof. Welch for examination, who gave it as his opinion that he could see no changes in the blood save the disintegration of red corpuscles which is found in other febrile diseases. Ricketts was unable to identify a parasite within the red blood cells.

FIG. 1.—Map showing the distribution of cases reported as follows: Montana: (1) by Wilson and Chowning, (2) McCullough, (3) Gates; Idaho: (4) Maxey; Wyoming (3) Gates, (5) Kieffer, (6) Boyle and Ewing, (7) Gray, (8) Patski, (9) Curtin; Nevada; (10) Wilson and Chowning, (11) Stiles, (12) Mooser; Oregon: (13) Geary, (14) Patterson, (15) Steiner; Washington: (16) Smith; Utah: (17) Noyes, (18) Wherritt; Colorado: (19) Braden.

Craig proffers an explanation of the *Piroplasma hominis.* He made no investigation of this disease, however. "In the examination of thousands of specimens of blood, I have often observed appearances coinciding in every particular with the description by Chowning, Wilson, and Anderson of *'Piroplasma hominis'* (so called), which were not parasitic in nature but rather of a degenerative character, due to some unknown action of the disease-producing elements in the cases studied. I have observed these bodies in a large number of diseases, especially in fevers such as typhoid, malaria, small-

pox, measles, grip, and very frequently in pneumonia and tuberculosis."

Kieffer also searched for the parasite, but was not convinced of its entity. He found some few objects within the red blood cells but says of them: "A very careful study of these bodies leads me to the conclusion that they are either artefacts or, more likely, evidence of vacuolization of the erythrocyte with deposit of the staining materials in the margins of the vacuole."

It is very apparent that the *Piroplasma hominis* awaits confirmation.

The hypothesis of Wilson and Chowning that the burrowing squirrel (*Citellus columbianus*) or spermophile represents the original host of the disease has neither been confirmed nor disproved.

Fig. 2.—Eruption of Rocky Mountain spotted fever (Anderson).

Philo E. Jones of Salt Lake City, who has had considerable experience with the disease, expresses his opinion relative to the etiology as follows: "Among the cases that I have seen and attended, less than 25 per cent. have been bitten by ticks. I have a suspicion that when the intruding host has been found it will be that of our mountain mosquito. As the snow recedes from the foot hills in June, close up to the snow line there are swarms of these mosquitos, and they are biters of no mean order. All the cases of spotted fever that I have seen give histories of having been bitten by these insects."

No history of tick bite, and even denial of this, is found in a considerably large number of cases reported. Probably no attempt was made to elicit a history of mosquito bites from several of these patients. Stiles reports a case in which tick bites were denied, but there were many abrasions on the feet and legs all said to be due to scratching mosquito bites. In view of the above facts and inasmuch as the original host of the disease has not been definitely determined, it is not improbable that the mosquito gets the virus from the same source as the tick. This hypothesis certainly deserves investigation.

Wilson and Chowning could find no record of one individual having contracted the disease from another so these investigators were led to examine the skin for indications of direct inoculation. They found evidence of tick bites on every patient under observation and thought this a probable source of infection. Working on this they found: "Ticks are known to appear in the spring as soon as the snow melts from the sunny exposures; in other words, in the Bitter Root valley, as early as February 15. They are, however, chilled and inactive until the latter part of March or first of April. In relation to this, scattering cases of 'spotted fever' appear during the latter part of March and first of April and are most numerous during May and June. Ticks become less numerous about the middle of June, and finally disappear about the middle of July. In connection with this it should be noted that cases of 'spotted fever' become less and less numerous from the middle of June until the middle of July, after the twentieth of which month no cases have been observed."

Some dispute has arisen as to the genus to which this arachnid belongs but Stiles, a recognized authority, says of it: "I have been able to compare the specimens of ticks from Montana with specimens of *Dermacentor reticulatus* from France and I think they are different. For some time I considered the Montana form a distinct species which I named *Dermacentor andersoni* but more recently I obtained the original type of *Dermacentor occidentalis* from California. So far as I have been able to make out the Montana form agrees with *occidentalis*. My studies are not yet quite completed. I expect very shortly to finish a paper on this subject and will then straighten out the nomenclature. From the present indications the Montana form is *occidentalis*."

Ricketts has established the following points concerning the relationship of *Dermacentor occidentalis* to Rocky Mountain spotted fever: "(1) Infected ticks exist in the so-called infected districts in nature. (2) Both the adult male and the adult female may acquire the disease by feeding on an infected animal, and may transmit it to a normal susceptible animal for a period of several weeks thereafter. (3) During either of its intermediate active stages, larval or nymphal, the tick may acquire the disease in the same manner, retain it during moulting, and prove infective when it reaches the subsequent active stage. (4) The infected female may transmit the disease to her young through the egg. It is possible that this does not happen in all instances, and it is quite certain that the brood of an infected female may include many uninfected larvæ. This seems to have been proved in three of my experiments in which the infectivity of the females had been proved before oviposition; the larvæ in these experiments failed to infect normal guinea pigs. (5) The virus exists in both the salivary glands and the gut of infected ticks at a certain time, and since it also invades the generative organs of the female the condition is probably one of a generalized infection, at least for a period. The disease is not highly destructive for the tick."

A parasite has not been satisfactorily demonstrated by culture or the microscope, but inoculation and filtration experiments locate one in the body fluids generally and not essentially in the erythrocytes or leucocytes. Attempts to pass it through a Berkfeld filter have been unsuccessful.

Inoculation of defibrinated blood of patients suffering from Rocky Mountain spotted fever infects the guinea pig and monkey and the virus may be kept alive by alternate inoculation of monkey and guinea pig or continuous passage through the guinea pig.

The infectiousness is largely destroyed by grinding infected blood in the ball mill, which process probably crushes the organisms and thereby liberates the toxic substances.

The writer has been unable to find an authentic example of a second attack of the disease under discussion. It seems possible that one attack renders the body immune. In the monkey and guinea pig Ricketts found that "one attack of the disease establishes a rather high degree of immunity to subsequent innoculation."

Morbid Anatomy and Histology.—The amount of autopsy work in this disease has not been sufficient to justify one in making too positive assertions as to constant lesions found post mortem.

Anderson found that rigor mortis is usually intense and appears early.

On the dependent parts there is a lividity of the skin. The remainder of the body shows petechial spots, dark purple in color, found to the greatest extent about the ankles, wrists, arms, and back. Bowers thinks the spots are due to a sanguineous exudate, probably into or beneath the corium. The capillaries are congested. Sometimes jaundice is very marked.

The pleuræ show no special lesions. The lungs are edematous or hypostatic pneumonia is present. Rarely they are normal. Stiles reports an enlargement of the bronchial nodes.

The pericardium appears normal, but an excessive amount of fluid in the pericardial cavity has been described. Anderson found a few small petechial hemorrhages under the epicardium over the left ventricle in seven cases. Wilson and Chowning reported two autopsies in which were found small hemorrhagic areas over both ventricles. The right heart is full of blood while the left is empty and contracted. The myocardium is frequently pale and flabby and miscroscopic examination reveals granular and fragmented fibers with poorly stained nuclei.

The spleen is enlarged, weighing from 500 gm. to 700 gm. (three or four times the weight of the normal organ). It is usually purple in color; the capsule is distended and thinned, and on section the tissue is dark red. The outlines of the Malphigian bodies are lost. There is considerable infiltration of polymorphonuclear leucocytes in the region of the Malphigian bodies. Anderson found "many mononuclear leucocytes, containing from one to four red corpuscles."

The kidneys are enlarged and the capsule usually strips without difficulty. The seven cases studied by Anderson and six of Wilson and Chowning showed small subcapsular hemorrhages on the ventral surface. On section the cortex was seen to be congested and swollen; the pyramids were well outlined and deep red in color, and small hemorrhages were present in the pelvis. The microscope disclosed minute extravasations of blood in the cortex, veins filled with blood, nuclei of convoluted tubules poorly stained, cells granular and in places detached, and newly formed casts in the tubules.

The stomach is usually normal. Hypostatic congestion is sometimes seen. There is no constant lesion of the intestines. The mesenteric and retroperitoneal nodes are not enlarged. Ricketts found "generalized enlargement of the lymph glands, including those of the mesentery and mediastinum" following inoculations of guinea pigs.

There have been but few autopsies in which there was not an enlarged liver. The general appearance is pale, consistency is normal, and areas are outlined by bile pigment. Section usually manifests a fatty infiltration. The gall-bladder shows no special lesions.

Anderson found the pancreas to be twice its normal weight. In one case it was normal in appearance except for enlargement.

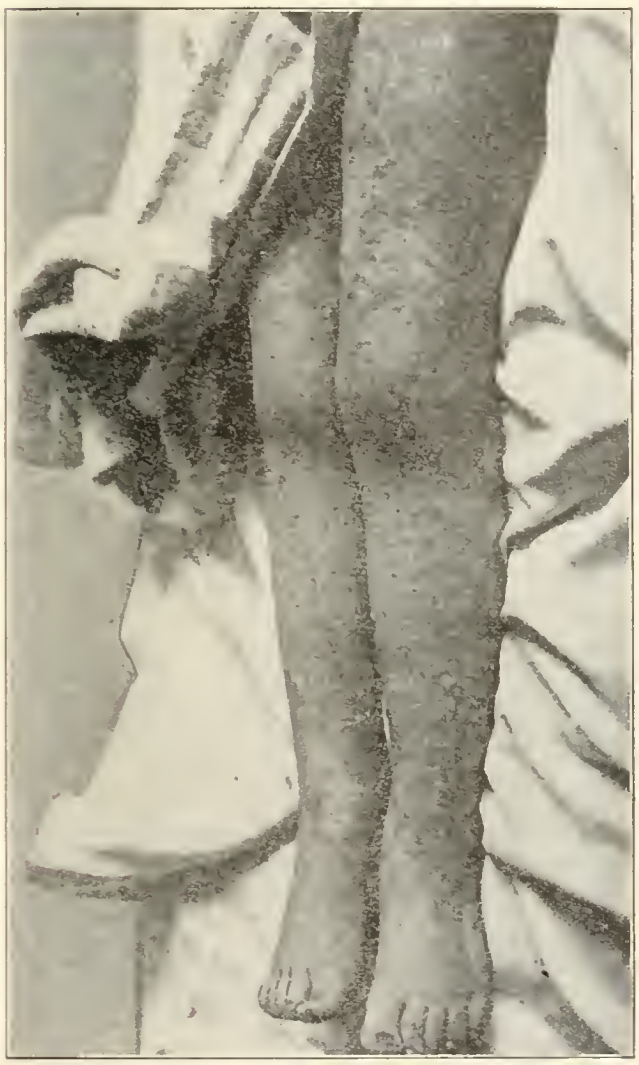

Fig. 3.—Appearance of eruption two hours after death (Chowning).

The urinary bladder is usually normal and contains a small amount of dark urine. Congestion of the ventral wall has been reported.

In severe cases the scrotum and testicles are swollen and gangrene and sloughing sometimes occur. Following inoculations of guinea pigs, Ricketts observed "the scrotum and testicles became enormously swollen, and on the sixth day the skin of the scrotum was occupied by large dark colored hemorrhages of irregular outline . . . this swelling of the testicles and scrotum and the hemorrhage into the skin of the scrotum is the most characteristic sign of the disease as produced in the male guinea pig."

Wilson and Chowning found a slight congestion of the meninges and some distention of the peri-

cellular spaces in the cortex. Anderson reported only a slight hypostatic congestion of the meninges.

Symptoms.—The period of incubation is thought to be from three to ten days, seven days being about the average.

Onset. The patient has chilly sensations, malaise, nausea, and possibly vomiting, pain in the back, headache, coryza, loss of appetite, nosebleed, and finally a distinct chill. The muscles, joints, and bones are sore; some cases even simulating dengue. The bowels are constipated; the tongue is coated and has a red tip and edge; sordes appear early, and the urine is scanty, high colored and contains traces of albumin and granular and blood casts.

During the period of incubation the morning temperature is normal, but a slight elevation is noted in the evening. After the initial chill an abrupt rise to 103° to 104° is common, and according to a number of observers a rise in the evening with a slight morning remission, the maximum being reached on the eighth to the fourteenth day, is the rate (Chart 1). The temperature then returns to normal about the sixteenth to the twentieth day, followed by a subnormal period of a few days (Chart 2). Kieffer described an intermittent type: "The fever rapidly rises to 103° or 104° and remains high with narrow fluctuations for 48 hours in the ordinary type of paroxysm. In some few cases the febrile stage lasts only 24 hours. After this stage is passed an intermission or remission occurs, during which the temperature falls to or near the normal. * * * The intermission lasts 48 hours, thus completing the cycle, when a second chill takes place and the second paroxysm begins and terminates as the first; a two days' fever and a two days' intermission" (Chart 3).

This cannot be an extremely uncommon type. Jacquette, Smart, and others designated the temperature as intermittent or remittent and some were led to class the disease as a malarial infection on this account, but quinine had no controlling effect on the paroxysms. In fatal cases the fever usually remains high, although "the temperature occasionally becomes normal or subnormal eighteen to twenty-four hours before death" (Chart 4).

At the onset the pulse is slow, full, and of high tension but later it becomes rapid, running, and weak. There is a slight disproportion between pulse and temperature, but not so marked as in enteric fever. The character of the pulse is doubtless significant of an increasing toxemia.

The respiratory rate is increased to from thirty to fifty per minute, reaching as high as sixty in some cases. It is rather shallow and regular. Occasionally there is slight bronchial cough. Hypostatic pneumonia may develop.

The eruption appears during the first week of the disease, from the third to the fifth day. The spots are first noticeable about the ankles, wrists, and forehead and later spread over the entire body, sometimes invading the eyes, causing photophobia. There are fewer spots on the trunk than on the extremities, especially is this true of the abdomen.

Upon first appearance they are hyperemic maculæ 3 mm. to 6 mm. in diameter, which disappear readily on pressure, rapidly to return. In three or four days they enlarge to from 6 mm. to 8 mm., become papular and are modified only slightly on pressure (Fig. 2). Frequently petechiæ are seen, which may extend to an area of ecchymosis as large as a hand. As the fever declines the eruption begins to fade. It disappears slowly, a few days to several months being required for complete absorption to take place. Exposure to cold or a warm bath may cause the spots to show distinctly months after recovery.

In addition to the eruption the skin is congested and cyanotic, giving to the face a bloated and stupid expression. Ordinarily, jaundice is met with, first noticed in the conjunctiva. As will be seen in the blood picture, hemolysis takes place to a more or less marked degree, which is probably responsible for the jaundice, although pressure from an enlarged pancreas or mucosal swelling of the bile ducts as possible causal factors should not be lost sight of.

Desquamation begins upon convalescence and extends over the entire body. Gangrene of the scrotum, penis, and toes may occur in severe cases. In fatal cases the spots turn purple and remain post mortem. (See Fig. 3.)

During the first week the appetite is often good, but some nausea is present and vomiting is an occasional symptom. The teeth are covered with sordes and early the tongue has a heavy white coat with red tip and edge. Later the coat becomes brown and the mouth is parched and dry. In some cases marked irritability and pains in the stomach are experienced. Constipation is usual during the entire illness, although diarrhea may occur. Tympanites and tenderness of the abdomen seem to be absent.

The liver is somewhat, although not markedly, enlarged and the gall-bladder gives rise to no symptoms.

Headache is perhaps the most common symptom of the development of the disease. The patient also complains of pains in the back, muscles, joints, and bones. On this account restlessness and insomnia are common early, but later there is almost freedom from pain. Kernig's sign is absent. Photophobia is not extremely rare. The pupils react normally to light and accommodation. External divergent squint is reported by Mills and irregular dilatation of the left pupil by Geary.

The urine is considerably reduced in amount, high colored, acid in reaction and contains traces of albumin in varying quantities. Occasionally it is loaded with amorphous urates. Granular and blood casts are perhaps most commonly found, although the hyaline and epithelial varieties are not infrequently present. According to Wilson and Chowning, hemoglobinuria is absent or very slight. This is not the picture of a piroplasmatic disease.

Although jaundice is a common symptom, I have been unable to find any record of biliuria. This may be due to failure to make the test, but Stiles reports no bile present (Gmelin) in one case.

The red cells and hemoglobin show a progressive decrease. Five cases of Wilson and Chowning, at an altitude of 3,500 feet where the normal count is above rather than under 5,500,000, gave the following results: 4,100,000, 4,200,000, 4,300,000, 4,500,000, and 4,600,000. Kieffer recorded a greater decrease than this. The fall was from 5,800,000 (altitude 6,200 feet) to 2,600,000. (See chart No. 5.) The macroscopic appearance of the blood in his cases was characteristic of a piroplasmosis—thin, watery, and pale—while in those of Wilson and Chowning "the blood appears somewhat darker than normal as well as somewhat less fluid." Poikilocytes are present. The malarial parasite is not found. The entity of *Piroplasma hominis* is not established.

No marked leucocytosis is present; from 8,000 to 13,000. A constant feature, apparently, is an increase in the large mononuclear cells. A differential count made six times by Kieffer resulted as follows:

Polymorphonuclear.	76.6	77.	72.	71.	73.	72.
Large mononuclear.	12.4	13.6	15.6	16.5	15.6	16.6
Lymphocytes	9.6	9.	11.	12.	10.	11.
Eosinophiles	.8	.4	.9	.6	.8	.4
Mast cells	.6	.0	.5	.0	.6	.0
	100.	100.	100.	100.	100.	100.

An average in two counts made by Anderson gave similar results: Polymorphonuclear, 77.7; large mononuclear, 11.4; small lymphocytes, 10.0; eosinophiles, 0.9.

Occasionally there is a peculiar urinous odor about the patient which persists in spite of care and cleanliness.

The *diagnosis* of Rocky Mountain spotted fever is not difficult to physicians in the localities where the disease is known to exist. The laity also recognize it.

Its occurrence from late February to early July; history of tick bite, or possibly mosquito bite; headache; malaise; nausea and vomiting; constipation; pain in the muscles, bones, and joints; a chill, followed by a rise in temperature; the appearance between the third and fifth days of an hyperdermic, macular eruption, first about the ankles and wrists and later becoming diffuse, are the clinical features upon which a diagnosis may be made. The absence of the eruption does not render the diagnosis untenable because in the mild form no rash appears.

Differential Diagnosis.—Cerebrospinal fever.—Delirium, followed by stupor and coma, occurs at the onset. Herpes appears and the rash is variable. Retraction of the neck, tremor, rigidity of the muscles, and Kernig's sign are important diagnostic features. Lumbar puncture usually gives a turbid but sometimes purulent or bloody fluid and in coverslip preparations the diplococcus intracellularis is seen. A leucocytosis of from 25,000 to 40,000 is an early finding.

Enteric Fever.—After reaching the fastigium by a step-like rise, the fever is subcontinuous for a week or longer. The rose spots differ from the eruption of Rocky Mountain spotted fever in that they are distributed principally upon the abdomen and chest in successive crops, the first appearing from the sixth to the tenth day. Isolation of typhoid bacilli from the blood, stools, and urine, and the presence of rose spots afford fair evidence of the disease. The Widal reaction of typhoid has never been obtained in Rocky Mountain spotted fever. The Diazo reaction may be of service.

Typhus Fever.—Physicians have diagnosticated Rocky Mountain spotted fever as typhus fever. The highly contagious character of the latter is important and the eruption appears first upon the abdomen and chest, later upon the extremities, which is the reverse to the Rocky Mountain type. It is not limited to the spring and selects its victims in crowded cities rather than among the roomy ranchers. A mousy odor is peculiar to typhus.

Measles.—The contagious and epidemic nature of measles, together with the catarrhal condition of the respiratory tract, the enanthem (Koplik's spots) and the papular efflorescence, appearing first on the face, enable this disease to be differentiated with comparative ease.

Dengue.—The pandemic character and rapidity of diffusion are important in dengue. It has the highly infectious character of exanthematic fevers and occurs in tropical and subtropical regions. The onset is remarkably sudden, the joints are swollen and a pleomorphic eruption appears over them.

Purpura Rheumatica (Schönlein's disease).—The eruption varies greatly in character: purpura urticans, erythema exudativum, and pemphigoid purpura. The temperature range is not high. Sore throat and multiple arthritis are quite constant features.

Purpura Hæmorrhagica.—The prodromes and systemic disturbances are slight, and only a mild fever is present. Bleeding from the mucous surfaces may cause profound anemia.

Malarial Fever.—The absence of an eruption, the presence of the plasmodium malariæ in the blood, and the specific therapeutic action of quinine serve to differentiate this from Rocky Mountain spotted fever with comparative ease.

Prognosis.—The disease seems to be more virulent in some districts than in others. In the Bitter Root Valley the mortality is higher than in other localities. Anderson gives the mortality in Montana as varying from 70 to 90 per cent.; Wilson and Chowning as from 70 to 80 per cent. Of the Idaho cases, Maxey says: "The prognosis in spotted fever is, as a rule, very favorable if the patient is transmitted to the lower valleys where he can have home comforts and proper care." According to Mooser the Nevada cases are not so fatal as those in Idaho, Utah, and Montana.

During certain years the percentage of fatalities is reduced below that of other years.

The development of jaundice, delirium or other involvement of the nervous system, or of the hemorrhagic diathesis is almost invariably followed by death. The cause of death seems to be toxemia and exhaustion.

As will be seen in the accompanying chart (No. 6) of fatalities the patient most frequently perishes from the sixth to the eleventh day.

Anderson thinks the abundance of the eruption bears no relation to the severity of the disease. In the mild type, however, death almost never occurs. Geary reports an intercurrent diphtheritic infection which yielded to treatment by antitoxin.

Treatment.—The treatment is principally expectant and symptomatic. No medicinal agent seems to exercise any specific power over the disease.

An attempt to exterminate the tick would seem useless, as this would mean extermination of all animals, wild and domesticated, which are the chief hosts for ticks.

As prophylactic measures, some of the Western physicians advise early removal of the arachnid by applying a volatile oil, such as kerosene or turpentine, which causes him to let go, and cauterization of the wound with 95 per cent. carbolic acid. This, however, has been futile in most instances.

Pioneer settlers tell me their method of treatment was by the administration of wild sage tea.

After the supposed discovery of the *Piroplasma hominis* it was suggested that quinine be given hypodermically in large doses. At present there exists considerable diversity of opinion as to the propriety of administering this drug, some maintaining that it increases the subjective discomfort and is very unsatisfactory, while others affirm that good results are obtained by its use.

Calcium sulphide is spoken highly of by a number of physicians.

Kieffer is quite convinced that arsenic has a controlling and curative effect on the disease. He recommends the subcutaneous injection of 1 to 2 c.c. twice daily of the following solution:

R	Sodii arsenitis.....	0.1
	Cocainæ hydrochlor.....	0.4
	Aquæ	10.0

The cocaine is added to prevent burning.

If Kieffer's observations be correct, atoxyl might prove of value in this disease, as a greater quantity

of arsenic can be borne when given in this form. In view of the results obtained from this drug in trypanosomiasis and the promising results in syphilis, it may be well to try this drug in Rocky Mountain spotted fever.

A dark, quiet room is preferable. As constipation is the rule, the bowels should be kept open by some laxative. The relief of pain has been obtained by Dover's powder and the coaltar products. The latter may be too depressing in this toxic condition.

Anderson states that warm sponge baths or packs reduce the fever and relieve the congestion of the skin.

The heart is kept up by strychnine, alcohol, and digitalis; while diruesis is accomplished by the administration of an abundance of fluid. A liquid or semisolid diet is advised.

The following report of a case of Rocky Mountain spotted fever is made by Dr. J. G. Patterson, of Merrill, Oregon.

Fred Steemans, homesteader on the southeast slope of a range of hills separating Lower Klamath Lake basin from Tule Lake basin. Patient had been engaged in clearing sage brush land and had many ticks on his body. He first came into my office April 19, 1906, complaining of headache, anorexia, general lassitude, hebetude, soreness of muscles, especially those of the back and limbs, which symptoms had existed for two days. Tongue was furred, conjunctiva injected, discomfort in splenic and hepatic regions, temperature 103° F., and pulse slow and full.

I was called to see him again April 22, 1906. His temperature was then 104.4° F., he had great thirst, constant headache, photophobia, and profound prostration, and had suffered from nausea. There was present at this visit a profuse rash which had come out first on the anterior aspects of the limbs, especially the legs. This rash was first a macular roseola and later papular. It seemed to terminate in rather indefinite petechia and in some places there were distinct blotches. A slight bronchitis developed. The bowels were constipated throughout the attack and the urine contained a slight amount of albumin (febrile).

I visited the patient on April 28, 29, May 4, 9, and 23. During this time the original symptoms continued. His mind was clear except when the temperature was high, at which times there was a tendency to delirium.

He left his bed May 27 (after a period of five weeks) but was unable to attend to work for several weeks after this date because of extreme weakness. The patient entirely recovered without any sequelæ.

Treatment was purely symptomatic and stimulant. The temperature was reduced by cold sponges. A dark but well ventilated room was occupied.

IMPRESSIONS DERIVED FROM A VISIT TO THE WARM SPRINGS OF VIRGINIA.

By ALBERT H. BUCK, M.D.,

NEW YORK.

A FOUR weeks' trial of the course commonly prescribed for those who frequent the Warm Springs of Virginia has set me to thinking upon the manner in which the use of these pools of water produces beneficial results in certain maladies. At the risk of "carrying coals to Newcastle," of calling attention to matters which in all probability are discussed in a more careful and authoritative manner in all standard treatises on balneology, I will state briefly the essential facts relating to these pools and to the manner of using them.

There are two of these pools (one for men and one for women), in both of which the water comes up from the bottom in large volume; and with the water comes a considerable amount of gas, which bubbles up at numerous points throughout the cen-

tral part of each pool.* Presumably, this gas is composed in part, perhaps chiefly, of carbonic acid, but no analysis is needed to satisfy one that sulphuretted hydrogen enters into its composition. The temperature of the water is 98° F. The pool for women has an average depth of 5 feet, and that for men 6 feet, but the outlets of both are so arranged that the attendants can, in a minute or two, diminish the depth to the extent of twelve or fifteen inches. Several dressing rooms are located around each pool, and over the central point the sky is visible through a large circular opening in the dome-like roof of the wooden building which encloses the pool. The buildings and the entire equipment are of the simplest character, having been constructed more than one hundred years ago; but they serve their purpose well, and the beauty of the pools themselves is such that the visitor is not disposed to criticize the primitive character of these accessories.

Those who enter the pool for the first time are advised by the attendant not to remain in the water longer than ten minutes, and this seems to be good advice, for I was distinctly conscious, after my first bath, of a sense of fatigue; and this lassitude was felt on subsequent occasions, although I had increased the duration of the bath to only fifteen minutes. Upon leaving the pool one finds the attendant waiting, at the entrance of his dressing room, ready to rub him down briskly with a large bath towel and then to subject him to a brief series of slapping and kneading manipulations which quickly remove all sense of chilliness. (The nights here in October are frequently frosty.)

One cannot help asking oneself the question: How does systematic bathing in such a pool as that which I have described produce greater therapeutic effects than a similar amount of bathing in a hot bath at one's home would produce? I do not feel competent to give a complete and satisfactory answer to this question, but I suspect that there exists here—and, for aught I know, at similar sulphur baths in other parts of the United States—a factor which certainly is not to be found in any ordinary tub bath.

Over the surface of each of these pools is constantly present a deep stratum (certainly 8 or 10 inches deep) of warm vapor lightly charged with sulphur. On a cool October day this vapor is plainly visible. The bather, whether swimming or simply resting in the water in an upright attitude, is obliged to inhale this sulphurous vapor so long as he remains in the bath, and it seems reasonable to believe that far more sulphur—a remedy of acknowledged value in rheumatic affections—enters the circulation by this route than can possible enter by any other—as, for example, by way of the skin.

There is another action which these pools produce upon the bather, an action which they possess in common with all other pools the water of which remains constantly at a temperature of about 100° F. Almost immediately after one enters the water, a very large quantity of blood is diverted from the more deeply seated parts of the body to the skin;† and one can scarcely be mistaken in attributing this effect to the action of simple hot water. Except in large bathing establishments, such as are found in only a few cities, it is very difficult, if not practically impossible, to keep the water in the bath at a constant temperature of 98°—100° F. Pools fed by hot springs supply all the conditions needed for the production of whatever benefit is to be derived from prolonged immersion in hot water; and if they are, at the same time, sulphurous in their composition, situated in the midst of beautiful scenery, and under the management of a hotel so admirably conducted as is the one at Warm Springs, this benefit may be looked for with confidence.

That the drinking of the water which bubbles up from a third group of springs in the immediate vicinity of the pools, contributes to the success of the case, I have no reason to doubt; but fear of getting beyond my depth compels me to abstain from the discussion of this part of the subject.

*The pool for men measures 40 feet in diameter, and that for women, 50 feet.

†The reduction of one's girth, in the case of a person who is quite stout, is strikingly great—often amounting to as much as five inches. The diminution of the blood-content of various abdominal organs affords a plausible explanation of this reduction of girth.

CHOLECYSTITIS, WITH SUGGESTIONS FOR THE PREVENTION OF GALL-STONES.

By HENRY WALD BETTMANN, M.D.,

CINCINNATI, O.

Cholecystitis is an inflammation of the gall-bladder due to infection. By far the most frequent cause is the colon bacillus; the typhoid bacillus is responsible for many cases; occasionally cholecystitis is caused by the pus-formers, the influenza bacillus, or the pneumococcus. Tuberculous cholecystitis is very rare. The manner of infection is not always clear. It is highly probable that in nearly all cases, the infecting bacteria reach the gall-bladder by way of the portal circulation. Ascent from the duodenum through the papilla of Vater is uncommon. Infection through the arterial circulation is also unusual. Just what conditions permit of an invasion of bacteria through the portal circulation is not always clear. The most frequent result of cholecystitis is the formation of gallstones. It may be considered as proved, that gallstones occur only as a sequel of catarrhal cholecystitis or cholangitis. The clinical history of gallstones has been pretty well worked out. We know the cause, the symptoms, the complications, and the cure. The underlying disease, viz., the cholecystitis, has not received nearly the attention it deserves. Cholecystitis is probably the most frequent inflammatory disease within the abdomen. Nevertheless it is scarcely recognized by the profession as a disease *per se*. The fact that it is so frequently complicated by gallstones, has focused the attention on the latter disease and has strangely retarded our recognition of the significance of cholecystitis as the primary and often the more important condition. The history of appendicitis is closely analogous. The most serious complication of appendicitis, viz., peritonitis, caused the nature of the underlying disease to be entirely overlooked up to within very recent times. Chiefly through the influence of the surgeons, the profession at large were taught to recognize appendicitis when they saw it, and it is only since the general practitioner has learned to diagnosticate the milder forms of appendicitis, that the enormous frequency of this disease has been generally recognized. Now exactly the same history will repeat itself in regard to the inflammations of the gall-bladder. Almost all the cases of mild cholecystitis have hitherto been entirely overlooked or wrongly designated. Countless cases are set down as attacks of gastritis, spoiled stomach, acute indigestion, or even appendicitis. As a result, we are

*Paper read at the eleventh annual meeting of the American Gastroenterological Association at Chicago, June 1, 1908.

not yet in a position to state just how frequent cholecystitis actually is, or under what conditions it may occur; we cannot say in what proportion of cases one attack is followed by others; we do not know in what proportion of cases gallstones are formed; we cannot say surely whether we can influence the formation of stones or not. In fact, the whole clinical history of cholecystitis remains to be written.

The object of the present paper is to throw a little light on a few of the more important clinical features of the disease. During the past 18 months I have had the opportunity of observing nearly 120 cases of gall-bladder disease. My conclusions are based largely on a study of these cases. In many of them, complete data were not obtainable.

The relation of cholecystitis to child-bearing.—A large number of observations has led me to believe that, in women, pregnancy and especially the puerperium directly lay the foundation for the primary infection of the gall-bladder. Furthermore, it seems exceedingly probable to me, from personal observations and a close study of the clinical histories, that in women the great majority of gallstones have their inception in attacks of cholecystitis during the active child-bearing period. These conclusions are based on the three following observations:—

(1) I have personally observed in many cases acute primary attacks of cholecystitis within a few weeks or months of parturition.

(2) I have repeatedly seen acute exacerbations of cholecystitis in the puerperium.

(3) Many women who are subject to gallstone attacks give an unmistakable history of cholecystitis immediately following some preceding confinement.

It is not hard to see why the puerperal state should predispose to infections of the biletract. It is generally said that pregnancy lends itself admirably to stagnation of the bile. Personally, I believe that the phrase "stagnation of bile" lacks scientific definiteness and has more theoretic than actual existence. Clinically, we know nothing of stagnation of bile, except that due directly to obstruction. During the puerperium, however, the pelvic lymphatics and veins are overloaded with waste products from the placental site and the involuting uterus. Even at its best, the liver is not always able to bar the progress of bacteria from the incoming portal blood into the bile. In the puerperium we have a frequent combination of constipation, overeating (often indulged in for the sake of the milk supply), physical inactivity, and a portal blood supercharged with waste material. What better opportunity could be offered the ever-ready *B. coli* for a successful invasion of the biletract?

Primary attacks of cholecystitis occur usually between the ages of 20 and 35. After the frequency of catarrhal cholecystitis becomes generally recognized by the profession, it will require some years of observation to determine definitely at what age cholecystitis is most prevalent. Autopsy findings indicate that gallstones are more common after 30 than before, and still more common after 40. My own observation leads me to believe that cholecystitis is comparatively rare before the age of 20, that it occurs with very great frequency between 20 and 30, especially in women, and that the majority of primary attacks occur before 35. Attacks of cholecystitis which take place after the age of 40 are usually recurrent ones, and in the majority of instances are already complicated by the presence of stones. If these observations and conclusions are correct, it would seem that cholecystitis in a very large proportion of cases precedes the formation of stones by months or years, and that patients frequently have recurring attacks of cholecystitis long before stones are formed. It is established by operations, that a certain proportion of sufferers from cholecystitis escape cholelithiasis altogether; but it is not possible in the present state of our knowledge to say just how large this proportion is.

The interval between the primary cholecystitis and the formation of gallstones is universally neglected by physicians. Kramer (*Journal of Experimental Medicine,* May, 1907) has shown that when colon bacilli are grown in a sterilized mixture of alkaline peptone bouillon and bile, a gradual precipitation of cholesterin and other components of gallstones occurs. At the end of four weeks a closely packed semisolid mass can be seen at the bottom of the tube. After six months, the supernatant fluid can be poured off, leaving a well molded mass resembling soft gallstones.

Ten years ago, Mignot showed that gallstones can be produced experimentally in dogs, in 4 or 5 months. Numerous cases are reported, making it seem very probable that human gallstones can be formed in from 4 to 8 months. So far as we know, the formation period may often be very much longer. Whether bacteria must continue to grow in the gall-bladder during this whole period, in order that stones should be formed, is not as yet definitely known.

Kramer has suggested that the precipitation may be due to the acid reaction of the bile induced by the growth of the *B. coli* or *B. typhosus.* Now it seems probable that the interval between the primary cholecystitis and the deposit of cholesterin would be a most fruitful one for therapeutic endeavor. It may be regarded as conclusively demonstrated that the usual treatment of the gall-bladder is effective in reducing inflammatory conditions and in a measure preventing their recurrence. No observer can doubt that the usual Carlsbad treatment or the Carlsbad method modified for home use, has a certain utility in well-established cases of gallstones. Now that the exciting cause of gallstones can be recognized clinically, months before their actual formation, it seems to me we permit the golden opportunity to escape, when we do nothing for our patients during the months following an acute attack of cholecystitis. During the attack, the patient should rest in bed and should have warm Priessnitz compresses over the upper half of the abdomen. Opiates should be given to relieve pain if necessary. The diet should be exceedingly limited during the first few days, and all cathartic drugs are contraindicated. After the swelling of the gall-bladder has subsided and the local soreness has disappeared, the patient may be out of bed most of the day. The diet should consist largely of cereals, meat, simple vegetables, bread and butter. Alcoholic drinks, acid foods, and fruits should be prohibited. The use of salines should be begun early.

Sulphate of sodium, phosphate of sodium, bicarbonate of sodium, and salicylate of sodium may be given in various mixtures. They are best administered dissolved in plenty of hot water, one-half to one hour before each meal. I do not believe there is any special virtue in the salicylate of sodium, not possessed by the other drugs mentioned; nor do I think it advisable for the patient to eat more than the three regular meals a day. It is possible that urotropin or other drugs may prove to have unusual value. Under this simple treatment, continued for months, or if need be for years, patients are given an excellent chance to escape recurrence of inflammation, and in fact all symptoms referable to the gall-bladder.

I cannot state with certainty that the formation of stones is thereby actually prevented. Proof of such an assertion would be exceedingly difficult to offer. If we get rid of the inflammation, the gall-bladder may of itself dispose of the salts already precipitated within it. This was experimentally demonstrated by Bain, in 1905, who showed that if gallstones are introduced into the healthy gall-bladder of dogs, they are dissolved in the course of a few months.

I do not believe that well-formed gallstones are ever dissolved within the human gall-bladder. Nevertheless, most of the symptoms of cholelithiasis are due not to the stones themselves, but to the associated cholecystitis. After the stones are formed, the tendency to recurrent attacks of cholecystitis is increased. Symptoms which do not promptly disappear under appropriate medical treatment or which recur notwithstanding proper habits of life, call for surgical intervention.

Leverone Building.

A CASE OF SYRINGOMYELIA.

SUGGESTING A POSSIBLE RELATIONSHIP WITH AN ACUTE CEREBROSPINAL MENINGITIS 18 YEARS AGO.

By L. S. MANSON, M.D.,

NEW YORK.

During the winter of 1890-91 a seven year old child with opisthotonus and other typical symptoms of acute cerebrospinal meningitis was seen in consultation by Dr. Francis Delafield. This physician admitted the desperate, though not absolutely hopeless, nature of the case, but would not sanction the rapid mercurialization of the patient—a method of treatment which, in spite of the absence of luetic taint, had proved successful in several similar cases in my experience prior to that date.

As the child's condition grew worse and worse and began to look hopeless I did employ about 3 ounces of oleate of mercury (10 per cent.) by inunction in four doses, every six hours. Before the twenty-four hours had expired consciousness returned, the patient began to converse with attendants, and made a rapid recovery. I reported what I had done to the consultant, who remarked in his characteristic droll but pleasant manner, "If the child had died it would have been a nasty job."

I next saw this patient July 27, 1908. He had been perfectly well in every way, bright and intelligent, was graduated from the public schools, had learned the trade of machinist, and was a good mechanic. About two years ago he began to notice a gradually increasing weakness on the right side commencing in the hand and arm. The gait became unsteady, he complained of frequent attacks of vertigo, and every few days he was seized with spells of overpowering drowsiness or sleepiness lasting several minutes without loss of consciousness. Weakness of the facial muscles and slight ptosis on the right side became manifest, producing a narrowing of the palpebral fissure and a stupid expression. During walking the body deviates somewhat from the median line, but there is not sufficient involvement of the spinal muscles to produce any marked lordosis. There is no distinct ataxia. The muscles of the hand are sufficiently wasted to make it impossible to use in writing, the patient being compelled to use the left hand for that purpose. The entire left side of the body up to the median line is insensitive to heat and cold and anesthetic, painful pin thrusts creating only tactile impressions. There is complete sexual impotence and loss of the stereognostic sense, the patient being absolutely unable, with the eyes closed, to distinguish objects such as a penknife, box of matches, or coins held in the right hand. The tactile sensibility is also markedly delayed, for with the eyes still closed tactile sensibility remains 8 or 10 minutes after removal of these objects. The muscles affected show diminished reaction to faradization, but no decided R.D. There is slight fibrillary twitching in some of the affected muscles, the knee jerks are greatly exaggerated, but there is no ankle clonus.

I saw the patient again on August 9, when his condition was practically the same, but during that night he died rather suddenly with symptoms of bulbar (respiratory) paralysis. An autopsy was not obtained. Here, then, we have a good clinical picture of syringomyelia with the lesion, a dilatation of the central canal with gliomatosis, probably involving the cervical segments and extending upward through the medulla and pons, in which an attack of cerebrospinal meningitis 18 years before was the possible etiological factor. This case is worthy of record because the etiology of this disease is practically unknown, or, to say the least, very obscure.

616 Madison Ave.

New Diagnostic Methods in Appendicitis.—Rovsing of Copenhagen has employed for the past three years an original and, as it appears, a very valuable method of examination in cases suspected of appendicitis or typhlitis. With his right hand he presses his left one, palm downwards, against the integument of the left iliac fossa and lets it glide upwards along the descending colon until it reaches the vicinity of the left colic flexure. By this procedure the gases contained in the large intestine are made to exert a greater pressure against the intestinal walls than before, with the result of eliciting severe darting pains in the region of McBurney's point. In each of his two first cases in which he tried his new method of examination there was strong suspicion of the affection being a perityphlitis judging by the usual signs. The one patient, however, did not experience the least pain in spite of rather vigorous massage of the descending colon, while the other patient felt at once severe pain, referred to McBurney's point, after a mere compression of the middle part of the descending colon. The subsequent operations explained the difference. The last-mentioned patient turned out to be suffering from appendicular peritonitis, whereas the first patient on being explored by laparotomy did not present any alteration of the vermiform appendix or intestine, but a retroperitoneal swelling, which lifted up the ascending colon and which a lumbar incision proved to be due to a perirenal phlegmon.

Judging from his experience in more than 100 patients, Rovsing considers his method a trustworthy, sensitive, and valuable diagnostic help. Its importance lies in a twofold direction. First, it will aid in the correct diagnosis in the many doubtful cases in which the nature of a painful swelling in the right iliac fossa cannot with any certainty be made out, such as those in which the diagnosis of a renal affection, a ureteric or hepatic lithiasis, or a salpingitis appears just as probable as that of an appendicitis. For only in those cases where the pain is caused by an affection of the appendix or cecum will it be elicited by pressure against the healthy descending colon. The trustworthiness of the symptom is well borne out by the following observation. In several cases of gangrenous appendicitis where the pain was referred only to the epigastric area and had therefore led to the suspicion of a gastric affection (perforating ulcer of the stomach), Professor Rovsing's method gave at once the correct diagnosis, pressure against the healthy descending colon immediately eliciting the typical pain over McBurney's point. The second field for application of the method is to be found in the acute cases where direct palpation is dangerous, painful, or impossible on account of defensive muscular rigidity and therefore must be omitted, whilst palpation of the healthy descending colon does not present any difficulty.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, November 28, 1908.

ABSURDITY IN RESEARCH.

WE believe that the majority of the medical profession does not look with favor upon such uncritical attitude toward new methods in medical art and science as has been displayed, for instance, in connection with the conjunctival reaction to the instillation of tuberculin. Whatever may prove to be its final value in the recognition of cases of tuberculosis not diagnosed by the older methods of procedure, it was self-evident from the start that the use of the conjunctival membrane for testing the effect of tuberculin must be connected with grave danger to the patient, a most delicate and most important organ of the body being exposed to injury or destruction by any unexpected severity of the reaction. Yet current medical literature was flooded for a time with papers recounting so and so many healthy and diseased persons upon whom the reactions were tried, even though the very first publications showed that to be of scientific value such work had to be done in institutions where the opportunities of verifying the clinical diagnoses by pathological examinations were frequent, where time and means were abundant to carry out the older methods of diagnosis properly, and where it was possible to follow the patient carefully so as to institute immediate treatment if the reaction was becoming dangerous to his vision. It is true that the unfortunate results reported have been few in comparison with the great number of tests made, but it is probable that many cases have not been made public; moreover, it must be remembered that the reaction in question is simply a means of corroborating a diagnosis and not in the least a method of treatment or, by itself, an indication for treatment. We doubt whether the presence of the reaction alone would justify a course of treatment for tuberculosis in the absence of other signs of the disease. Of course, many methods of treatment are accompanied with possible danger of injury or even of death. Collapse after the injections of antitoxin, death caused by anesthetics, deaths due to shock of operative procedures are instances of this kind, but the patient is usually well informed as to the possibility of such accidents and considers the risk worth taking in the attempt to get rid of a serious disease. That the great majority of patients on whom the ophthalmoreaction was tried were kept in ignorance of the meaning of the reaction as well as of the risks of it is, of course, probable, for every possible clinic and hospital material was utilized in getting up papers on the subject. It would seem that an attitude toward such patients was called for that was more in agreement with the Golden Rule.

An article in the *Wiener klinische Wochenschrift* for September 10, 1908, in which Oppenheim describes another "reaction to tuberculin," serves very well to point the above remarks. Oppenheim wanted to observe the behavior of the mucous membranes to tuberculin and selected for this purpose—the male urethra! This mucous membrane, of course, reacted quite frequently to the irritant, and the author was rewarded by the appearance of acute urethritis which sometimes occurred in patients in whom the cutaneous reaction was observed and at other times in individuals in whom that reaction was negative. No control experiments with the component parts of tuberculin other than the bodies and products of tubercle bacilli are reported by the author, and no mention is made of the fact that the urethra, especially in men who have once suffered from gonorrhea—and some of Dr. Oppenheim's patients gave the history of that disease—reacts quite readily to irritants of any nature. The conclusions of the author are quite characteristic: "Not only the conjunctiva but the urethral mucosa as well may give evidence of an allergic reaction to the injection of tuberculin; such reaction is weaker and less constant than the ophthalmoreaction; no practical diagnostic significance can be attached to the urethral reaction." It would seem that these conclusions could have been safely established by a little deductive reasoning without the necessity of carrying the experimental, inductive research to an absurdity.

The zeal of the physician to discover new facts in the art of science of medicine must not run away with his better judgment; and certainly the desire to figure in literary discussions and to be among the first to try every newly recommended procedure must not overcome his sense of duty to the patient and consideration for the health and comfort of the latter. Any other attitude is fraught with danger not only for the individual physician, in case of some untoward accident, but for the good repute of the whole medical profession as well.

A PURE MILK CRUSADE IN GREAT BRITAIN.

ONE result of the recent International Congress on Tuberculosis at Washington has been to show conclusively that the views of Dr. Koch as to the innocuousness of milk containing the germs of tuberculosis, are not those of the majority of the medical profession in all parts of the world. True, Dr. Koch presented his opinions at Washington in a considerably modified form, and stated that he now believed it to be possible to contract tuberculosis from tuberculous milk, but that such an occurrence was so rare as to be almost a negligible quantity. However, the consensus of opinion seemed to be that a large proportion of sufferers from tuberculosis contracted the disease by the agency of contaminated milk. Thus it may now be regarded as more or less definitely proven that milk infected with the germs of tuberculosis is a prominent factor in the spread of the disease. This, of course, is especially the case with infants, and it may, perhaps, be taken as demonstrated that the channel of infection is quite frequently the intestinal tract.

But, while tuberculosis is the most serious disease

which is propagated on a large scale by means of milk, yet dirty milk is a potent menace to public health in many ways. This statement is a truism, but it cannot be too constantly insisted upon in order that reforms may be instituted to insure a comparatively pure milk supply. In New York State and in New York City, in particular, the milk supply is controlled as well as, if not better than, in other large communities of the world. Compared with London and the many large centers of population in Great Britain, the manner in which milk is supervised in New York is distinctly satisfactory, but there is still room for improvement.

Up to a short time ago but little interest was taken in the British milk supply either by the medical profession or by the general public. The *Lancet* has from time to time endeavored to rouse the population to a sense of the dangers to which the careless methods in vogue were subjecting them, but until recently to no purpose. About two years ago there was published in the *Lancet* a series of articles dealing with the transportation to and distribution of milk in London, and since that time an intelligent concern in the matter has been constantly manifested. At the present time, judging from articles and reports which have appeared in British medical and lay papers, the interest in the matter is becoming acute, and London and all the large provincial towns have awakened to the responsibility of providing at least a fairly pure milk supply.

A feature of the greatest moment in the crusade against contaminated milk in Great Britain is that legislation is to be invoked to prevent, or, at any rate, to minimize the danger likely to occur from the milk and flesh of cows and cattle suffering from tuberculosis being sold without restriction. Exactly what steps are to be taken in this direction has not been decided as yet, and although preventive measures will probably not be so radical as is wished by some, there is little doubt that enactments will be put into force which will remove, to some extent, the menace of the spread of tuberculosis by the agency of diseased cows. This, of course, is an advance movement of the first importance to public health. If the spread of consumption is to be stayed, it stands to reason that the evil must be grappled with at its source, and so long as cows afflicted with tuberculosis, and especially with tuberculosis of the udder, are allowed to be the providers of milk, just so long will the disease flourish among the young. If our present conception of the matter is right, and the discussions at the Congress in Washington go to prove that it is right, then in the first instance, we must insist that our cows are not the means of spreading the malady.

Professor Delépine has recently made some instructive investigations in regard to the milk supply of Manchester, England. Perhaps the most interesting of his observations are that there is a distinct average correlation between the amount of dirt and the pathogenicity of the milk. That is to say, that dirty milk is far more capable of disseminating any disease than is a clean milk. London is seeking powers for extending the control which is now possessed as regards tuberculous milk to that which is dirty and contaminated, even though it comes from perfectly healthy cows, and other large British cities are following in its wake.

Koch's pronouncement some years ago, did much harm, but now that it is almost universally recognized that his assertions were premature and based on lack of knowledge, the harm can be remedied. The solution of the problem of how to procure a reasonably pure milk supply is in sight. The knowledge is possessed, and it only remains to put it into effective practice.

INHALATION ANESTHESIA IN "HEALED" PULMONARY TUBERCULOSIS.

In submitting patients to operation the condition of the lungs is seldom given so much attention as the importance of these organs most assuredly merits. No surgeon would think for a moment of neglecting careful and conscientious examination of the anatomical part upon which he intends to operate. Ordinarily he also demands an analysis of the urine and blood, and seldom neglects an examination of the heart. Examination of the lungs, however, is often omitted or left to an assistant. The anesthetist also is apt to feel that he has done his duty by a patient if he has inquired as to recent ingestion of food and the presence of false teeth, and if he has determined the absence of organic lesion of the heart. But it is not the heart which is the most important in many cases. A vital question is the matter of glandular tissue if it appears in excess, so as to obstruct breathing, or if it leads one to fear a status lymphaticus. From an operative viewpoint the condition of the lungs is also of prime importance, and a tuberculous focus in these organs is just as much a matter of vital concern as a mitral insufficiency or a chronic diffuse nephritis.

An example of this fact came to notice a few weeks since in reference to a patient who had been operated upon for fistula *in ano*. Previous to this event, which was described as an insignificant affair, this patient had suffered from pulmonary tuberculosis, but had been "cured" in the mountains of California. He had been able for some years to carry on the management of a large business without difficulty, and had always described himself as a well man until the appearance of the fistula. Ten days after the etherization he went through a severe attack of tuberculous pleurisy. It seems probable that in this case an old focus was broken down either through violent coughing or through the direct irritating action of the fumes of ether.

If an operation is essential to the life or well-being of a patient with pulmonary tuberculosis, effort should be made toward the use of either rectal or local anesthesia. It is quite impossible to say when a tuberculous focus is "healed." Mere arrest of symptoms is no criterion of the pathology of the condition, nor does it predicate the possible virulency of a so-called latent process. Nature's protecting wall may be adequate for ordinary purposes, but when subjected to special strain may prove quite unable to resist the attacking force. It behooves every surgeon therefore to handle such conditions with the utmost care, and when undertaking an operation under ether to be mindful of what can and may happen from pursuing a contrary course.

MEDICINE'S LOSSES AND GAINS.

Under the above caption the *Nation,* in its issue of October 1, attempts to give a comparative estimate of the present and past status of medical science as seen from the layman's viewpoint. It thinks that the general impression is coming more and more into prominence that various schools of mind cure are carrying on a winning fight against orthodox medicine. This impression is founded on the growing number of spiritual healers, on the prominence given to them by the press, on the well-known persons they convert, and on the fact that so-called religious clinics are springing up in connection with church activities. Professor Osler is cited as maintaining that practically our entire pharmacopeia might be discarded without appreciable loss to the general public health, but, fortunately, Osler is no longer accepted as an authority in therapeutics. To be sure, there are only a few diseases for which we possess specific remedies, but so long as these diseases are not preventable, or, rather, not prevented, we cannot do without mercury in syphilis, quinine in malaria, or the salicylates in rheumatism. Symptoms may be improved by diet, exercise, massage, rest, and mind therapy, but none of these is germicidal, and so long as the germ is active just so long will the infected patient be menaced by latent manifestations of his malady. The assertion is made that "the human mind has always felt the anomaly of giving the mastery over life and death into the hands of men who are no better than ourselves," which strikes one as bad psychology and worse judgment. To feel an anomaly, mentally speaking, is, to say the least, an uncanny thing, and its spectral existence is disproved by the eagerness with which the aid of a physician is sought when a human being is in great pain. Even the Christian Scientist is forced to submit to the fell stroke of Tyrant Pain. There is no compromise save by the knife or hypodermic needle.

But even admitting that rational medicine is losing a few of its educated devotees, it is gaining converts among the immigrant millions. To quote again: "The Jews of the East Side have called in the doctors, whom in poverty-stricken Russia they could not afford to consult. . . . In view of such successful effort as medical science is making against tuberculosis and other diseases, it would be absurd to maintain that medicine is being discredited as a science or art." Just so soon as people can be made to understand that physicians are not merely dispensers of pills and potions, but are experts in the management of disease prevention, just so soon will disease be lessened and the sum total of human misery dependent thereon approach the vanishing point. It is not alone knowledge, but wisdom—wisdom on the part of both physician and patient—which shall triumph in the end over disease.

The Effects of Pleuritic Exudate Upon Pulmonary Tuberculosis.

Enforced rest, whether compelled by the subjective sensation of pain or by some mechanical means, is among the first phenomena observed in the spontaneous response of the organism to injury effected. Only if some important function is involved, this mode of response is somewhat modified or delayed, but even then the principle of symmetric repetition of organs allows of partial rest or of complete rest for a limited period of time. It is in imitation of such natural phenomena that a number of physicians have tried to influence the course of pulmonary tuberculosis by the production of artificial pneumothorax upon the side of the lung affected by the disease. In the majority of cases reported distinctly a favorable effect has been noted in consequence of the procedure, but the number of patients in whom it could be tried has been very limited. An analogous natural phenomenon, however, the formation of a pleuritic exudate, has not been sufficiently studied for its effect upon the course of tuberculosis and, indeed, has been frequently interfered with in a routine way without individualization of the treatment adopted. In the *Beiträge zur Klinik der Tuberculose* (Vol. X, No. 4) Dr. Konzelmann makes up for this omission by reporting the effects of pleuritic exudates in a number of patients under his observation. In the majority of these patients the complication seemed to have been productive of very marked improvement in the symptoms of the disease and, indeed, in a few cases it seemed to have initiated convalescence which ended in recovery. Among the signs of improvement there were noted diminution in the amount of sputum, disappearance of the bacilli from the sputum, fall of temperature after an initial and marked change for the better in the general condition of the patients. The conclusion seemed warranted that the compression of the lung by the exudate and the consequent enforced rest of the infected tissues enabled the natural resistance of the organism to the spread of the disease to assert itself much more strongly than the constant motion of the active organs allowed before the appearance of the exudate. Thus direct proof is given of the benefit that artificial measures such as the production of a pneumothorax may exert; yet more important is the changed point of view with which pleuritic exudate in pulmonary tuberculosis must be regarded. Of course, every natural response to injury may have to be interfered with, because in serving the local needs of the tissues it may do irreparable harm to the organism in general. But whenever this is not the case, such exudates should be considered as distinctly beneficial factors in the struggle of the organism with the infective process in the lungs.

Lordosis and Orthostatic Albuminuria.

The discovery that intermittent albuminuria often depends for its existence upon the posture of the patient, appearing during the day and disappearing at night, or vice versa, has stimulated the interest of the medical professon in the influence of mechanical factors upon the functions of the kidneys. After Jehle had shown that lordosis is a frequent accompaniment of orthostatic albuminuria it occurred to Bruck to study the effect of posture simulating lordosis upon the excreton of albumin by the kidneys. His findings, reported in the *Münchener medizinische Wochenschrift* for November 3, 1908, completely bore out the truth of *apriori* conclusions in the matter; children, who excreted no albumin whatever when in their natural postures, quickly showed albuminuria if kept in a posture of artificial lordosis, the amount of proteid excreted increasing with the period of time during which the constrained position was enforced. This phenomenon was not at all exceptional, for over 18 per cent. of the children examined passed albumin under such condi-

tions; any coexistent disease of the kidneys was excluded by the examination of the urine during three months previous to the experiments. Other related phenomena consisted in the fact that the amount of urine was markedly diminished during the period of excreton of albumin and that such excretion was much more marked in the intervals between meals than just after sufficient nourishment had been taken. The whole series of observations throw light upon the so-called functional disturbances of the organs, for it is probable that physical circumstances of temporary nature are often at the bottom of such disturbances. That lordosis causes changes in renal circulation or in the relation of the kidneys to the ureter is, of course, very probable, and it is these changes that somehow modify the normal activity of the organs and lead to the excretion of albumin. But one autopsy has been recorded, that of Heubner, upon a patient who in life showed the symptom of orthostatic albuminuria; the kidneys proved to be quite normal. It would be interesting, however, to follow all such cases as well as those in which albumin may be caused to appear by the assumption of any posture modifying the renal circulation; it seems hardly probable that such gross disturbance as the excretion of albumin can appear in perfectly healthy organs upon such little provocation. It may be that such tendency shows a predisposition to renal disease, and long observations should clear up this point. If such is the fact then experiments similar to those performed by Bruck will become a valuable means of diagnosing inherent weakness of the kidneys and thus increase our knowledge of the prophylaxis of renal disease.

Cholesterin in the Treatment of Tetanus.

That tetanus antitoxin has a distinct preventive action has been amply shown by the annual experience with the ugly wounds that follow in the wake of our barbaric celebration of the Fourth of July, on which occasion we risk our lives and limbs and encourage our children to do likewise for the doubtful pleasure of setting off some fireworks. This antitoxin, however, has proved to be of very little value after the disease has developed, and every once in a while some new remedy is proposed for the dreadful affection. These remedies, necessarily, can be tested in but a very limited way in the human subject and the first enthusiasm that attends their introduction is usually succeeded by disappointment as time offers more opportunities of showing their uselessness. Yet every new remedy must be tried because of the very helplessness with which we are compelled to face cases of tetanus at the present time. Some years ago Wassermann and others showed that the tetanus toxin is quickly bound by the central nervous symptom. Two Italian physicians, Almagia and Mendes, succeeded in showing that lecithin and cholesterin are the substances that fix the toxin in this manner and were led to try the effect of these substances upon the experimental tetanus of animals. Numerous experiments of this nature showed that cholesterin has a distinct inhibitory action upon the toxin, much larger doses being required to kill animals if cholesterin had been previously introduced into their bodies. Recently opportunity was offered to test the remedy in cases of human tetanus, and the two patients in whom it was tried recovered from the disease though the infection seems to have been very severe in both cases ("International Clinics," Vol. III, 18th Series). The authors properly remark that only a large number of cases can determine the value of this mode of treating the disease, but the appalling mortality of the infection justifies the publication of even such limited experience with the effect of cholesterin in cases of human tetanus as is detailed in their article.

News of the Week.

Harvey Society Lectures.—The fourth lecture of the Harvey Society will be delivered by Dr. Wilhelm Falta of the University of Vienna, on Saturday, November 28, at 8.30 o'clock, at the New York Academy of Medicine, 17 West Forty-third street. Dr. Falta will speak on the subject of Therpeutics in Diabetes.

Dr. Francis C. Wood, Professor of Clinical Pathology at the College of Physicians and Surgeons, New York, spoke before the Hospital Graduates' Club on Thursday evening, November 19, on the subject of the Practical Value of Some Recent Laboratory Tests. Dr. Wood described the tuberculin tests for tuberculosis, and the reactions for syphilis, and discussed their value from the practitioner's standpoint.

Dr. Thomas E. Satterthwaite of New York City received the honorary degree of LL.D. from the University of Maryland on November 11, on the occasion of the celebration of "Academic Day."

An Emergency Man.—After a recent serious explosion in the excavation for a new sewer in Brooklyn, and when there was considerable confusion among the different city departments engaged in the work of rescue, Mayor McClellan ordered Sanitary Superintendent Walter Bensel to take charge with authority over all other officials. Commenting on this, the New York *Sun* says: "Dr. Bensel seems to be a municipal emergency man, capable and called in to do all sorts of hard jobs. When the Street Cleaning Department seriously needed attention Dr. Bensel was borrowed to do what was necessary. Now he is selected for a work that would fall naturally to the police. Apparently a handy man to have around is Dr. Bensel, Sanitary Superintendent."

Woman Doctor a Mayor.—For the first time in its municipal history, Great Britain has a woman mayor in the person of Mrs. Garret Anderson, M.D., recently elected Mayor of Aldeburgh. Mrs. Anderson is the pioneer woman physician of England, having received her degree in Paris in 1870, after the English medical college had refused to admit her. Her fight to enter the medical profession was used by Charles Reade as a part of the theme of his novel, "The Woman Hater." After the establishment of the London School of Medicine for Women, Mrs. Anderson served as its dean from 1876 to 1898, and in 1896 was elected president of the East Anglian branch of the British Medical Association. She was senior physician to the Euston road Hospital for Women from 1866 to 1890, having received a license to practise five years before she passed her final examinations. She is an ardent woman suffragist.

Disease Among Cattle.—For the first time since their establishment, in 1863, the East Buffalo stockyards have been quarantined. The outbreak of foot-and-mouth disease, which was first noticed in Pennsylvania, has spread to the Buffalo yards, and all have been closed. It is feared that a disastrous shortage in the milk supply may result from the destruction of cattle. The disease prevails in twelve counties of the State of Pennsylvania, and

it is feared that extension to other counties will take place. Stringent measures have been adopted to prevent the spread of the disease, and more than 200 head of cattle have been killed to this end. There are seven centers of original infection. Those whose stock and property are destroyed in the endeavor to eradicate the disease will be indemnified, the State making good one-third of the loss and the Federal Government two-thirds. It is anticipated that the quarantine will be maintained for at least six months. The British Board of Agriculture has forbidden the importation of cattle, hay, and straw from Pennsylvania, New York, and New Jersey. So far as is known this is only the second time the disease has appeared in North America, the first outbreak having occurred in the New England States in 1892. The source of the infection has not yet been definitely learned.

Tuberculosis in Prisons.—Dr. J. B. Ransom, physician of Clinton Prison, Dannemora, N. Y., speaking before the New York State Conference of Charities and Correction recently, called attention to the danger of infection by tuberculosis in prisons, and stated that only twenty-one prisons in the United States had in any degree attempted to make any special provisions for the tuberculous prisoner. He estimated that from 16 to 25 per cent. of the total number of prisoners in this country were infected with some form of tuberculosis, and suggested the establishment in every State of a special institution for the care of prisoners with tuberculosis.

Smallpox in Vermont.—A small epidemic of smallpox is reported in Brattleboro, Vermont, but the situation has been well controlled by the State Board of Health. The schools and colleges have been closed, and there has been a general vaccination of the townspeople. There has also been a slight outbreak of the disease in a mild form in Amsterdam, N. Y.

Street Car Accidents.—The Public Service Commission reports that during the month of October, 47 persons were killed and 106 were seriously injured by the street cars of New York. As is usual the greatest number of accidents occurred while passengers were alighting from the cars. A coincidence of the report is that exactly the same number of persons, 47, were killed, and exactly the same number, 15, had fractured skulls, during October, 1908, as during October, 1907.

Health in Indiana.—The Indiana State Board of Health reports that the continued drought has had serious results, and a new disease called "dust fever" is described, which is thought to be an outcome of the dry weather and the greater amount of dust in the air. The symptoms are severe headache, backache, and chills and fever. Generally, however, health conditions are reported to be much better than during October of last year.

Fire in Roosevelt Hospital.—A small fire in the drug room of the Roosevelt Hospital early on the morning of November 18, was extinguished by the House Staff before the arrival of the firemen. The flames followed the explosion of an oxygen retort, and caused about $500 damage. As the drug room is in the basement of the administration building and the smoke was confined to that part of the hospital, there was no excitement among the two hundred patients in the east and west wings.

New East Side Hospital.—The official opening of the new east side hospital, a nonsectarian institution, but built and supported by the Jews of the city, occurred on November 15. The original name chosen for the hospital, Mount Moriah, has been changed, by the substitution of the Hebrew word for mount, to Har-Moriah, in order to avoid any possible confusion with Mount Sinai Hospital. The money for the new hospital, which is situated on lower First avenue, has been raised entirely by popular subscription, the largest individual contribution being limited to $250. A guarantee fund to meet all expenses for five years has also been provided. The hospital contains eighty beds, besides a children's ward and operating room.

Brooklyn Jewish Hospital.—The annual report of the President of the Board of Trustees of the Jewish Hospital of Brooklyn shows that during the past year 2,720 patients were received, an increase of 60 per cent., and that the dispensary visits numbered 19,152, an increase of 61 per cent. The hospital now contains 175 beds, and an urgent appeal for funds to erect an additional wing for wards, and another to be used as a home for the nurses in the training school, was made.

Chicago Contagious Disease Hospital.—The new city hospital of Chicago for contagious diseases will be opened in a few days. The total cost to the municipality is about forty-five thousand dollars, which means that the important reforms put into effect by Health Commissioner Evans have been accomplished with a minimum of expense and a maximum of results. Up to the present time the city, except in smallpox cases, has been dependent upon the limited facilities of the contagious disease department of the County Hospital.

Cook County Hospital Alumni Association.—This Association held its forty-seventh annual meeting November 23, at the Illinois Athletic Club, Chicago, under the Presidency of Dr. Samuel C. Plummer. The program included addresses by Dr. William E. Quine, on "Nicholas Senn as a Man;" by Dr. William L. Baum, on "The New County Hospital;" by Dr. Arthur B. Eustace, on "Our First Regular Resident Staff," and by Dr. Theodore Tieken, on "The County Hospital as a Field for Scientific Work."

New Cottages at Illinois Hospital for Insane.—There have been two new cottages erected at the Illinois Hospital for the Insane, Bartonville, at a cost of $100,000, and equipment with eight solaria, for the continuance of the work of phototherapy inaugurated by the Superintendent, Dr. Zeller. These cottages will be dedicated Thanksgiving Day. The solaria are equipped, two in ruby, two in violet, two in amber, and two in opal.

Polyclinic Hospital.—The trustees of the New York Polyclinic Medical School and Hospital have elected the following officers for the coming year: *Chairman,* John R. Abney; *Vice-chairman,* Patrick F. McGowan; *Secretary,* Dr. John A. Wyeth.

The Eastern Pennsylvania Institution for the Feeble-minded and Epileptic at Spring City was officially opened on November 16. The plant has been in course of construction for two years and is only partially completed. Seven buildings are ready for occupancy and three more are about ready for acceptance by the State. The plans provide for an ultimate group of 23 structures, whose early completion is looked for. Some $350,000 has already been expended on the buildings and the total cost will be about $1,000,000. When finished the institution will accommodate about 1,000 patients. Dr. Henry M. Weeks has been selected as Superintendent.

New Maternity Hospital.—The facilities of Grace Hospital, Hartford, Conn., have recently

been increased by the gift of a house situated in the grounds adjoining the hospital building to be used as the maternity ward of the hospital. In honor of the donor the addition will be known as the Mary J. Munsill Maternity Ward. Accommodation will be provided for about twenty patients. It is planned to connect the two buildings by a tunnel leading from the kitchen.

Mrs. Margaret Benton Hayre, known to both the Union and the Confederate forces as the American Florence Nightingale, for her work at the Nashville (Tenn.) Hospital during the war, died recently at El Paso, Texas. In recognition of her services Mrs. Hayre received two bronze medals, one from the Confederate soldiers and one from the Grand Army of the Republic.

Gift of Library.—The Medical School of Maine has received as a gift the library of the late Dr. Harold Charles Martin, of the class of 1895.

The University of Vermont College of Medicine began its fifty-fifth annual session on November 11, with an entering class of over seventy students, the largest in several years. Dr. J. W. Scane of McGill University addressed the students. A course of instruction in *x*-ray work has been added to the curriculum.

Chicago Physicians Warned to Obey Ordinances.—Medical men who have been neglecting to report their cases of tuberculosis have lately been warned to obey the ordinances which apply to this disease as well as other infectious diseases. Tuberculosis has been designated a reportable disease for a number of years; it is so shown on the regular postal card reporting form furnished by the Department.

Dairy Law in Louisiana.—Following the action of the New Orleans Health Board in suspending the tuberculin test in cattle, the dairymen of Louisiana are agitating the repeal of the present law, the abolition of the ordinance requiring the test with tuberculin, and the enactment of a law drafted on the lines of that in New York.

Medical Society of the County of New York.—At the one hundred and third annual meeting of this society, held on November 23, the following officers were elected: *President,* H. Seymour Houghton; *First Vice-President,* John E. Weeks; *Second Vice-President,* Joseph Brettauer; *Secretary,* John Van Doren Young; *Assistant Secretary,* J. Milton Mabbott; *Treasurer,* Charles H. Richardson.

The Rockingham County (N. H.) Medical Society held its fourth annual meeting at Portsmouth on November 12. The following officers were elected for the ensuing year: *President,* Dr. A. W. Mitchell of Epping; *Vice-President,* Dr. W. D. Junkins of Portsmouth; *Secretary,* Walter E. Tuttle of Exeter; *Treasurer,* Dr. Alice M. Chesley of Exeter; *Delegate to State Medical Society,* Dr. George H. Guptill of Raymond; *Censor for three years,* Dr. Fred S. Towle of Portsmouth.

The Ohio Valley Medical Association, at its annual meeting at West Baden, Ind., elected the following officers: *President,* Dr. Curran Pope, Louisville; *First Vice-President,* Dr. A. E. Sterne, Indianapolis; *Second Vice-President,* Dr. G. F. Lydston, Chicago; *Third Vice-President,* Dr. Earl Harlan, Cincinnati; *Secretary and Treasurer,* Dr. Benjamin L. W. Floyd, Evansville.

The Worcester County (Mass.) Homeopathic Medical Society held its forty-second annual meeting on November 12, at Worcester, and elected the following officers for the ensuing year: *President,* Dr. Henry I. Klopp of Westboro; *First Vice-President,* Dr. George M. Lapham of Rutland; *Second Vice-President,* Dr. Albert E. Cross; *Secretary and Treasurer,* Dr. Lucy E. Wetherbee; *Auditor,* Dr. John P. Rand; *Librarian,* Dr. Jennie T. Lane; *Censors,* Dr. J. K. Warren and Dr. Carl Crisand, and Dr. E. R. Miller of Leominster.

Obituary Notes.—Dr. John R. Cook of Fairmont, Va., died at his home on November 9, from septicemia due to an operation wound. Dr. Cook was born in 1863, and was graduated from the Jefferson Medical College, Philadelphia, in 1884. He established the Cook Hospital, the first in the vicinity, in 1899, and served as attending physician to the time of his death. He was a member of the American Medical Association, and an honorary member of the Royal Gynecological Society of London.

Dr. Samuel G. Renshaw of New Orleans died on November 9, from injuries due to a fall a few weeks ago, aged 79 years. Dr. Renshaw was graduated from Dartmouth Medical School in 1852, and served as a surgeon in the army under the command of the Emperor Maximilian in Mexico, and later in the United States Army.

Dr. William H. Grafton of Los Angeles, one of the proprietors of the *West Coast Magazine,* died at his home on November 8, aged 80 years. He was graduated from the University of Maryland in 1849, and after two years' service as quarantine officer in Baltimore settled in Iowa, where he practised for over forty years.

Dr. Elihu T. Mendenhall of Newcastle, Ind., died at his home on November 14, after five weeks' illness, aged 64 years. Dr. Mendenhall was graduated from the Ohio Medical College in 1877, and had served for many years as county health officer.

Dr. Carman C. Stokes of Rushsylvania, Ohio, died on November 10, aged 59 years. Dr. Stokes was graduated from the Cincinnati College of Medicine in 1874, was a member of the American Medical Association, and was well known as a chemist and author.

Dr. Charles M. Gravis of Martinsville, Ind., died on November 11. Dr. Gravis was a veteran of the Civil War, having enlisted at its outbreak in the Eighty-ninth Ohio Infantry, and was a prisoner for fourteen months in Libby and Andersonville prisons. After the war he began the study of medicine and was graduated from the Indianapolis Medical College.

Dr. John T. Van Marter, for fifty years a practising physician of New Brunswick, N. J., died at his home in that city on November 20, after several months' illness. Dr. Van Marter was born in 1837, and was graduated from the Medical Department of the University of Pennsylvania in 1855.

Dr. William L. Fleming of New York, died at the Lincoln Hospital on November 20, of acute meningitis, aged 73 years. He was graduated from the New York Homeopathic College in 1873.

Dr. Benjamin A. Ver Nooy of Pulteney, N. Y., died in Penn Yan on November 18, at the age of 35 years. He was a graduate of the Bellevue Hospital Medical College in the class of 1896, and had practised until a year ago in Waldwick, N. J.

Dr. George E. Babbitt of Orange, N. J., died on November 23 of injuries received from being thrown from his buggy. He was born in Madison, N. J., forty-nine years ago and was graduated from the Medical Department of the University of Pennsylvania. He had been in practice in Orange for five years.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SCIATICA—CRETINISM—WAR ON RODENTS, DANGER OF POISONS—MOUSE CARCINOMA—OBITUARY.

London, November 6, 1908.

Dr. Wilfred Harris discoursed at the Medical Society of London on the diagnosis and treatment of sciatica. He laid down that acute cases might be considered as rheumatic (sometimes gouty) perineuritis of the sheath of the nerve. It might start at the pelvic notch or a little lower and extend down to the middle of the thigh. Two modes of onset were common—(1) preceded by a lumbago or lumbosacral fibrositis; (2) preceded by exposure to wet and cold in the back and thigh, as, *e.g.,* sitting in wet clothes. In acute cases he advised the patient to be kept in bed on a water or air bed, of course with two blankets over the rubber. This alone often relieved and let a patient lie on his back who had been obliged to lie only on the sound side. It was often taught that galvanism should be avoided until after the acute stage, but Dr. Harris thought this was witholding a valuable remedy. A strong current, of course with great care, he approved of, and the effects were increased by sod. salicyl. To prevent adhesions, massage and passive movements of the hip were useful—but only at the right time. Too early, *i. e.,* while the sheath was acutely inflamed, it must do harm. Too late, *i.e.,* after adhesions had become tough, the same might be said. It was a nice point when to begin massage. He usually did so after about a fortnight in bed, when the water mattress might be removed and galvanism given once daily. The indications for the change were disappearance of pain when lying still, ability to lie on the affected side, disappearance or great diminution of tenderness on pressure over the nerve, and increased range of flexion of the hip, keeping the knee straight without causing pain at the back of the buttock. Under such treatment, Dr. Wilfred Harris said, few cases of sciatica would continue along until constant pain and wasting muscles showed that the perineuritis had become interstitial neuritis, invading the nerve bundles and injuring their fibers by the pressure of the inflamed fibrous tissue. Two conditions of the nerve might be relieved by surgery—(1) external adhesions between the sheath and surrounding structures, from the sciatic notch to the middle of the thigh; (2) the toughened and contracted condition of the nerve itself resulting when the cases had gone on to chronic interstitial neuritis. Dr. Harris pronounced nerve stretching, acupuncture, and injections of all kinds useless and unscientific for the treatment of a mixed sensory and motor nerve. Blisters might have more said in their favor, but personally he preferred to do without them. In conclusion he deplored the pessimism of too many. To tell patients they must bear the pain until the disease wore itself out indicated a cynical state of mind which was not justified by modern pathology or therapeutics.

Endemic cretinism in India has been carefully studied by Captain R. McCarrison, I.M.S., Agency Surgeon in Gilgit, and he has communicated to the Medical Section of the Royal Medical Society an analysis of 203 cases comprising all the cretinous inhabitants of the Gilgit and Mastuj districts, extending over about 500 miles of the Himalayan country. There were racial and other differences which he remarks are of importance in any comparison of results. Concerning the association of endemic goiter, cretinism, and deafmutism, there seemed no exception to the general rule, though there were some facts suggestive of the import of the prevalence of goiter. Indeed, Dr. McCarrison is of opinion that the degree to which cretinism is associated with goiter is determined by the time it has prevailed in a district and the variations observable are in direct relation to the prevalence of goiter among the adult population.

Further, cretinism is seldom, if ever, due to the development of goiter in the individual. The thyroid may be an effect—not a cause. He regards defective thyroid function in the mother as the chief factor in producing cretinism. But other debilitating influences on the mother are not altogether to be excluded. Fright, worry, mental depression, and so on were noted in about 40 per cent. of the cases. Alcoholism was practically absent on account of the religion of the people. Syphilis and tuberculosis were also rare. Consanguinity on the contrary seems important. In Gilgit there are a few Syeds, and they, being descendants of Mahomet, cannot marry out of their sect—so that the stock is tainted and inbreeding accentuates the effect. The thyroid defect is then congenital, but may remain latent. Cretinism is the result of the toxins produced by the thyroid defect acting on the developing thyroid of the unborn child. The defect is one of the whole mechanism—thyroid and parathyroids—and the variations observed result from the extent to which the whole or a part of the mechanism is involved.

Sir Victor Horsley regretted that the natives did not like operative measures, as with so much material the advisability of grafting in cretinism might have been decided. A graft of normal human thyroid could be obtained from an adenoma when shelled out and the small portion for a graft could be had without risk. He had done this with success and anyone with a marked case of cretinism under his care should consider the question at the earliest time.

Mr. J. Berry said Captain McCarrison's results confirmed those of Swiss and other observers. He deplored the notion spread abroad of late that the parathyroids were special glands with a distinct function and hoped the work of Dr. David Forsyth had dispelled such a superstition.

Dr. Gossage thought cretinism might be an inherited condition, allied perhaps to hæmophilia.

The war on rodents has begun very vigorously, but there are already indications that it has not been conducted with prudence. Some areas have been practically cleared, but there is little to be gained by working in small localities, for they will soon be reoccupied. The public have been satisfied with restricted operations by dogs, cats, and traps, but that these are inadequate to deal with the trouble has been shown by the Association for the Destruction of Vermin, the members of which by no means advise neglect of such measures. In fact, some of them seem to think that the cat is almost enough, but I have found that this natural enemy, when domesticated, is very neglectful of its duty. I know places where cats are kept and yet mice abound. On one occasion I saw a well-fed cat reposing in front of a fire and a mouse quietly walk over it without disturbing it. It is obvious that if cats or dogs are to be trusted to eradicate vermin they must not be overfed with more agreeable food. Perhaps, too, certain breeds should be preferred.

Bacteriologists have again and again recommended that a virus should be sought which would produce a fatal disease in rodents and in some cases success has attended this plan under the supervision of experts. This, of course, was heard of by the advertising fraternity and rat poison has for some time been sold to the reckless British public, the vendors guaranteeing it to get rid of rats and mice but to be harmless to human beings and domestic animals. The Medical Officer of Health for the city (Dr. Collingridge) questioned this and considered it dangerous that such poisons should be used except under skilled direction or should be freely sold to the public. A case has been investigated by him which fully confirms his view. In a city house where dinner is provided for the employees twelve men became simultaneously attacked with febrile symptoms, vomiting, and diarrhea, colic and collapse. Investigation pointed to infection of the food. The only point in common was that all dined in one room. Further inquiry elicited that a virus poison for mice had been laid about. Under the floor dead mice were found. Dr. Klein found in the excreta of the patients and in the poison bacteria resembling Gaertner's bacillus. It has been shown that injections of such bacteria produce a disease fatal in from two to four days. No doubt vermin can be got rid of in limited areas by various poisons, but not without danger. A virus may destroy an enormous number, but a small percentage will remain to propagate, or immigrants will soon arrive. Interference with nature's arrangements is always risky. We have practically exterminated owls, weasels, etc., and have petted our dogs and cats into lazy gluttons and are now finding out that the rodents are swarming more than ever. It will be more disastrous if we manufacture new diseases by distributing their germs.

Some experiments concerning a possible serum treatment of cancer have been made on mice by Mr. C. E. Walker, assistant director of cancer research at Liverpool University. Considering the reproductive cells and those of malignant growths as having in some sense passed out of coordination with the organism, he asked himself whether the reproductive cells injected in large numbers would have any effect on the whole body. To test this he injected hypodermically several hens every day with a fresh emulsion of cock's

testes. Their combs and wattles grew enormously and other definite changes were produced. As the injection of the cells of an animal into another species might conceivably produce a change in the blood destructive to the alien cells, similar experiments were made on rats with an emulsion of the testes of mice. At the same time rats were injected with an emulsion of a spheroidal-celled carcinoma from mice. This was on the supposition that anything destructive of reproductive cells might also destroy other cells out of somatic coordination. Among mice treated with testis serum the tumors became gangrenous. In others treated with carcinoma serum they dried up and came away. The results with testis serum seemed to Mr. Walker more suggestive than the others on account of the destructive action on cells out of coordination. Other experiments were made to endeavor to find an explanation of the rarity of metastases in tumors caused by grafts in mice. Mr. Walker saw no essential difference in these tumors from those of similar structure in man.

Dr. Rushton Parker thought these researches valuable, but Dr. Blair said they were neither original nor new. It was easy to produce immunization against mouse serum and nothing was in sight as to human malignant growths. Dr. Glynn asked whether the gangrene might not be due to thrombosis or bacterial infection and whether spontaneous cure ever occurred by gangrene.

The death of Dr. James Adam on the 25th ult. at the age of 74 removes a well-known alienist who has filled various offices connected with the insane. He took the Edinburgh double qualification in 1857 with a gold medal and other honors. He added the M.D., St. Andrews, in 1860. He has been head of the female department at Colney Hatch, superintendent at the Caterhorm Asylum and of the Crichton Royal Institute and Counties Asylum at Dumfries. Subsequently he became resident physician and proprietor of the West Malling Asylum. His contributions to the journals were all connected with his specialty and included those on melancholy, catalepsy, self-mutilation by the insane, and pathological research in asylums for the insane.

Dr. Josiah Oliver died on the 24th ult. at Maidstone, where he had practised and taken a leading part in municipal affairs for nearly forty years. He qualified in 1869. After general practice for ten or twelve years he became a member of the Edinburgh College of Physicians. He was made a J.P. in 1883 and was elected Mayor of Maidstone in 1896. At the close of his year of office he received a handsome testimonial from his fellow citizens, who seem to have esteemed him as highly as an upright public man as they did as a medical adviser and friend.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

REMUNERATION FOR TESTING NEW DRUGS—THE OPINIONS OF KURSCHMANN AND EHRLICH ON THE SUBJECT—V. NOORDEN'S PRACTICE IN THE MATTER—THE QUESTION OF SPECIALISTS—OFFICIAL DEFINITION AND REQUIREMENTS.

BERLIN, November 1, 1908.

A VERY interesting question came up for discussion at a recent meeting of the Free Society of Medical Journalists; it was brought forward in the consideration of a report presented by a special committee of the Society, which dealt with the propriety of accepting payment for the examination of new remedies. Dr. Schwalbe of Berlin sent a circular letter of inquiry to fifty-eight heads of institutes and received fifty-three answers from the best-known workers in Germany. These answers were not at all uniform. Thus Kurschmann of Leipsic took a negative stand in the matter; he personally never undertakes an examination of a drug at the request of the manufacturers, nor does he ever allow them to send reprints of papers issued from his clinic together with circulars in praise of their preparations. On the other hand, Fr. v. Müller, A. Frankel, Gaffky, and Ehrlich did not consider it improper to receive payment for experimental work. Ehrlich called special attention to the differences existing between clinical and experimental research in this connection. There exists a great disproportion between the expenditures called forth in all experimental work by the necessity of providing laboratory animals, complicated apparatus, and specially trained assistants and the means provided for the work in German institutes occupied with this branch of medical science. It seems to him, therefore, that any support given by the manufacturers to experimental work can only be considered as of great assistance to the medical profession. It would be very desirable in the future to precede any clinical study of new drugs by much more extensive experimental study of their properties and value than has been the case in the past. The desirability of such study calls forth a careful consideration of all possible means of arranging the relations between physicians and manufacturers so that the aims of both could be properly served.

A number of workers defended the propriety of requesting payment for clinical work in connection with testing the actions and the value of a new drug. Thus von Noorden of Vienna is always well paid for any clinical work requested of him by the manufacturers; all money received by him from this source he diverts to the establishment of free beds in hospitals or toward the promotion of scientific research. One-half of the money is always to be paid when the drugs in question are offered for clinical trial while the rest is to be sent when the resulting articles are published. In this manner a portion of the profits made by the manufacturers in exploitation of new remedies is used for the benefit of the general public.

Most of the speakers on the subject considered only the question of payment for clinical research, and in general agreed that the decision is best left to individual workers in the field; it seemed reasonable to accept some reward for the painstaking work required in the testing of new remedies and such work, of course, would be more often performed if the workers were sure of compensation for their time and effort. The great duty of the professional press consists in taking all proper measures for insuring the appearance of scientific articles only; in this connection no work should be accepted for publication that is not offered to the editors by the author himself or by the Institute at which the research was performed. There is no valid objection to naming the firm which markets the product described nor to the distribution of reprints by the firm with the aim of advertising the uses of the remedy. The manufacturers should also be allowed to acquaint themselves with the contents of any such article before publication and in contracting for the work should have the privilege of not having the paper published if the preparation considered is not brought out on the market or different findings have not been published.

During the past summer the question of medical specialists has been very eagerly discussed in the professional press and in the various meetings of physicians. There is no question that the great mass of the public considers the specialists as much more trustworthy in certain diseases because he has had wider experience in those special fields, than the general practitioner. This attitude of the public is, of course, a potent factor in the increase in the number of specialists which has been witnessed in recent years. In this differentiation of medical work a good many regrettable things have occurred; many specialists, for instance, have assumed this title without having done sufficient special work to equip them for their chosen practice. It is not to be wondered, therefore, that individual voices are heard calling for the establishment of special examinations or at least for the promulgations of some conditions which are to be fulfilled before the title in question may be assumed by a physician.

In July of this year the Ministry of Public Instruction took part in this discussion by the publication of the following order addressed to all the subordinate officials of Prussia: The Minister of Instruction has requested that the scientific deputation give him their opinion in the matter of medical specialists and has received the following answer. The designation "specialist" should only be used after the fulfillment of certain conditions. The following specialties may be considered: Internal Medicine, Surgery, Ophthalmology, Diseases of the Throat, Nose and Ear; Obstetrics and Gynecology, Skin and Venereal Diseases, Nervous and Mental Diseases, and the Diseases of Children. Every specialist should have done a certain amount of extra work in the field to which he wants to devote himself; such work should have consisted in scientific study and practical experience in the special field during a period of time which has proved sufficient by previous experience to enable such a worker to carry on independent work in a special field; as a rule, three years should be considered to be such a period of time. Such special work should be performed in the capacity of an assistant in universities, academies, large hospitals, or in association with well-known specialists; the list of names and places of this character will be made up and published every year. The time and the success of such special work should be attested by a certificate obtained from the physician who acts as the instructor. The scientific deputation has further declared that the whole question of specialties in medicine is a professional one and should be left for the consideration of the various professional organizations.

Such, then, is the opinion of the Ministry in this ques-

tion; now professional societies are to be heard, but in the meantime the various views on the subject are reflected in the medical periodical press. It seems to be the most generally held opinion that any hard-and-fast definitions of the preparation required from specialists should not be promulgated. As opposed to the few dishonest individuals among specialists there stand a great number of self-taught men who enjoy the best of reputations for their knowledge and skill in their chosen fields; yet these men have not enjoyed anything like the prescribed amount of instruction in their work. Moreover, if any physician wants to deceive the public he will probably find the means of doing so under any regulations. Another set of critics point out the fact that the ministerial declaration given above mentions altogether too few special fields of practice; indeed, the number of specialties is not constant, for even now certain professional activities are becoming more and more specialized. It may be concluded that the best way out of the difficulty is to drop the title specialist altogether; the patients should then be apprised of any special attainments of certain physicians by means of personal recommendations from others.

THE RELATION OF THE MEDICAL PROFESSION TO THE ALCOHOL QUESTION.

To the Editor of the Medical Record:

Sir:—The writer is hardly in accord with Dr. Jacobi's criticism of professional writing on alcoholism in the lay press, for it really seems as if the general public is calling on the medical profession to make a more definite statement as to the physical effects on the human body of the moderate use of alcohol than has yet been declared. Nevertheless, it seems as if a medical symposium of opinion of some value could be created, using the medical press as a medium.

It is somewhat remarkable that so general a harmony of opinion among medical men has been arrived at during the past twenty years on many related branches of the subject. There are still, however, opinions held by a few that are fairly twenty-five years behind the age. It is a matter of surprise that, in the face of advanced knowledge as to the possibilities of supporting methods of nourishment, any medical man should make the statement that a radical immediate cutting off of alcoholic beverages would result in race decadence. It is true that there may be a very few individuals who would retrograde or cease to exist when cut off from alcohol; but most persons, if properly nourished at the time of the cutting off of the alcohol, as a rule, would be physically benefited. To be sure the cutting off of the supply would create temporary wide-spread suffering, due to the hunger for alcohol; but there are very few individuals indeed who would not be immediately benefited if intelligently treated, and it is questionable if the world would not be well rid of the few whose existence would be cut short by a public invasion of the individual rights of indulgence.

We all hold together on the advantages of using alcohol under certain conditions of ill health. We all hold that under such conditions the good to be gained from its use overbalances the injury it effects; but we want a general discussion of the following propositions, namely: (1) The habitual use of alcohol in small quantities which to superficial observation does no harm, really does physical damage by inducing a habit of dilatation of the arterioles with secondary results due to throwing undue arterial pressure on various organs. (2) That any individual using alcohol even in small doses is in the grasp of the alcohol habit, and is injured in proportion to the amount ingested and to the regularity of indulgence. (3) Under all ordinary conditions of health any physical advantage due to the pleasure of indulgence or to the nutritive effects of alcohol is far outbalanced by its evil effects, which are not perceived immediately, but are cumulative. (4) That the primary physiological effect of apparent stimulation is only the beginning of paralysis due to the coagulative effect of the alcohol on cell peripheries, and that deepening of the effect to the cell centers reduces vital activity in the cell. (5) That so-called moderation results in the vast majority of cases in indulgence that is measurably immoderate, and usually shortens life, and weakens self-control.

The question that is now before society for its decision is whether society must suffer the consequences of the grossly ignorant and damaging use of alcohol, in order that those who are only slightly hurt by moderate indulgence may be allowed the pleasures of that indulgence; whether this agent is to remain in force as one of the influences for ridding the world of those least fit to survive, or whether this substance, so potent because of its peculiar properties, is to be placed with things too dangerous for general use.

East Orange, N. J. J. M. W. Kitchen, M.D.

Progress of Medical Science.

New York Medical Journal, November 14, 1908.

Adiposis Dolorosa.—T. Klingman defines this affection as a hemopathic condition of unknown cause, occurring in women with neuropathic heredity and characterized by painful fatty swellings occurring in various parts of the body. The condition is preceded or followed by asthenia. Many other symptoms, varying from a slight functional derangement to organic degeneration, are incidental expressions of an inherited unstable nervous system occurring in many other nervous disorders. Treatment is in an unsatisfactory state. No one remedy gives uniform results. A few cases have been relieved and one apparently cured by thyroid extract. Removal of the swellings by operation has proven of great though temporary benefit. The condition is a progressive one. The distinct lesion is an overgrowth of fatty tissue, and the most constant organic lesion is in the thyroid gland. In one case, however, coming to autopsy the gland was normal. The author adds one personal experience. About forty-five cases altogether are on record.

Generalized Xanthoma Planum in a Child.—A. Abrahams reports one case unique in the age of the patient and the general distribution of the lesions. The patient was a three-and-a-half-year old boy of Russian parentage. At the age of two and a half years he had scarlet fever. During the period of desquamation, to quote the boy's father, "small, pin point pimples appeared here and there over the body. The pimples after awhile flattened and became yellow. In a short time more of the same kind appeared and kept on coming," until on the day of presentation the eruption covered every part of the body except the scalp and mucous membranes. The chin, neck, upper and lower extremities, both extensor and flexor surfaces, thorax, abdomen, groins, and gluteal region, including the cleft of the nates, were the seat of hundreds of small and large citron yellow patches, some flat, some slightly raised at the edges, smooth to the touch, and all typical of xanthoma planum, as seen in adults on the upper and lower eyelids. The eyelids and upper parts of both cheeks were free from the lesion, contrary to the usual distribution of the disease. The largest of the patches were found around the nates and anus. A few good sized ones were to be seen on the deltoids; the largest patch was the size of a cent and the smallest that of a lentil. There were no subjective symptoms. There were no constitutional or local disturbances at the time of appearance of the xanthoma. The urine was repeatedly examined with negative results. The child was well nourished and was in the best of health. Objections on the parents' part have thus far prevented the author from excising a portion of skin for microscopical examination.

The Resistant Breathing Tracts.—W. H. FitzGerald makes a plea for nasal breathing, calling attention to the carelessness of most parents in allowing their children to breathe through the mouth, and enumerating some of the evils which may follow in later life unless the faulty method of breathing is rectified by proper intervention. He says, among other things, that when we consider that faulty breathing is largely responsible as well for nearly all so-called catarrhal conditions of the upper breathing tract, for the majority of middle ear difficulties, for a large percentage of eye trouble, to say nothing of innumerable affections of the rest of the economy, that we should warn, not only the medical profession, but also non-medical members of society engaged in one of the most commendable of projects, namely, the attempted obliteration of the white plague—that they are not doing their full duty unless they endeavor to make absolute nasal breathing a universal practice. In so doing they are not only fighting pulmonary tuberculosis along rational lines, but practically every other disease man is heir to as well.

Journal of the American Medical Association, November 14, 1908.

Viscosity of the Blood.—G. W. McCaskey discusses the literature of the viscosity of the blood and describes methods of determining it. His own device is simply testing its ascent in a capillary tube under negative pressure, the tube being standardized with distilled water at a known temperature. The temperature is important, as the viscosity falls about 2 per cent. with each degree of centigrade rise, and if there is a marked change in the room temperature at the time of the test from that of the time of standardization, corrections have to be calculated. The viscosity varies considerably under normal conditions, owing to various causes, among which may be mentioned the injection of large amounts of water or food. The percentage of blood corpuscles is accountable for the greater part of the viscosity, but it is also influenced by substances in the

plasma. It is probable that this is in some way connected with the fibrin. Alcohol markedly increases it at once, and asphyxia influences it more profoundly perhaps than any other known factor. Hemorrhage lowers it and the effect is lasting as opposed to the evanescent lowering from injection of salt solution. In vegetarians, according to Determann and others, the viscosity is materially lower than in meat eaters. McCaskey's conclusions are summed up as follows: "1. The viscosity of the blood is an important physical property dependent on both the corpuscles and the plasma, which furnishes a considerable part of the peripheral resistance to the circulation of the blood. 2. It undergoes considerable fluctuations as a result of physiological changes connected with food, drink, exercise, etc. 3. Under pathological conditions, the changes are much greater and the viscosity may be so much increased, as, for instance, when the blood is charged with carbon dioxid, that the heart will be embarrassed in overcoming it. 4. The viscosity of the blood is actually low in the large majority of cases of chronic Bright's disease owing to existing hydremia, but there is probably an earlier stage with high viscosity. 5. It seems probable that an increased peripheral resistance in the circulation of the blood, due, in part, to increased viscosity, is at least one of the factors in the production of the cardiac hypertrophy of Bright's disease. 6. Venesection greatly lowers the viscosity of the blood by withdrawing its solids and attracting the fluids from the surrounding tissues. 7. Alcohol introduced into the circulation greatly increases viscosity, and in this way interferes with the peripheral circulation and burdens the heart. 8. The approximate determination of the viscosity of the blood as a routine clinical procedure is desirable in nutritional and toxic disorders, and should be made by a method rapid and simple enough to be practicable for routine use. 9. Individual diseases do not change viscosity in any characteristic way except as they incidentally modify the blood. 10. The determination of viscosity should be made promptly before the corpuscles have time to settle, for obvious reasons. The use of hirudin, if it leads to considerable delay, is therefore objectionable unless the homogeneous mixture of plasma and corpuscles is again reproduced. 11. The viscosity of the blood is not altogether dependent on its specific gravity, for in fevers the former may be high and the latter very low."

Pigmentation of the Mouth.—H. G. Anthony enumerates the different forms and, as regards congenital pigmentations, he is convinced, in spite of the negative literature, that the ordinary pigmented mole may occur on the oral mucosa, and that he has seen one such case himself. Occurring there, they would usually be melanotic, and he suggests as likely that the melanosis observed by Roy (*Laryngoscope*, 1907, p. 868) antedating an oral endothelioma was really a mole. Acquired pigmentations may be the result of traumatic hemorrhage, Addison's disease, scleroderma and phthiriasis. He has not observed or found records of them being due to arsenic or lichen planus. The largest number of mouth pigmentations, however, cannot be credited to any of these disorders, and are almost invariably located on the mucous membrance of the lips. They are usually well-defined areas of black pigmentation, and the patients are frequently unaware of their existence. Anthony has never observed them in healthy persons, but has found them on the lips of patients suffering from gastrointestinal intoxication, diabetes, and neurasthenia.

Transplantation of Vessels, Organs, and Limbs.—Alexis Carrel gives an account of the experimental work on animals in auto and heterotransplantation of vessels, organs, etc. He shows that vascular suturing, under aseptic conditions and correctly applied, gives excellent results, but a fault of technique, even very slight, can be followed by obliterative thrombosis. Success depends less on the way of handling the needle or passing the threads, than on a knowledge of the causes determining a deposit of fibrin in the line of anastomosis, and their removal. Occasionally after transplantation of veins as a substitute for arteries, late obliteration may occur, hence this procedure seems to be a little less safe than the direct anastomosis of artery with artery. Carrel finds it possible, however, to preserve the vitality of extirpated arteries in Locke's solution at low temperature for some days or weeks, so that good results can be obtained after transplantation, though marked histological changes take place. Other methods have been less successful. It is not always true, moreover, that the transplanted vessel must be from the same species of animal, but the success is greatest when the species are most closely related. Experiments with transplantation of various whole organs, such as the kidney and spleen, with reestablishment of their circulation by vascular anastomosis, have also been successful and transplanted kidneys have functionated normally. In case of glands like the thyroid, parathyroid and ovaries, the reestablishment of the circulation by anastomosis is hardly necessary, though in case of the ovary it might be advantageous. In heterotransplantation of the intestines the difficulty is to avoid infection which caused the failure of both of Carrel's experiments of this nature. Heterotransplatation of rather extensive anatomical regions such as the ear and scalp, with their artery and vein, has been successfully done in a dog, and Carrel has succeeded in transplanting a leg from one dog to another. The difficulties here are chiefly surgical, and he says if further experiments in this line sufficiently demonstrate that the functions of the transplanted limb are reestablished, it may be permissible to try this operation in a suitable case on man. In a general way, however, it is necessary to emphasize that even a method that gives excellent results on animals must not be directly applied on man. There are marked anatomical and physiological differences between the human tissues and organs and those of the dog and cat, and the methods should be modified accordingly. The experiments he records have been performed within the past two years, and it is too soon to tell what may be their practical value.

Endoaneurysmorrhaphy.—R. Matas analyzes a total of 85 operations by 52 surgeons, up to the present date. The legitimate mortality of the operation itself he finds to be 2.3 per cent.; of secondary hemorrhage, 2.3 per cent.; of gangrene, 4.6 per cent. Eliminating 3 of the gangrene cases in which there was simultaneous injury and ligation of veins or secondary ligature of an artery, the percentage of this accideot is 1.1 only. The total postoperative deaths from all causes was 7, to 78 recoveries. The percentage of relapses, which occurred only in the reconstructive operations (4 in 13, or 28 per cent.) was only 4.7 per cent. to the total. Matas believes that the fundamental principle on which the operation is based, viz., that the endothelial lining of the vascular system which is continued in the aneurysmal sac, is analogous in its pathological behavior to the reactions and reparative processes which occur in the endothelial surfaces of the other serosæ, such as the peritoneum and the pleura, has been absolutely confirmed by the experience in these 85 cases. They have also disproved Scarpa's law that complete obliteration of the vessel is an essential to the cure, which result is also supported by the facts of the suture and repair of arteries. An important point of the technique is the prophylactic hemostasis, which must be made absolute, and the problem increases in complexity and difficulty the higher the operation, and Matas mentions the methods and appliances for this purpose. Experience demonstrates that in all sacciform aneurysms with a single orifice of communication, the closure of this orifice by suture without interfering with the lumen or the capacity of the vessel is to be looked on as obligatory. The indications for the reconstructive operation, however, in fusiform aneurysms with separate orifices of entrance and exit must still be considered *sub judice*. In the vast majority of cases of aneurysm of the extremities the simple obliterative procedure proved satisfactory. It gives a cure with less risk to the distal parts than either the ligature or the method of extirpation. The indications in any given case will not be entirely satisfactory until we have a sure clinical proof of the adequacy of the collateral circulation. Korotkow's method of testing the most peripheral blood pressure may be the solution of the problem.

Ligation of Innominate Artery.—W. Britt Burns reports a case, the ninth with recovery, of ligation of the innominate artery. The patient was a colored man, aged 27, suffering from subclavian aneurysm, the innominate only was tied with a largest sized braided silk ligature in a "granny" knot drawn just tightly enough to approximate the vessel walls but not to crush its coats. The ligature came away fifty-one days after the operation while the wound was being dressed; the recovery was good practically in twenty days. Burns tabulates and reviews the prior operation showing that unless Burrell's case is counted as a recovery, the one he reports is alone in the class of cases where the artery was tied by itself for subclavian aneurysm.

Cardiovascular Prognosis.—H. W. Cook emphasizes the importance of examination of the heart and circulation by life insurance examiners. Cardiovascular diseases are increasing and especially among the individuals who apply for life insurance, and he remarks that examiners are apparently too often satisfied regarding the cardiovascular system when there is no heart murmur and no irregularity or increase of rate in the pulse. Competent examination should practically exclude heart and arterial diseases, apoplexy, and nephritis from the first year's mortality, and should largely eliminate them from the first three years. He gives specifications as to what the examination should be in the family and personal history of the applicant and his physical inspection. He lays stress on the use of instruments, especially the sphygmomanometer, and the importance of urinary examinations. He summarizes, in conclusion, as follows: "The combined cardiovascular dis-

eases constitute the largest element in general mortality, and are even more important elements in insured mortality. The evidence of incipient cardiovascular disease are discoverable in many cases by careful attention to the details of the examination. Greater care and thoroughness in this particular would produce a large saving in insurance mortality, especially during the first five years."

The Lancet, November 7, 1908.

A Case of Thymic Death.—The patient reported by M. S. Smith was a boy of eight months, who died suddenly in a convulsive seizure in his mother's arms. He had always been in good condition and never sick. Rickets, syphilis, and tuberculosis could all be excluded. On removing the ribs and sternum a greatly enlarged thymus gland was exposed. This consisted of two large lobes, each two and a half inches in length, which completely covered the trachea. From the upper part of each lobe a prolongation extended posteriorly. Thus the two lobes and their prolongations very nearly encircled the trachea. The weight of the gland was one ounce (28 1-3 grams). The lymphatic glands of the thoracic and abdominal cavities were all greatly enlarged, especially those of the latter, which formed a solid mass in the mesentery. There was no sign of any caseation, neither were the cervical and inguinal glands markedly enlarged. The brain, the heart, the kidneys, the liver, and the spleen were all normal. There were ecchymoses on the surface of the lungs, which otherwise were healthy. The stomach and the intestines showed no signs of gastroenteritis or of any congestion, but all the lymphoid glands in the walls were very prominent and stood out from the surface of the gut. The tonsils were moderately enlarged and adenoids were present.

The Palliative Treatment of Inoperable Cancer.—H. L. Drage discusses this question, adding certain remarks concerning some of the recent developments in therapeutics considered from the chemical standpoint. He declares that in the use of internal remedies for the purpose indicated it is necessary to make such an alteration in the blood as will increase the power of the human economy to starve the parasitic growth, to check the changes which are the result of the life of a parasite in the body, and to introduce an obstacle in the growth of fresh foci of disease. He claims that it is possible to treat cancer with a varying degree of success by a method which consists in administering such drugs as cinnamic and coumaric acids or their sodium salts, which produce a leucocytosis, especially when they are accompanied by the local treatment of the disease, when this is possible, by such substances as the oleate of copper and the oxide of antimony. The position which leucocytosis occupies with reference to the curative action of these remedies is necessarily a speculative one, and it is more than probable that it is an alteration in the serum which is the factor of the greatest importance. The drug which he uses is the orthocoumarate of sodium in a 22 per cent. solution in water, injecting 25 minims subcutaneously up to thrice weekly. In addition to this he gives either cinnamic aldehyde in doses of one minim in capsules three times daily after meals, or 5 grains of acetylo-coumaric acid (tylmarin) in a similar way. In addition he adds antimony oxide (pulvis antimonialis) in one grain doses with the view of applying a destructive agent to the growths. He has also used plasters containing oleate of copper, an ointment of this remedy with equal parts of thorium oleate; also ovules of the same for insertion in the rectum and vagina.

British Medical Journal, November 7, 1908.

Ophthalmia Neonatorum Treated by Zinc Ions.—H. K. Ramsden describes the recent treatment of a case, claiming that many cases of corneal opacity can be prevented by the method employed. The conjunctiva of the diseased eye was everted and a positive electrode which consisted of some cotton-wool saturated in a 2 per cent. solution of zinc sulphate was applied. The nurse held the negative electrode in the child's hand. The battery employed was an ordinary bichromate battery, which gave twenty volts, and half a milliampere current was passed for three minutes. Twelve hours after the application the inflammation was subsiding and another application was made. Two days later the case was cured. In the author's experience the case ordinarily treated by silver nitrate or protargol applications (twice a day) would have taken fourteen days and would have been an anxious one.

Stomatitis Parasitica.—G. A. Stephens was called to see a child suffering from this affection, the patches on the tongue and cheeks being so thick as to prevent the protrusion of the former. The pain felt by the child was considerable, so he was chloroformed and his mouth cleaned out. The question of causation came up for consideration. The disease is one that is very intimately associated with filth, but in this case the child, aged 2 years, and the only one, had no opportunities of roaming for filth. After much cogitation on the part of the mother, she suddenly remembered that a few days before the attack she had left him on the lawn for a few moments, to find him on her return nibbling a piece of bread that a bird had dropped within grabbing reach of him. She cleaned the mouth as well as she could, and thought no more of the incident until searching for some explanatory cause.

Insufflation in the Newly Born.—W. C. Adams reports the birth of a child by breast presentation. The labor pains had almost ceased from exhaustion, and the extraction of the head was a matter of some difficulty. The child was born apparently asphyxiated, and artificial respiration was begun. At the end of a quarter of an hour there were no voluntary efforts at inspiration, and the body was pale and cold. The author then thought of insufflation, and, taking the rubber tubing off a feeding bottle, succeeded without difficulty in introducing it into the glottis. Placing the other end in his mouth, he inflated the child's chest with his breath. He did this twice, and then, to his extreme gratification, a distinct voluntary inspiration occurred. After repeating this maneuver twice more the breathing of the child became thoroughly established, regular and deep, and the face and limbs began to assume a natural color. The child was shivering with cold. It had now been exposed nearly an hour, entirely naked and wet in a room a little over 60° F. It was given a hot bath and wrapped in warm cotton-wool, but the jaw still chattered. It made no attempt to suck, and could with difficulty be got to swallow a little hot milk and water. The child shivered without intermission for twenty-four hours, and then it died, apparently from cold and exposure. The author says that the great disadvantage of the usual methods of artificial respiration is the inevitable exposure of the body accustomed to a temperature of nearly 100° F. to one which averages 30 to 40° F. lower. The insufflation method can be practised even while the infant is in a warm bath. His general results with insufflation have been satisfactory.

Cancer in Travancore, South India.—W. C. Bentall summarizes his study of cancer in the region indicated, which embraces 1,700 cases collected from various localities. He notes that the age of maximum occurrence is some twenty years younger than in Great Britain. The overwhelming predominance as to site has been on the buccal mucosa. The prevalent habit of chewing the betel nut in India may have a bearing on this point. The female genitals are another favorite seat, as the native women rarely seek medical advice when thus affected. The author describes in detail the histological peculiarities of the buccal growth and adds some points of interest as to his methods of treatment and as to the betel nut chewing habit. The method of chewing in Travancore is usually to take a few bits of areca nut, and placing them in the mouth to chew for half a minute, and then, smearing the betel leaf with slaked lime, to add that. This is said to produce a pleasant, sweet taste, and the increased saliva becomes bright red in color; some swallow this, others spit it out. In about five minutes a portion of the prepared tobacco leaf is added, and the whole is chewed into a bolus, and located in the sulcus between the cheek and the lower jaw. Some keep it there for about a quarter of an hour until it has no taste, and then eject it, while others keep it in for a long time, even up to six hours. If the proportion of lime be increased, there is marked burning sensation and local anesthesia lasting for several hours. If the tobacco be increased there are all the symptoms of nicotine poisoning. Many men with their betel can work hard all day without any food.

Münchener medizinische Wochenschrift, November 3, 1908.

The Virus of Smallpox.—Prowazek and de Baurepaire filtered the virus of smallpox through filters having the closest pores, yet were able to produce with the filtrates lesions in the corneas of rabbits characterized by the presence of Guarnieri corpuscles. Filtration through colloidal membranes seemed to keep the virus out of the filtrates, no inoculation of rabbits being possible after this procedure. Smears of the material retained by the membranes showed the presence of perfectly round bodies smaller than the smallest bacteria; these bodies took the red and azure stains. The blood of smallpox cases seems to contain but little virus for inoculation with it taken from various organs was usually negative; no antibodies could be shown to exist in the blood. These results justify the conclusion that smallpox is an ectodermal disease, and immunity to it depends upon some condition of the skin which can be produced by active disease only. The excitants of smallpox seem to require a symbiotic organism, a streptococcus, to produce the characteristic lesions of the disease; inoculations with the virus in the absence of streptococci were unsuccessful. Complement in the shape of normal serum is likewise required to activate the virus.

Deutsche medizinische Wochenschrift, Oct. 22 and 29, 1908.

Indications for Chondrotomy in Apical Tuberculosis.—Harrass says that the principal indication for chondrotomy is given by the existence of incipient apical tuberculosis in consequence of an advanced ossification of the cartilage of the first rib. Advanced lesions in the lungs and foci in other organs counterindicate surgical interference with the ribs. If the mere shortness of the first rib is thought to favor the progress of a tubercular lesion operation may be undertaken only after respiratory gymnastics have not proved successful in bettering the expansion of the apices. Every operation of this character should be preceded by careful examination with the *x*-rays for the combination of ossification with primary anomalies of the rib cartilage are factors in making the prognosis worse, and in some cases may serve to contraindicate operative treatment. Postoperative treatment should consist in respiratory gymnastics combined with the usual tonic treatment of tuberculosis. The cases for the operation should be carefully selected, for the promise of success from the operation does not apply to each and every tuberculous patient with ossification of rib cartilages.

Cystoscopy and Catheterization of Ureters in Children.—Portner says that diseases of the bladder and of the kidneys are much rarer in children than in adults; they are much harder to diagnose because of the difficulty of interpreting the complaints of young children. Stone of the bladder, however, is more easily diagnosed by clinical observation and the study of the child's complaints than other conditions. Frequently, therefore, the cystoscope and the ureteral catheter must be used, but these instruments must be employed only if absolutely necessary The study of the urinary sediment should point out the best procedure to adopt. No cystoscopic examination should be performed in cases of bladder or kidney complaints that are not accompanied by abnormal urinary findings; separation of the urines is likewise useless in such conditions. Hematuria which forms a part of a hemorrhagic diathesis or is a mere symptom of severe nephritis is likewise not adapted to instrumental examination; mere pyuria that responds to the usual treatment does not require cystoscopic examination. If, however, doubts as to diagnosis still exist after hematuria or pyuria had continued for four weeks the question can and should be solved by the use of the cystoscope or the ureteral catheter. Cystoscopy and catheterization of the ureters is possible in female children after the first year of life; in male children the cystoscope may be introduced after the second year while the catheter cannot be used until the boy is eight years old. Special instruments must be used, the cystoscope being No. 12 in Charrière's scale and the ureteroscope Charrière No. 17. The procedures are not dangerous, but usually require full anesthesia to abolish the bladder reflexes; functional diagnosis of the kidneys may be combined with the separation of the urines by the ureteral catheters. Portner reports a number of illustrative cases in which he used these instruments for the purposes of diagnosis or of treatment of suitable conditions in children.

Vasomotor Trophic Neuroses.—Cassirer classifies under this term acroparesthesia, Raynaud's disease, erythromelalgia, sclerodermy, sclerodactyly, and angioneurotic edema. These conditions usually affect the tips of external organs, for example, the tip of the nose or of the chin, tips of fingers, of toes, and of ears. They are all due to some disturbance in the sympathetic innervation of the parts, and are all functional, in so far as no anatomical changes that could explain the symptoms have been discovered. Their general prognosis is good, as organic disease rarely follows them. Yet their course is obstinate and very chronic, with frequent exacerbations. Acroparesthesia is marked by unpleasant and queer sensations that usually affect the hands and forearms; loss of sensation may also be present in one or two fingers. Its prognosis as to recovery is not very good, but long intermissions are frequent. Prophylaxis consists in avoiding all external injurious factors, such as cold, wet, chemicals, etc. The treatment consists in the application of electricity, of warm compresses, and of gymnastic measures. Raynaud's disease in advanced cases is marked by gangrene of the finger tips; more frequently there is redness, some swelling, and very intense pain. It is usually limited to one or two fingers and occurs in successive attacks. Treatment is symptomatic, the pain often requiring the administration of opiates. Erythromelalgia is marked by redness and pain of the extremities; as a rule, the lower extremities are affected, thus differing from Raynaud's disease. Treatment is likewise symptomatic; elevation of the limbs, cold compresses, etc., may be tried. Angioneurotic edema may appear anywhere in the body and may affect the skin, mucosa, muscles, joints, etc. It is possible that the condition may even affect the meninges. General treatment, with special attention to the diet and the functions of the bowels, promises most relief in this condition. Arsenic and quinine are sometimes quite useful in relieving the edema.

Polycythemia and Blood Pressure.—Möller has made many estimations of blood pressure, together with counts of red blood cells in normal and sick persons, and concludes that there is no direct relation between the number of cells and the height of blood pressure. Increase of pressure does not increase the number of cells in peripheral blood, and polycythemia cannot affect a rise in pressure. The latter must be looked upon as the result of changes in the elasticity of the vessel walls, whether such change be caused by the increase of connective tissue in the larger vessels or by a contraction in the smallest arterioles, due to some toxins circulating in the blood.

French and Italian Journals.

New Method of Diagnosis and Classification of Scolioses of Adolescents.—J. Gourdon classifies scolioses in adolescents by the symptom rotation of the vertebra. This always exists, and precedes the appearance of the lateral deviation; it causes the scoliotic deformities which are most rebellious to therapeutics. Hence it is logical to follow its evolution, know its manifestations, and characterize it so as to establish a useful prognosis. He places the patient standing and then causes him to flex the body to the horizontal line. In dorsal scoliosis if the two sides of the back are on the same plane there is no dorsal scoliosis. A posterior increased elevation of the ribs without deformity of the sides means a benign scoliosis. A posterior costal deformity with the appearance of an obtuse angle is a scoliosis of medium gravity. A posterior deformity of the ribs with an acute angle is a very grave scoliosis. In lumbar scoliosis the patient must be examined standing and in anterior flexion of the trunk. If the two regions at the sides of the lumbar spine are alike there is an absence of scoliosis. If there is a paraspinal projection in the vertical position there is lumbar scoliosis. If in anterior flexion there is a lessening of the subelevation the case has a good prognosis. If it remains it is of medium gravity. If it is exaggerated the prognoss is bad. Scolioses of the first two degrees are curable. Those of the third are not.—*Archives Provinçales de Chirurgie*, No. 4, 1908.

Diffuse Adenoma of the Cervix Uteri.—H. Hartmann and P. Lecéne present a case of diffuse adenoma of the cervix uteri, and discuss its relation to cancer. These growths have a very slow evolution, and during the time that they are growing a cancer would have attained a much greater size than does the adenoma. In the author's case there was an immense ulceration of the cervix, ending abruptly, the growth not extending beyond its boundaries. Neither did it extend deeply into the tissues, being limited by the muscleconnective tissue layer of the cervix. The body of the uterus and the broad ligaments were not involved. The cavity of the cervix was filled with vegetations which consisted of many cavities lined with cylindrical epithelium similar to that lining the mucous glands of the cervix. The growth consisted of degenerated mucous glands apparently included by a basement membrane. The diagnosis of this affection from uterine cancer is not possible by symptoms alone, and only the examination of the growth after removal will serve to perfectly differentiate it from cancer. Its lack of infiltration and the integrity of the fundus and broad ligaments is an important point in diagnosis. The authors believe that these growths are benign, thus differing materially from cancer.—*Annales de Gynecologie et d'Obstetrique*, April, 1908.

Ureterovaginal Fistulæ Following Abdominal Hysterectomy.—Carlos Lepoutre says that ureterovaginal fistulæ are generally found after vaginal hysterectomy, but they occur also after atypical abdominal operations done for large growths, cancerous and fibromatous, and adherent salpyngitis. Here the ureter is so involved in the growth that it is impossible to follow it out and it is cut in the removal of the tumor. This troubles the patient principally by the flow of urine from the vagina which is continuous, day and night, standing or sitting, and is not controlled by the abdominal muscles. But the walls of the ureter become diseased and thickened, the track may become closed and pyonephrosis occur, and the amount of urine diminishes. To the clinical symptoms for diagnosis must be added the results of examination of bladder, vagina, kidneys, and urethra. Lumbar pain and pyonephrosis may be detected by examining the kidney. The orifice in the vagina may be found, and a tampon becomes saturated with urine. Vesicovaginal fistula is excluded by injecting a colored fluid into the bladder which does not appear in the vagina.—*Journal des Sciences Médicales de Lille*, June 6, 1908.

Book Reviews.

Atlas der Pathologischanatomischen Sectionstechnik. Von Prof. Dr. M. Westenhoeffer. Mit 34 Abbildungen. Berlin: Verlag von August Hirschwald, 1908.

This is a pamphlet of fifty pages giving the methods of postmortem examination used by the author. The text is clear and concise, and the illustrations give a good idea of the topographical anatomy of the body as it appears step by step during the autopsy. Histological methods are not included in the scope of the book, nor are the normal weight and size of organs given.

Diseases of Infancy and Childhood. Their Dietetic, Hygienic, and Medical Treatment. A Textbook Designed for Practitioners and Students in Medicine. By Louis Fischer, M.D., Attending Physician to the Willard Parker and Riverside Hospitals of New York City; Attending Pediatrist to the Sydenham Hospital; Former Instructor in Diseases of Children at the New York Post-Graduate Medical School and Hospital, etc., etc.; Fellow of the New York Academy of Medicine. Second Edition. With 303 Illustrations, several in colors, and 27 Full-page Half-tone and color Plates. Philadelphia: F. A. Davis Company, 1908.

The second edition of Dr. Fischer's book is improved by the addition of a new article on Hypertrophic Pyloric Stenosis, by the description of the new methods of diagnosing tuberculosis, and by the elaboration of some other parts of the book. Advantage has been taken of the reissue of the book to remove the offensive legend proclaiming the superiority of the work, but no corrections have been made in the many inelegancies of style that interfere very much with the reader's attention to the subject matter. The fact that a second edition has been called for within six months shows that the volume has found favor with medical readers; in consideration for them the book should have been carefully edited before being reissued.

A Manual of Midwifery. By Thomas Watts Eden, M.D., C.M. (Edin.), F.R.C.P. (Lond.), F.R.C.P. (Edin.); Obstetric Physician with Charge of Out-patients, and Lecturer on Practical Midwifery and Gynecology, Charing Cross Hospital; Physician to Out-patients, Queen Charlotte's Lying-in Hospital; Surgeon to In-patients, Chelsea Hospital for Women; Examiner in Midwifery and Diseases of Women to the University of Oxford, University of Leeds and the Conjoint Board of the Royal College of Physicians and Surgeons With 42 Plates and 236 Illustrations in the Text. Second Edition. Chicago: W. T. Keener & Co., 1908.

In the preface to the first edition of this book Dr. Eden stated that his purpose was to give a concise account of the theory and practice of midwifery; the call for a second edition within two years, at a time when new books on obstetrics appear so often, shows that he has attained his aim to the satisfaction of a wide circle of readers. The book is unusually full of the chapters dealing with the development of the human ovum and the physiology and pathology of the placenta, the original work and wide reading the author has done in this field peculiarly fitting him to deal with these questions. His lucid account of normal pregnancy is followed by the consideration of the phenomena and the management of labor and the puerperium, the facts being presented from the practical standpoint of the practitioner. Sufficient space is then allotted to the care of the newborn child, while the commoner obstetric operations are described in the last part of the book. Throughout the greatest accent is placed upon the necessity of asepsis in all obstetric work and the methods of procuring such asepsis in practical work are given at length. The present issue is enlarged to about fifty pages of text, by a new series of illustrations of the normal and contracted pelvis, and by a full set of plates illustrating the application of forceps. The book is unreservedly recommended to the student of medicine and to the busy practitioner.

The Law in General Practice. Some chapters in everyday Forensic Medicine. By Stanley B. Atkinson, M.A., M.B., B.Sc. of the Inner Temple, Barrister-at-Law; Justice of the Peace for the County of London; Member of the Central Midwives' Board; Hon. Secretary of the Medico-Legal Society (Lond.). London: Henry Frowde, and Hodder & Stoughton, 1908.

This is an uncommonly entertaining volume on an important and much neglected subject. There are eight chapters, entitled, respectively, Practical cautions and precautions; Medical evidence and medical witnesses; Medical certificates and reports; The law of defamation in relation to the medical practitioner; Negligence and malpraxis in medical practice; Some difficult clinical occasions; Cases arising in the coroner's court, and Some limitations of medical evidence. The sixth chapter, on "Some difficult clinical occasions," discusses several topics, such as: Spontaneous and criminal abortion, Anesthesia, Determination of age in the living, Drunkenness, Epilepsy, Good Health, Management of acute mental cases, Pregnancy late in life, Undue influence; Poisoning, Threatened or attempted suicide: Treatment of criminals and their victims. The legal cases cited are English, but the general principles of law which underlie the cases and decisions will, as a rule, apply equally in this country. In a few minor details such as the relations of physicians to the police, the practice in the two countries is slightly different, but these do not detract in the least from the real value of the work. The book is written by one who is conversant with, and has graduated in, both law and medicine, who has moreover a wide acquaintance with general literature and an ample knowledge of human nature; and there is not a chapter in the volume which will not prove interesting and instructive to the general practitioner.

A Manual of Clinical Diagnosis. By James Campbell Todd, Ph.B., M.D. Associate Professor of Pathology, Denver and Gross College of Medicine (University of Denver); Pathologist and Clinical Microscopist to Mercy, St. Anthony's, and the Denver City and County Hospitals. Illustrated. Philadelphia and London: W. B. Saunders Company, 1908.

The aim of the author of this volume, as stated in the preface, is to "present a clear and concise statement of the more important laboratory methods which have clinical value, and a brief guide to the interpretation of results: it is designed for the student and practitioner, not for the trained laboratory worker." The author has fulfilled this purpose most satisfactorily, and the student and practitioner will find in this volume a sufficiently full account of the various examinations they will be required to make, of sputum, gastric contents, urine, blood, feces, etc. The methods given are practical and do not require either complicated and costly apparatus or an unreasonable expenditure of time. The space allotted to the different topics is well proportioned, the tests are well selected, the descriptions are accurate and clearly expressed; the book is well printed and illustrated, and is of convenient size, and can be confidently recommended to the student and practitioner as one of the most useful works on the subject.

Pain. Its Causation and Diagnostic Significance in Internal Diseases. By Dr. Rudolph Schmidt, Assistant in the Clinic of Hofrat von Neusser, Vienna. Translated and Edited by Karl M. Vogel, M.D., Instructor in Pathology, College of Physicians and Surgeons, Columbia University; Clinical Pathologist and Assistant Attending Physician, St. Luke's Hospital; and Hans Zinsser, A.M., M.D., Instructor in Bacteriology, College of Physicians and Surgeons, Columbia University; Assistant Pathologist, St. Luke's Hospital. Philadelphia and London: J. B. Lippincott Company, 1908.

Actuated by the realization of the fact that the young physician is but rarely able to utilize in diagnosis the subjective complaint of pain, so often heard from patients, Dr. Schmidt has analyzed this symptom and has classified its causes and its significance in internal diseases. He first points out the information to be obtained from the patient in order to render the complaint of pain as little vague as possible; such information consists in determining the topography of pain, its time intensity, quality, and the influence of such factors as position, motion, pressure, food, drugs and the exercise of function. Consideration of the topography of various painful sensations closes the general analysis, and the study of specific instances of pain is opened with the description of the painful sensations that can be traced to the nervous system. Organs of motion are then considered, followed by a chapter treating of pain observed in connection with the digestive apparatus. This, the most important chapter of the book, abounds in practical hints for the utilization of the subjective complaints of patients in analyzing their sources. Finally, the urinary system, the spleen, the organs of respiration and of circulation are considered. The book is of value in so far as it fills a deficiency both in medical literature and in the teaching of medicine; its practical worth, however would be much enhanced by condensation and by the substitution of direct statements for the frequent and distracting circumlocutions of the author. The translators have added to the completeness of the book by summarising the researches of Head in regard to the cutaneous areas of tenderness accompanying visceral disease and by reproducing the diagrams of that author giving the areas of referred pain and tenderness.

Society Reports.

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Eleventh Annual Meeting, Held at Chicago, Ill., June 1 and 2, 1908.

(Special Report to the MEDICAL RECORD.)

Monday, June 1—First Day.

THE PRESIDENT, DR. JOHN P. SAWYER OF CLEVELAND IN THE CHAIR.

The President's Address.—Dr. SAWYER, in his opening address, first referred to the recent death of Dr. John Dutton Steele of Philadelphia, who was one of the earlier members of the Association, and whose personal qualities and professional attainments had won the highest esteem of his colleagues. The speaker then briefly reviewed the work of the Association during the past year, and called attention to the fact that its membership was composed of surgeons, pathologists, physiologists and internists, and that such a composite membership could not but result in broad discussion, and in an eliminative consideration of the ideas presented.

Ischochymia.— Dr. FRANK HALL MURDOCH of Pittsburg defined ischochymia an an affection characterized by the constant presence of food in the stomach, even in the fasting state. It might be acute or chronic. Whether acute ischochymia, or acute dilatation of the stomach, as it was termed by Boas, Hunter, and others, was due to a paralysis of the gastric muscles, or to a spasmodic contraction, or to both, was as yet undecided. It was usually brought on by some gross error in diet, though it occasionally followed chloroform anesthesia. Out of 64 cases known, 47 proved fatal. Of the total number of cases, 29 followed chloroform anesthesia, and in eleven of these the operation had not involved the abdomen, but was at points remote from it. The chronic form was caused (1) by mechanical obstruction of the pylorus; (2) by absolute or relative weakness of the expulsive forces; in other words, atonic conditions of the muscularis. Usually, in ischochymia resulting from stenosis of the pylorus, only the coarser particles of food were found in the stomach in the morning before the patient had eaten anything, the finer particles and the liquid contents having passed into the intestine. On the other hand, when stagnation of food was due to atony of the gastric musculature, the coarser particles of food would pass through the pylorus, and only a small quantity of the finer particles would be found in the stomach in the morning before the patient had taken any food. In the treatment of ischochymia due to mechanical obstruction of the pylorus, surgical interference was demanded if the obstruction was due to malignant stenosis, to benign stenosis of high degree which would not yield to medical treatment, to adhesions of the pylorus to neighboring organs, to cicatricial bands, or to tumors which by pressure obstructed the outlet of the stomach. Formerly operation was considered necessary in all cases of benign stenosis of the pylorus, of whatever degree, but now we know that such was not the case, for under proper medical treatment, including diet and lavage, many patients entirely recovered.

Dr. G. W. MCCASKEY of Fort Wayne was inclined to question the correctness of the limit of seven hours as the time in which a healthy stomach should empty itself, and beyond which a case should be labeled ischochymia.

Dr. MAX EINHORN of New York agreed with Dr. McCaskey that the name ischochymia should be restricted to those cases in which the stomach had not emptied itself by morning, and that those cases in which food was present six or seven or eight hours after a meal should be regarded as cases of atony of the stomach.

Dr. FRANKLIN W. WHITE of Boston said if we defined ischochymia as a condition in which there was a food stasis of twelve hours or longer, the probabilities were then that we were dealing with an obstructive condition, and most of those cases would eventually go to the surgeon.

Dr. HENRY WALD BETTMANN of Cincinnati said the important point was to determine whether the stomach was able to propel the food through the pylorus in sufficient amount to nourish the patient. The greatest single advance that had been made in the treatment of ischochymia was that of Kussmaul, in 1868, when he introduced the stomach tube into clinical medicine, and he subsequently reported a number of cases of very advanced stenosis of the pylorus which were relieved by gastric lavage.

Dr. ALFRED D. KOHN of Chicago said it had been the experience of many that gastroenterostomy for benign stenosis, so called, was frequently followed by fatal ulcers of the jejunum. In cases where hyperchlorhydria existed, and an immediate operation was absolutely essential, it would be advisable to resort to a preliminary jejunostomy until the urgent symptoms had cleared up.

Dr. JOHN A. LICHTY of Pittsburg said the operation that should be done to relieve this condition was pyloroplasty, and when the surgeons became more familiar with the technique of that operation he believed the death rate following it would be no higher than that of gastroenterostomy.

Dr. J. C. JOHNSON of Atlanta thought there was something distinctive about ischochymia which could not be altogether explained by the degree of stenosis or the degree of impairment of the gastric musculature, and we should always be very guarded in making our diagnosis.

Dr. JOHN P. SAWYER of Cleveland mentioned a case coming under his observation which bore upon the observation of Dr. Einhorn that mechanical obstruction need not be present in connection with ischochymia.

A New Method of Estimating the Permeability of the Pylorus, and an Attempt of Testing the Pancreatic Function Directly.—Dr. MAX EINHORN of New York had beads of different sizes attached to a silk thread and had them swallowed in order to see whether they passed the pylorus or not. In normal conditions they would pass; in stenosis they would remain in the stomach. As the length of the thread in itself was not a sufficient guide to decide whether the bead was in the duodenum or not, we had to look for a different indicator for that purpose. He first used beads coated with mutton tallow; later, beads filled with methylene blue and coated with mutton tallow. As the fat was dissolved mainly in the duodenum, a green or blue color of the urine would show that the bead had already passed the pylorus. This occurred in from three to five hours. He tied another similar bead for control purposes to the thread at a distance of 50 centimeters from the lips. This bead could not pass through the stomach. For the purpose of testing the pancreatic function, Dr. Einhorn had constructed a duodenal bucket, on the same principle as the stomach bucket, but much smaller. This bucket, tied to a long string of braided silk, with a mark at 75 centimeters, was placed in a gelatin capsule and given about one hour after a small meal. It was left in the digestive tract for three hours, and then was slowly withdrawn. It was still better to have the patient swallow the bucket before retiring and withdraw it in the morning in the fasting condition. Usually, the bucket returned full. Its contents might be removed by means of a pipette and placed in a small porcelain dish.

Dr. FENTON B. TURCK of Chicago said that attempts to explore and determine the condition of the stomach and duodenum with the aid of capsules had proved of the greatest service to him in his work.

Dr. G. W. MCCASKEY of Fort Wayne said that in regard to the tests with thymus gland, while a positive result would be of great value, a negative result would be of no value in determining the absence of pancreatic disease. A carcinoma might involve half the pancreas and there would still be enough pancreatic juice to carry on digestion.

An Explanation of the Motor Activities of the Alimentary Canal in Terms of the Mesenteric Reflex.—Dr. Walter B. Cannon of Boston stated that the reflex for the intestine contraction above and relaxation below a stimulated point was also proved true of the stomach and of the lower esophagus. The cardiac and pyloric sphincters obeyed the same reflex. The alimentary canal was therefore a unity, made orderly by the local reflex in the mesenteric plexus. Evidence was at hand indicating a reversal of this reflex in states of increasing or high tonus. About a year ago Dr. Cannon said he showed that the presence of acid in the stomach stimulated the opening of the pylorus, while the presence of acid in the duodenum closed the pylorus and prevented the outflow of food from the stomach. Since that time he had made some observations, the details of which were still unpublished, in regard to the control of the cardiac sphincter of the stomach, and those observations indicated that the cardiac sphincter likewise obeyed this law, namely, that the presence of acid in the stomach normally kept the cardiac sphincter closed during digestion, and that the stimulation below caused the contraction above. The cardiac and pyloric sphincters therefore obeyed the same law as that prevailing in the intestines. This observation he said was not entirely his own. Hirsch, about fifteen years ago, observed that when acid was introduced into the duodenum, there was a cessation of discharge from the stomach. No proof was given, however, that the effect was on the pylorus. Indeed, the result had been attributed to the effect of the acid on the peristaltic movements of the stomach. It was not until the *x*-ray was introduced that we could differentiate between these two factors of gastric discharge.

Plastic Peritonitis.—Dr. G. W. McCaskey of Fort Wayne reported this case in detail, and showed the specimen. The patient was a man about 35 years old who consulted Dr. McCaskey about a year ago on account of persistent vomiting, abdominal pain and general debility. The pain was in the lower half of the abdomen, principally in the right lower quadrant. A diagnosis of appendicitis had been made by a physician in his home town. The vomiting of which he complained was irregular in character; it sometimes occurred after eating, and sometimes without reference to meals, and it had been going on for some months. The vomitus was always of a greenish color; this did not resemble bile, but had the appearance of the pigment produced by *Bacillus pyocyaneus*. The man's temperature remained normal, even perhaps subnormal until just before his death. The pulse was also substantially normal. An analysis of the stomach contents showed a normal amount of hydrochloric acid. The patient was finally turned over to Dr. Miles F. Porter of Fort Wayne for exploratory operation, with the provisional diagnosis of plastic peritonitis. The operation showed the intestines matted together in a peculiar way. It was impossible to unfold them, and as nothing further could be done, the abdomen was closed. The case ended fatally, and the autopsy showed that a slowly progressive peritonitis, probably of long standing, had firmly matted the intestines together. The plastic exudate forming on the peritoneal surfaces had gradually contracted the intestines, longitudinally infolding them close together, and thus obliterating at least three-quarters of the intestine.

Cholecystitis.—Dr. Henry Wald Bettmann of Cincinnati read this paper (see page 923).

Dr. Gustav Futterer of Chicago asked whether anything could be done to destroy or mitigate the effects of the typhoid bacilli within the gall-bladder. Ten years ago he injected typhoid bacilli into the gall-bladder of animals, and then gave them various kinds of medical treatment without any effect whatever on the bacilli. Probably the most logical preparations would be the salicylates. Stadelmann of Berlin, who had studied cholagogues all his life, had come to the conclusion that ox-gall and the salicylates were the best cholagogues, and as a salicylate was at the same time a disinfectant, the combination seemed to be a very good one. Still, Dr. Futterer said he had never seen any benefit from it. The acute symptoms of cholecystitis he had found yielded very quickly to oil of wintergreen, which he preferred to the salicylate of sodium. He knew of only one method in dealing with typhoidal infection of the gall-bladder, and that was to open the gall-bladder, wash it out, and drain it.

Dr. John A. Lichty of Pittsburg asked Dr. Bettmann how he was able to recognize this pre-gallstone period, and how he was able to say that a certain case was or was not one of pure cholecystitis, without the presence of gallstones.

Dr. Jesse S. Myer of St. Louis thought Dr. Bettmann had underestimated, perhaps, the importance of stagnation, not only in the development of the chronicity of a cholecystitis, but also in the formation of gallstones. About 80 or 90 per cent. of gallstone cases were in women, and a large proportion of those met with in the male sex were in old men. There must be some definite reason for this, and the most probable one was that it was due to the stagnation of bile in the gall-bladder as a result of a disturbance of intraabdominal pressure. The speaker said he was convinced that pregnancy was not only a factor in the causation of cholecystitis, but especially in its prolongation.

Dr. Franklin W. White of Boston said that Dr. Bettmann's paper emphasized the fact that prevention was likely to be the only satisfactory medical treatment of gallstones. Naunyn of Strasburg had found no evidence of the dissolving of gallstones by medical treatment excepting in two or three instances out of one thousand. The great difficulty in the way of the preventive treatment lay in making a sufficiently early diagnosis. In the vast majority of cases, gallstones probably remained latent for long periods of time.

Dr. J. C. Johnson of Atlanta said that in the production of gallstones emphasis should be laid on the stagnation of bile. As regarded treatment, he believed that such remedies as phosphate of sodium, oleate of sodium, and olive oil owed their value to their laxative effect on the duodenum, thus increasing the patency of the ducts. Anything which favored muscular relaxation of the parts would favor the passage of the stones.

Dr. Bettmann, in closing, said he thought there was no longer any doubt that cholecystitis was always due to an infection, that gallstones only formed in an infected gall-bladder, and that the causative factor in the majority of instances was the colon bacillus and in the minority of cases the typhoid bacillus. The more virulent forms of infection did not lead to the formation of gallstones, because they destroyed the mucous membrane of the gall-bladder. Cholecystitis, the speaker believed, was too often mistaken for what we termed "spoiled stomach," "acute intestinal catarrh," "appendicitis," and so on, and if in those cases we examined the gallbladder region we would be surprised in how many instances we could actually demonstrate the presence of an enlarged, inflamed and therefore very tender gall-bladder. The mere frequency of acute cholecystitis was proof of the fact that we had overlooked it. His investigations on the subject had led him to believe that it was never latent, and that we could recognize it if we hunted for it. If gallstones were due to cholecystitis, and we were able to recognize the latter, were we not neglecting our patients when we did nothing for them. We knew the cholecystitis preceded the formation of gallstones, and we might prevent their formation by keeping up the flow of bile and resorting to the medical expedients which we knew were successful in reducing inflammatory conditions.

The Behavior of Some Indigestible Carbohydrates in the Alimentary Tract.—Dr. Lafayette B. Mendel of New Haven reviewed the studies conducted by himself in the Sheffield Laboratory of Physiological Chemistry at

Yale University of the digestibility and utilization of various polysaccharide carbohydrates recommended for dietetic purposes in the form of lichens and algae. They were for the most part not altered by the digestive juices or fermentative organisms of the alimentary tract. Such studies of the utilization of these products as had already been completed in the laboratory with which the writer was connected indicated a very unsatisfactory utilization of the constituent carbohydrates, which were scarcely attacked by familiar alimentary enzymes, nor profoundly altered by such bacterial agencies as they might be expected to become subject to in the digestive tract of man. The upshot of the review was the emphasis which it placed upon adequate digestion as a prerequisite for the physiological utilization of carbohydrates, and the preeminent value of a few specific carbohydrates in nutrition. The lessons of the experiment warned against the hasty acceptance of every carbohydrate food product into the category of true nutrients. We must build upon the foundation of actual experiments in metabolism. Many of the modern products doubtless had a deserved place in the dietary in health or disease as food accessories, serving uses quite apart from any direct nutrient function. What was true of the carbohydrate constituents was applicable in many instances to other components. For example, the writer's experience with mushrooms, in which the nitrogen was found to exist largely in the form of unavailable non-protein compounds, taught further caution in drawing inferences respecting the nutrient value of such plant products. Perhaps the fact that so few of the suggested food materials of the kind under consideration had found favor in any general way, despite their widespread distribution in nature, was an almost instinctive expression of their non-nutritive make-up.

The Nervous Influence on the Production of Sugar in the Body.— Dr. J. J. R. MacLeod of Cleveland in this paper, which embraced an exhaustive study of the subject based upon original experimental work, summarized his findings as follows: Stimulation of the great splanchnic nerve caused in dogs intense hyperglykemia, accompanied by glycosuria and diuresis. It was improbable that the mechanism involved was one of vascular disturbance of the liver, for the following reasons: 1. Ligation of the hepatic artery did not produce hyperglykemia. 2. Neither did obstruction of the blood flow in the portal vein. 3. When the hepatic nerves were cut, splanchnic stimulation, although it produced the usual changes in the general blood pressure, was not followed by hyperglykemia. 4. Direct stimulation of the hepatic nerves usually caused hyperglykemia, but no constant change in blood pressure. Atropine did not diminish the hyperglykemia due to splanchnic stimulation.

Tuesday, June 2—Second Day.

Intestinal Sand; One of Its Sources.—Drs. Jesse S. Myer and Jerome E. Cook of St. Louis, in this paper, said the term "intestinal sand" should be applied only to sand-like particles occurring in the feces, and not to larger bodies, such as had been described by the French and English authors. The French, under the title of *sable intestinale,* described bodies ranging from the size of grains of blotting-sand to that of a pigeon's egg. The subject was in a rather confused state, because of the confounding of terms. Mucomembranous colitis was considered by many writers, especially the French, as a causative factor. The gouty diathesis, appendicitis, constipation and "lithogenic intestinal catarrh" as a disease *per se,* had all been suggested as etiological factors. In the authors' opinion these conditions seemed to bear little if any relationship to the phenomenon, the occurrence of the sand in these cases being, in all probability, accidental. The character and composition of the sand described varied greatly, the organic matter, for instance, ranging from 20 to 96 per cent. The distinctions between "true" and "false" intestinal sand did not seem to be well founded. In the case reported in detail by the authors, the intestinal sand proved to be of vegetable origin, and was derived from the banana. In the stem, as well as in the fruit of the banana there were vascular bundles accompanied by milk tubes, symmetrically arranged, and separated from them by one or two layers of parenchymatous cells. These milk tubes consisted of a row of vertical cylindrical cells, one above the other. They contained large, homogeneous, highly refractive resin balls or masses suspended in a fluid very rich in tannin. These resin balls, the contents of the cells, suspended in a fluid rich in tannin, were affected by the secretions of the intestine in a manner similar to the action of ferric chloride (by which they may be artificially detected), hardening the resin and producing an insoluble tannate. The authors stated that the similarity between the sand obtained in their case and that found in a great number of the cases in the literature suggested that the substance in those cases was derived from the same vegetable source as in their own.

Dr. Henry Wald Bettmann of Cincinnati said that about ten years ago, at a meeting in Cincinnati, specimens of intestinal sand similar to the artificial ones shown by Dr. Myer, were exhibited. They were sent to Washington for examination, and were traced, as in this case, to the banana.

Dr. John A. Lichty of Pittsburg said he had noticed that patients who suffered from mucous colitis were apt to pay close attention to their stools, and some of these had reported the presence of sand. He had also found it in the stools of children who had nervous mothers, but hereafter, instead of attributing its presence to the nervous mother, he would be on the lookout for the banana.

Dr. Franklin W. White of Boston said that probably there were other vegetables than the banana that produced sand in the stools—perhaps of a different character.

Dr. Myer, in closing, said in reply to a question that they had never made any experiments with the cooked banana. When one knew of the presence of these grains in the stools, it was not difficult to see them with the naked eye, but they readily escaped observation unless carefully looked for. They appeared as small black granules.

A Comparison of the Guaiac and Benzidin Tests for Invisible Hemorrhage in Diseases of the Digestive Organs.—Dr. Franklin W. White of Boston said that in comparison with a guaiac test, the Schlesinger and Holst modification of the benzidin test was from five to seven times as delicate for blood in watery solutions and gastric contents as the guaiac test, and about twice as delicate for blood in the feces. The chief advantage of the benzidin over the guaiac test was the greater value of a negative result in ruling out hemorrhage, the greater ease and rapidity of its performance, and the greater clearness of the color reaction in the feces.

Dr. Henry Wald Bettmann of Cincinnati took the extra precaution of excluding from the patient's diet all green vegetables for a few days prior to making the test.

Dr. John P. Sawyer of Cleveland said it was not easy to find assistants who could be relied upon to do this work, and the references we found in literature as to whether the benzidin test was negative or positive practically meant nothing unless we knew the men who carried out the work.

Dr. John A. Lichty of Pittsburg said that in cases of suspected gastric ulcer or carcinoma, the test for blood in the feces might prove negative in patients whose mixed diet had been stopped, and where the stomach had been put at rest by restriction to a milk diet. Under such conditions he did not always feel comfortable about the result of the test, and was rather inclined to believe that a positive reaction would have occurred if the hemorrhage had not been checked by diet.

Dr. White in closing said that in green vegetables, the oxidizing ferments were practically destroyed at the time

they passed through the alimentary canal, and he did not think it necessary to exclude them for special examination. He had found that green vegetables, even with the gastric contents, interfered very little with the test, and if we filtered and boiled the contents, we could safely allow them. In making the test, the finger should not be used to close the test-tube when it was shaken; rubber stoppers should preferably be used to avoid a possible positive reaction due to sweat, etc.

Management of Gastric Ulcer.—Dr. J. W. Bell of Minneapolis, in a paper on this subject, said the following conclusions seemed warranted: 1. That an early and complete diagnosis was the first essential in the successful management of gastric ulcer. 2. That all cases of acute gastric ulcer were amenable to proper medical treatment, the only exceptions being cases characterized by uncontrollable hemorrhage and perforation. 3. That all uncomplicated cases of chronic gastric ulcer were amenable to proper medical treatment and should be so treated. 4. That chronic indurated ulcers of long standing, involving especially the pyloric portion of the stomach, including their complications and sequela, frequently demanded surgical interference. 5. That the end results following gastroenterostomy for the relief of chronic ulcer were not satisfactory. 6. That the ideal surgical treatment of chronic indurated ulcer was excision in some form.

Dr. Jesse S. Myer of St. Louis said he had obtained his best results during the first week with the use of some form of soluble carhohydrate, and of late he had been using a prepared flour made of peas, lentils, and barley; these were partially dextrinized, and evidently formed no solid mass in the stomach. This food showed the finest possible division. It was first given in a perfectly liquid state, about the same consistency as milk, and then the quantity of flour added to it was gradually increased. Later on, one might add a little milk, and then gradually bring the patient up to the use of milk in the second week, and in the course of time add other foodstuffs.

Dr. J. C. Johnson of Atlanta said that in some cases in which the milk was badly borne, one might use one-third limewater and two-thirds milk, to which he added half a teaspoonful of bismuth and bicarbonate of sodium.

Dr. Gustav Futterer of Chicago said that in the treatment of ulcer cases we should not lose sight of the fact that they were anemic, and became more so after hemorrhage. Anemia played a prominent part in gastric ulcer, and in the treatment of these cases he considered it of the utmost importance to attempt at once to bring up the hemaglobin; if we did not do that, we delayed the healing of the ulcer, we prolonged the period of danger of hemorrhage and perforation, and later on of carcinoma. Rectal feeding the speaker regarded as unsatisfactory, even under the most favorable conditions.

Dr. Fenton B. Turck of Chicago referred to Lenhartz' method of treating gastric ulcer, and said that the use of meat in these cases, as recommended by him, had been of unqualified benefit. Meat was especially indicated because it was quickly digested, particularly when it was first treated by hydrolyzation. Discussing the question of operation for gastric ulcer, Dr. Turck called attention to the fact that Moynihan, in his recent writings, discouraged the idea of operating in the presence of hemorrhage, and personally he had become more and more convinced of the inadvisability of operating in the face of severe gastric bleeding.

Dr. Franklin W. White of Boston said he agreed entirely with Dr. Turck in regard to the question of hemorrhage and operation. In Boston they no longed advised surgical interference in acute gastric ulcer with dangerous hemorrhage, first, because the surgeons had found it difficult or impossible to locate the ulcer within a reasonable length of time; second, because almost every operation of this kind had thus far proved fatal.

Dr. John P. Sawyer of Cleveland said that in the treatment of acute gastric ulcer, he believed it advisable to give the stomach a short period of rest, and rely upon rectal feeding. In spite of what had been said, he still believed in the advantage of a certain period of complete physiological rest.

Dr. J. W. Bell of Minneapolis, in closing, said he agreed with Dr. Sawyer in regard to the advisability of giving the stomach at least a short period of rest after the occurrence of hemorrhage, especially in the management of acute gastric ulcer. The length of that period should depend on the nature of the case.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, May 18, 1908.

The President, Dr. Robert T. Morris, in the Chair.

Observations on a Case of Cancer of the Mouth.—Dr. C. Am Ende presented a man, 64 years old, who had been referred to him by the President, Dr. Robert T. Morris, and at whose request the case was shown. The man gave a history of having received an injury to the mouth about two years ago. This was immediately cauterized and then treated by various methods, but it failed to heal, and about a year later a whitish speck developed on the inner aspect of the cheek and gradually increased in size. The patient was treated by various physicians without resulting benefit, and he stated that he was refused treatment at the New York Skin and Cancer Hospital. When Dr. Am Ende first saw him, on December 29, 1907, there presented on the inside of the cheek an erosion somewhat larger than a silver dollar, deeper anteriorly than posteriorly, and covered by a firmly adherent, whitish, necrotic mass. There was a similar line of necrosis along the edge of the gum, which was inflamed and swollen. Removal of this necrotic tissue revealed an eroded, bleeding surface. One of the glands in the submaxillary region was enlarged and indurated and firmly adherent. Scrapings from the eroded surface were submitted to Dr. F. M. Jeffries, who pronounced them carcinomatous. The treatment, besides some bland local applications, consisted of exposure to the *x*-ray, twice weekly, first through the mouth and afterwards from outside the cheek. The internal treatment consisted of a teaspoonful of thyroidal fluid extract, three times daily, and thiosinamin, two grains daily, dissolved in the thyroidal extract. In addition to this the patient received one grain of thiosinamin hypodermically three times a week. Under this treatment the excruciating pain from which the patient had suffered soon subsided, and the local conditions rapidly improved. The erosion on the gum healed in about a month, and that involving the cheek was almost completely healed, although the new mucous membrane was not yet normal in appearance. The indurated gland in the neck was also considerably smaller. Dr. Am Ende, in reply to a question, said that injections of thiosinamin solution, in his hands, had not produced any appreciable pain; he was inclined to attribute such pain to the solvent rather than to the thiosinamin itself.

Remarks on the Ultraviolet Ray, High-frequency Currents, and Tabes.—Dr. Henry G. Piffard said that the papers and discussion that made up the symposium on progressive locomotor ataxia at the meeting of the Association in March had convinced him that there was still a great deal of misconception or lack of information among members of the medical profession in regard to certain radiological principles. For example, many were to-day using what they regarded as ultraviolet rays, and exploiting the therapeutic value of this agent, when as a matter of fact they were employing something entirely different. The ultraviolet rays belonged to the invisible rays of the spectrum; they became visible only through certain media, and their proportion was increased in certain kinds of light. Their penetrability through certain substances was limited: thus, the glass walls of a tube constituted a very

serious obstacle to their exit, and in spite of the fact that a certain writer had published an article entitled "Locomotor Ataxia Successfully Treated with Ultraviolet Rays," it was doubtful that they penetrated even through the entire thickness of the skin, and that these very superficially acting rays should penetrate the skin, the fascia, the protecting cartilaginous and bony walls of the vertebral canal, and influence the tissues of the spinal cord was to him utterly unbelievable. There were certain substances, however, such as quartz, water, ice, and rock salt, through which the ultraviolet rays readily passed, and it was well known that other substances, if exposed to the rays, would respond by the development of a luminosity and of a color quite different from that which they ordinarily possessed. To this condition the name fluorescence had been applied, and the use of such substances was one of the means adopted to render the presence of the ultraviolet rays manifest. Foremost among them was fluorescin; they also included various kinds of minerals, especially willemite and some of the calcites. The fluorescent quality of certain substances could also be demonstrated by other means than the ultra violet rays, such as the *x*-rays. Fluorescin, on the contrary, while extremely fluorescent under the action of the ultraviolet rays, failed to respond to the *x*-rays, and Dr. Piffard said he did not know of a single fluid substance that would fluoresce under the *x*-rays, while there were a good many that would fluoresce under the ultraviolet rays. The ultraviolet rays from a spark high tension electric were accompanied by still another class of radiations, which were distinct from both the *x*-rays and the ultraviolet rays; they had been called the Piffard rays, but thus far he had been unable to classify them. They could be demonstrated by means of the electroscope, and both physically and physiologically they were more active than the ultraviolet rays. They represented a form of radiation which we did not yet understand. In discussing high frequency currents, regarding which there seemed to be a great deal of misapprehension, Dr. Piffard said it was to d'Arsonval that we owed the introduction of high potential and high frequency currents into clinical medicine, and that in this country particularly attempts had been made to confuse the mind of the profession by giving the name of high frequency to currents which bore no physical relationship to them. They were originally developed out of some experiments made by Tesla, who was really one of the first to produce high frequency currents, while d'Arsonval was the first to utilize them. To produce such a current required something more than the mere terminals of a static machine or coil. The d'Arsonval high frequency currents were three in number, namely, the derived current or "shunt" current; the "autoconduction," and the "autocondensation" current. The essential features connected with the production of these currents were: (1) a suitable capacity, either Leyden jars or a flat condenser; (2) a solenoid (d'Arsonval) or a spiral (Piffard). If a static machine was employed as the source of high tension energy, the large jars were put in place, and the ends of the solenoid or spiral were connected to the outer armatures of the jars. After describing in detail the method of developing the current, the speaker said it had been quite extensively employed as a therapeutic measure, either for the purpose of affecting the general system, or to produce local changes only. The intensity of the current was under absolute control, and the effect, locally, might vary from a slight temporary congestion to absolute necrosis, which might be produced in a few seconds. Malignant or semimalignant lesions of the skin, epithelioma, lupus, lupus erythematosus, and sarcoma when of small size and conveniently located, had been destroyed in very many instances by the caustic spark from a metallic electrode connected to one terminal of a coil transformer, the other terminal being grounded or connected to the person of the patient. The little operation was exceedingly painful for the moment, but it lasted but two or three seconds at the utmost. There were many reports in confirmation of this treatment, chiefly from France, where it was first used by Rivière of Paris about seven or eight years ago. In concluding his remarks, Dr. Piffard said he would like to ask of the neurologists present what distinction they made between tabes and pseudotabes, to which reference had been made at the March meeting of the Association? In spite of painstaking investigation, he had been unable to find two neurologists who agreed as to the symptom-complex upon which the diagnosis of tabes dorsalis should be made. All agreed that it was unnecessary that all the symptoms should be present. Some argued that the Argyll-Robertson pupil should be present; others that it might be absent, and the same was true of the Babinski phenomenon and of the loss or diminution of the tendon reflex. It had appealed to him, the speaker said, very much as did the popular distinction made between the mushroom and the toadstool: if you ate it and lived, it was a mushroom, while if you died, it was a toadstool. In referring to the use of potassium iodide, Dr. Piffard said that while his experience with the use of the drug in tabes was limited, he had used it extensively in syphilis and had come to the conclusion that it should never be used in early syphilis and only rarely in late syphilis, of which tabes was now generally regarded as a manifestation.

Dr. Leonard Weber said the fulgurating process of dealing with cancers by the high frequency spark, which was first taken up as an adjuvant to surgery by de Keating-Hart of Marseilles, was now quite extensively tried at Munich and Heidelberg, where the operator worked in conjunction with the surgeon and applied the method to cancers of even large size, particularly those of the breast. The cancer was first thoroughly excised, and immediately following this, and with the patient still under complete narcosis, the high frequency d'Arsonval current was applied to the exposed tissues, until disintegration or necrosis of the surface was accomplished. This process usually gave rise to a decided reaction, with considerable edema and superficial tissue necrosis, together with a free flow of serum, followed by good healing. During any extensive cancer operation, with the more or less prolonged handling of the tissues entailed thereby, there was always danger of the cancer cells finding their way into the lymphatics or open veins, thus increasing the likelihood of metastases, and it was the claim of Hart and others that by the destructive action of the high frequency current the danger of metastases was largely avoided. The results thus far seemed to be very encouraging, and the treatment had recently been adopted at the Cancer Clinic at Heidelberg by Prof. Czerny, whose reputation for caution and conservatism was well known. Coming to tabes, Dr. Weber said that while he did not wish to pose as an expert on that subject, quite a number of cases had come under his observation, and during the years 1890 to 1894, at the Virchow Laboratory in Berlin, he had examined many hundreds of cross-sections of tabetic spinal cords in which the sclerotic process was well marked. These had shown, as was well recognized, that in a classical case of tabes, with all the characteristic symptoms, the nerve matter was replaced by connective tissue, which was distributed in wavy lines, and was not always confined to the posterior columns, the wasting disease having its origin in the posterior roots, as we now know. Marie and Guyon have tried to show that the virus of tabes—we did not know what it was and it was certainly not the *Spirochæta pallida* or its primary toxins—first affected the minute arteries and lymph spaces of the leptomeninges and thence interfering with the nutrition of the posterior roots and the posterior columns. There was first an atrophy of nerve-matter of ganglion fiber, followed by proliferation of connective tissue with its dire results. A sharp distinction must always be drawn between a classical case of tabes and one of *syphilis tabetica*, and it was the cases of latent

syphilis or syphilis of the spinal system that were favorably affected by mercury and potassium iodide. Upon a case of classical tabes these remedies had no effect, and the speaker said he could not recall a single case in which specific treatment had been of any avail whatsoever. The same was true of every other form of treatment, excepting the palliative effect of the electric current, according to Erb's method, hydrotherapeutic measures, and the Frenkel exercises. During the past three months, Dr. Weber said, he had been experimenting with a preparation of thiosinamin, which had been used these last ten years with some success for the purpose of dissolving cicatricial tissue. More recently it had been recommended as an adjuvant in the treatment of old strictures of the urethra, and personally the speaker thought he had seen some good results from it in three cases of urethral stricture in which he had resorted to it hypodermically. It then occurred to him that it might also prove of service in at least retarding the onward march of tabes, and he had tried it in three classical cases of at least five or ten years' standing. In two of these he had not as yet noticed any effect from the medication, but in the third the lightning-like pains from which the patient had suffered for five years disappeared after the sixth injection of 30 minims each. It was perhaps reasonable and justifiable, Dr. Weber said, to give this method of treatment a more extended trial in classical cases of tabes.

Diseases Conveyed by Insects—Dr. John B. Huber, in this paper, first discussed the common house fly. The tubercle bacillus, he said, was unquestionably distributed by flies, and it was equally true that flies helped greatly to swell the infant death rate. The infant mortality was greatest in fly time. There were few more congenial culture media for bacteria than milk, especially amidst the uncleanliness which obtained in the homes of many poor people. This fluid readily became contaminated with the excreta of flies, and with the noxious matter clinging to their feet. Tuberculosis was thus in some measure contracted by children, as was also dysentery and diarrhea. Typhoid fever was certainly disseminated by flies, although there were, of course, other sources of infection. Flies polluted the food and drink by means of the excreta which they carried from dungheaps, manure pits, and the like. They bred almost exclusively in fecal matter. They certainly disseminated cholera, and cases of tetanus seemed to have originated through their agency. Dr. Daniel D. Jackson, in the course of his work in behalf of the Merchants' Association of New York, in his report made the statement that the fly captured along the river front carried in its mouth and on its legs 100,000 fecal bacteria. The fly had been behind the large packing boxes down by the wharf, and was on his way to the nearest milk pitcher. We had long looked upon the house fly as a sort of necessary nuisance; a kind of scavanger which people must put up with who would persist in uncleanly habits. It was only recently, however, that we had come to look upon it as a dangerous pest. Dr. Jackson computed that in New York City it was the occasion of some 50,000 cases of sickness, of some 650 deaths from typhoid, and 7,000 deaths from diarrhea. We looked upon typhoid as an autumnal fever. If we counted back two months from the fall rise in typhoid deaths to the time when the disease was contracted, it would correspond exactly to the curve of prevalence of flies and to the curve of rise in deaths from diarrheal diseases of both children and adults. It was therefore erroneous to attribute these diseases to hot weather alone. Climatic conditions might predispose by reducing the vitality, but they were not the essential cause; temperature did not produce the specific germ—the casual agent—which invariably accompanied the disease. The activity of the house fly was in proportion to the temperature, and the times when this insect was most active corresponded exactly with the time of contraction of diarrhea and of typhoid fever. The body louse, it would seem, had possibilities of disease propagation beyond the pruritus and the local lesions it occasioned. An epidemic of relapsing fever had been related by Mackie in which the *Pediculus corporis* seemed a causative factor, and it was possibly also a factor in spreading typhoid fever. Among other disease-conveying insects considered in Dr. Huber's paper was the bedbug, which seemed to be associated with epidemics of smallpox. Tubercle bacilli had been found in the blood of the bedbug, and Metchnikoff believed that this insect formed an intermediate host, or at least an agent, for conveying intermittent fever, a disease very common in some parts of Russia.

Mr. Daniel D. Jackson, Director of Laboratories for the Department of Water Supply, said that during the Spanish war the fact was well demonstrated that flies took an active part in the dissemination of typhoid fever. His investigation had shown that of the cases of typhoid fever occurring in New York, about 30 per cent. were brought in from outside, and that the majority of all cases were due to the transmission of the disease through the medium of flies. In many sections of the city, the waterfront was strewn with fecal matter, and during the fly season these pests traveled back and forth from the wharves to the nearby residences, and thus they were a prolific source, not only of typhoid fever, but also of intestinal disorders in children. It could be demonstrated by a study of the statistics of the Health Department that deaths from these causes were most frequent in localities where filth and flies were most abundant.

The President, Dr. Robert T. Morris, said there was no doubt that many diseases were carried by insects, and he was glad to see that the subject was receiving the attention it did. In his surgical work he not infrequently saw phlegmonous lesions resulting from the bite of a flea or bedbug. If the streptococci and straphylococci were so readily transported by insects, there was no doubt that this might also be true of other bacteria. During one of his visits to the North, Dr. Morris said, he had gained a bit of information in connection with this subject which perhaps indicated that nature gave some compensation for what she did, and that the companionship of some of these insects was not always an unmixed evil. He had endeavored, during his travels, to instill some elements of cleanliness into his guides, particularly in regard to the body lice, with which they were infested, and he was told that the presence of these insects was a sign of good health. There seemed to be some evidence that body lice departed in the face of certain illnesses.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 17, 1908.

Dr. Herbert S. Carter in the Chair.

Cardiac Complications in Pulmonary Tuberculosis.—Dr. Lawrason Brown of Saranac Lake read this paper. He said that the position of the heart in patients with pulmonary tuberculosis depended directly upon the pathological changes that had taken place in the lungs, and the displacement of the heart was usually more pronounced when the right lung was affected, for the displacement was more often associated with contraction of one lung. When an extensive cavity formation had occurred on the right, when a pneumothorax or an effusion occurred upon the left side, when the right lung was the seat of fibrosis consecutive to pulmonary tuberculosis, or, as some affirmed, to pleurisy, the heart might be found entirely upon the right side. Meyer of Hoboken had three cases of dextrocardia, all in fibroid phthisis, two of which occurred suddenly. Pulmonary tuberculosis was probably by far the most fre-

quent cause of non-congenital dextrocardia, but this usually developed only when the left lung was slightly affected and was not bound down by pleuritic adhesions. Since Laennec announced that the heart was small in pulmonary tuberculosis many famous authorities had argued for and against this belief. Post-mortem observations were not entirely satisfactory for the solution of this problem, for some affirmed that changes in the heart could not be detected at necropsy, but surely the musculature was much more accurately measured. Dilatation of the heart occurred far less frequently than would be supposed, and, as was to be expected, late in the disease. The area of cardiac dullness was rarely changed in 1,289 patients at the Adirondack Cottage Sanatorium unless some valvular disease was present; in fact, all murmurs were classed as functional when there was no change in the area of cardiac dullness and when no definite cardiac symptoms were present. In 55 patients absolute cardiac dullness was noted as absent. A study of the hearts of these 1,289 patients showed that 65 per cent. presented slight variations from normal, while for the various stages of the figures were: Incipient, 63.5 per cent., moderately advanced, 64 per cent., and far advanced, 79 per cent. (only 24 cases). Functional murmurs were present in 6 per cent. of these 1,289 patients. Reduplication of the heart sounds had been rarely noted in the 1,289 cases. Irregularity of the heart action and the skip of the beat was infrequent in the early stages. The pulse in tuberculosis was a very valuable guide both for prognosis and in the regulation of exercise. Heart disease developing during pulmonary tuberculosis might be found in the order of frequency, in the pericardium, the endocardium, or the myocardium. Changes in the myocardium were not infrequent at autopsy but difficult to diagnose clinically. They were very rarely tuberculous in nature and consisted in fatty degeneration, fragmentatio myocardia, as well as hypertrophy of the muscle nuclei, brown induration, and interstitial myocarditis. Tuberculosis of the myocardium occurred about once in 1,000 tuberculous autopsies. It had little clinical significance and was practically never diagnosed except post mortem. The pericardium was said to be more frequently attacked in tuberculosis than the endocardium or the myocardium. In 1,300 patients at the Adirondack Cottage Sanatorium no symptoms suggesting pericardial involvement occurred except once. Tuberculosis ranked next to rheumatism in the etiology of pericarditis. Clinically endocarditis was found associated with pulmonary tuberculosis much more frequently than pericarditis, but at autopsy it was less frequent. In pulmonary tuberculosis it might be due to secondary organisms or to the tubercle bacillus. A history of rheumatism in tuberculous patients who presented signs of endocarditis was very common. He said he had no recollection of endocarditis developing in a patient with pulmonary tuberculosis. Thrombi of the right ventricle were rarely if ever diagnosed ante mortem. The great frequency of pulmonary tuberculosis made it probable that, other things being equal, a large number of patients with heart disease should have also pulmonary tuberculosis. In over 3,000 patients who had been closely followed for a number of years he had yet to see an instance where undoubted valvular disease developed in a patient with pulmonary tuberculosis. Mitral insufficiency was certainly the most frequent cardiac lesion in pulmonary tuberculosis. Stenosis of the mitral valve, far less frequent than insufficiency, had long been looked upon as antagonistic to pulmonary tuberculosis. Patients with mitral stenosis often did remarkably well. Aortic insufficiency was much rarer than many older authorities stated. In the 1,300 cases this lesion occurred twice. He had seen no instances of aortic stenosis. Pulmonary stenosis was rare. In summarizing, Dr. Brown said that pulmonary stenosis was always the primary disease, mitral insufficiency and aortic insufficiency usually the secondary. The most frequent cardiac lesion secondary to pulmonary tuberculosis in patients up and about was mitral stenosis. Pulmonary tuberculosis occurred more frequently in patients with pulmonary stenosis than in any other form of cardiac disease. Mitral insufficiency was associated with pulmonary tuberculosis more often than any other form of valvular disease, but aortic insufficiency was not very much less frequent. Aortic stenosis was rarely associated with pulmonary tuberculosis and pulmonary stenosis was infrequent in pulmonary tuberculosis. Involvement of several valves simultaneously was rare in these cases.

The Cerebral Complications of Ulcerative Endocarditis.—Dr. T. B. Futcher of Baltimore read this paper. During the past year he had under his personal care two very interesting cases of cerebral embolism complicating acute ulcerative endocarditis, and the subject matter of his paper was based chiefly on a summary of the main features presented by these cases, together with a brief analysis of the cases of cerebral embolism complicating acute or ulcerative endocarditis that had occurred in the wards of the Johns Hopkins Hospital since its opening in 1889. So far as he was aware, the only other cerebral complication of ulcerative or malignant endocarditis that occurred was a suppurative meningitis. The first case reported was of unusual interest owing to the rarity of the symptom complex. There was a condition of embolic or thrombotic obstruction of the posterior inferior cerebellar artery. Only about seven cases of this nature had been reported in the literature. As a result of the obstruction of this vessel the field of softening was always situated in the dorsal and lateral aspect of the medulla and always the same structures were more or less involved. These were as follows: (1) The lateral part of the reticular formation. (2) The descending root of the fifth nerve and its nucleus. (3) Gower's ventrolateral ascending tract. (4) The direct cerebellar tract. (5) The inferior cerebellar peduncle and the fibers going to it. The second case he reported was one which illustrated the type of cerebral lesion and group of nervous symptoms usually seen in embolism of heart disease, namely, blocking of one or other middle cerebral artery with a hemiplegia of the opposite side. The heart and brain were shown in this case.

The Clinical Features of Myocardial Disease.—Dr. Alfred Stengel of Philadelphia spoke on this subject. He said that every one must admit that there were many cases of myocardial disease that could not be recognized during life, and came to us as autopsical surprises. Again there were cases which, after the most painstaking care in making the examination, seemed to be cases of myocardial disease, but at autopsy were found not to be cases of myocardial disease at all. Notwithstanding these facts, a large proportion of the cases of myocardial disease was recognizable during life. In discussing the clinical aspects of myocardial disease he considered the question from two points of view: (1) of the heart itself and (2) of the individual pathological lesion. In regard to the first point, ever since Da Costa's and other papers had appeared the term "weak heart" had become a part of medical parlance. The condition of weakened heart might be due to a variety of causes, and was an expression of functional derangement. Weakening of the heart, or failure of the heart power, or chronic insufficiency of the heart, or hyposystolism, showed itself, in the first place, by symptoms more or less referable to the heart itself. These were often so vague that mistakes in

diagnosis were perhaps commonly made. The subjective symptoms were early expressions of this weakening of the heart muscle. As some put it, the myocardium began to resent the ordinary strains of life. He recalled the case of a man, sixty years old, who had curious attacks of pain referred always to the pyloric end of the stomach; the attacks usually came on in the middle of the night. Very hot water by mouth relieved him of these attacks, and he had accustomed himself to taking water at a very high temperature. After some study of this case he came to the conclusion that these attacks were primarily due to the condition of the myocardium. After careful observation and with but little medicine, this gentleman attained a better state of health. He was recently in the city and fell in with a friend of his, a physician, to whom he told his symptoms. This friend had surgical proclivities and urged him to have his gall-bladder explored at once. He consulted Dr. Janeway, who told him his trouble was situated more "northerly than the diaphragm." This gentleman kept his gall-bladder. These cardiac symptoms were referred to the pyloric end of the stomach; more commonly, however, oppression and weight were the earliest symptoms of myocardial disease. After the preliminary stages have been passed through, the patients began to show evidences of failing circulation. This was the mechanical result of failing heart muscle, when visceral manifestations occurred. Of the visceral manifestations hepatic symptoms were the most common. Enlargement or congestion of the liver often took place and might exist for a long time before evidences of failing compensation developed. Other peripheral lesions, such as occurred in valvular diseases, occurred in myocardial diseases, but were late in appearance. When one considered the failing circulation in the periphery in the form of cyanosis, or edema, or dropsical conditions, it was a fact that they occurred later in cases of myocardial disease than in valvular disease. Aside from the circulatory symptoms there were cases of myocardial disease in which the only symptoms were general in nature, such as nutritional and neurotic. He said he was convinced that nutritional and nervous symptoms and disorders were the earliest expressions in myocardial disease in many cases. Evidences of the cardiac condition might underlie failures in nutrition. He reported two cases of congenital defects accompanied by cyanosis, and said that there were many cases of myocardial disease accompanied with bad nutrition. The nutrition in cardiac disease was certainly to be studied and when interfered with in many cases first directed attention to the cardiac disease. With regard to the nervous manifestations, a neurasthenic condition had in many cases a cardiovascular basis for its persistence. There were a number of myocardial diseases which should be separated. First, he wished to consider myocarditis, pure and simple. Myocarditis had its origin in infectious diseases, or rheumatic fever, or some of the infections of later life. Myocarditis might also result from severe strains occurring in early life. Second, he wished to consider myocardial disease which was associated with sclerosis of the coronary vessels. Third, he wished to consider the degenerative conditions of the myocardium, such as fatty heart, and the fibroid changes which were associated with abdominal diseases. Another important condition to consider was syphilis of the heart muscle. Then there were a variety of other conditions, such as cardiac lesions following simple hypertrophy of the heart, or hypertrophies associated with nervous conditions, or in excessive alcohol drinkers, etc. In simple, or pure chronic myocarditis, there were the same symptoms that were said to be significant of a weakened heart in general. Often after typhoid fever there occurred a bradycardia; this was due to a myocardial weakness, an irregularity of the heart following an infection. The physical signs in myocarditis, pure and simple, were often distinct. The heart might reach to a great size. Quain had described the changes occurring in such hearts. In myocarditis there might be a notable enlargement of the heart. In many cases, of course, there was associated an hypertrophy of the muscle. In many cases of chronic myocarditis he said he had found an enlarged heart with inadequate apex impulse, as well as an inadequate wrist pulse. In the absence of fat about the heart, or pericardial effusions, or aortic stenosis, one usually considered a heart with a feeble impulse one that was significant of primary or chronic myocarditis. On the other hand, there was a type of cases in which the reverse of things occurred. Here the heart was enlarged, but instead of a feeble impulse there was a strong impulse. This was pointed out as being evidence that the heart muscle fibers were in a relaxed condition and gave a "slapping impulse" and there was a weakened condition of the heart muscle. There was much slack to be taken up, so to speak. With regard to the heart sounds, in pure chronic myocarditis, in the average case there would be prolonged vibrating first sound, which easily became "murmurish." Again, there was a group of cases associaed with sclerosis; these were associated with angina and gave paroxysms of asthma. These attacks did not occur spontaneously. The effect of exercise on the heart in developing an attack was the same as the effect of exercise of the leg muscles in developing cramps and weaknesses of the legs. The physical signs of myocardial disease associated with coronary sclerosis were not distinguishable from those occurring in myocarditis. Cases of idiopathic hypertrophy of the heart occurring in beer drinkers, in athletic persons, and other forms of chronic myocarditis resulting from prolonged overstrain, he believed could be recognized only by the general cardiac symptoms. When one studied cases of pure degeneration of the heart, this would be found to be one of the most difficult fields in diagnosis. A diagnosis of fatty degeneration of the heart, except as a conjectural diagnosis, was impossible. There was another form of degeneration of the heart he said he wished to allude to, *i.e.* a degeneration, fibrous in character, occurring in cases of fibroid tumors of the uterus and adnexa. A number of cases of sudden death had occurred after a myomectomy because of this condition of the heart muscle. There was considerable enlargement of the heart muscle associated with syphilitic disease of the heart. Dr. Stengel then took up the physiological consideration of cardiac action. Disturbance of heart rhythm might occur in various ways. There might be disturbances of rhythmicity; this was best shown in persons who were not particularly ill. Irregularity of the heart might occur when there were disturbances in conductivity of impulses from the venous sinus of the auricle, or when there were disturbances in contractility of the heart muscle. Two types of irregularity might be recognized. First, that type in which a beat of the heart occurred: then before the regular interval the second beat, followed by a long interpause. Second, that type in which a beat of the heart came at a time removed by twice the average space. This was the so-called extrasystolic space with compensatory pause. These extrasystolic spaces originated in the ventricle itself. In heart block the want of correlation between the auricle and ventricle did not necessarily depend upon any block in conductivity. There might be a partial block due to functional conditions. It had been shown that digitalis could produce disturbances of conductivity in the bundle, and so produce disturbances in rhythm. In the same category belonged toxic conditions and reflex disturbances, perhaps indirectly influencing the

cardiac mechanism. In conclusion he said that a distinct effort should be made to diagnose cases of either pure myocarditis, or pure myocardial degeneration, or even myocardial degeneration in association with arteriosclerosis.

Dr. W. Gilman Thompson, referring to Dr. Brown's remarks about the malposition of the heart taking place in the course of tuberculosis, said it was interesting to see how much malposition of this organ could exist without any special functional disturbances. A few years ago an interesting series of experiments were made at Bellevue by the late Dr. H. P. Loomis, producing an artificial pneumothorax with nitrogen gas in order to arrest disease in portions of the lung by compression. Nitrogen gas was used because it was not absorbed for a long time. When introduced on the left side Dr. Thompson had seen the heart move over to the opposite side in the course of twenty minutes or more and without producing any special disturbances or discomfort to the patient, and without the production of any dyspnea. In tuberculosis, when the displacement occurred, it was a slower process and gave rise to very little disturbance. With regard to heart disease and tuberculosis, he said there was a distinct relationship between cause and effect. Although many statistics appeared, he thought they should tell more about the patients and the possibility of the cardiac lesion antedating the tuberculous process. The statistics at Bellevue Hospital showed many more instances of heart disease in association with tuberculosis; these patients had been subjected to deprivations, were alcoholic, or syphilitic, and there were many other underlying factors which weakened the resisting powers of the patient, and so they acquired tuberculosis more readily. Dr. Thompson said he was particularly interested in Dr. Stengel's classification of the varieties of myocarditis. This was a very pertinent subject and one of the most difficult problems before them presented itself when called to see and diagnose an early myocarditis in a patient who had not been previously subjected to examination. Many patients came with an irregular heart, or with symptoms, subjective or objective, and the physician would be asked to decide the severity of it. There were seldom clinical symptoms which might not be simulated by toxic conditions in the early state. When there was an advanced arteriosclerosis the diagnosis was more easily established. But it was difficult to diagnose early myocardial changes, and to discriminate between a true myocarditis and toxic conditions. In the latter the cause might be due to too much alcohol, too much tobacco, or to autointoxication. A diagnostic factor was the improvement which followed the regulation of the habits of life in such cases. Another diagnostic factor was the accompanying phenomenon of thickening of the arterial walls in the presence or absence of nephritis or other diseases. But even in a very careful study of these cases one was often led astray. The age of the patient might be considered an aid. Bradycardia might result from a neuritis of the vagus, or from other causes. This was a matter of clinical debate and was not one of actual demonstration.

Dr. Alexander Lambert said he was particularly interested in Dr. Stengel's remarks. He believed that they could tell the cardiac condition by the sounds of the heart to a certain extent. In the hearts of those who had suffered from acute rheumatism or acute diseases like diphtheria, or other infectious diseases, he believed they would discover this gallop rhythm, and patients with such a form of myocarditis would have hearts going on to brown atrophy or other fibroid changes. In any severe illness he advised against considering subjective or objective symptoms, but they should listen to the heart and see if any myocardial changes existed. Test with the ear and see whether on any extra exertion the heart could stand the strain, and whether the patient was comfortable or not. But if after extra exertion there was distress, shortness in breathing, etc., then one must decide that there was a myocardial change which followed an acute infectious disease. In looking over the reports of more than 125 autopsies at Bellevue Hospital, he had not found a single instance where a normal heart was found in an alcoholic. Degeneration predominated in the great majority of the cases. The young silent heart was a good heart.

Dr. Henry Koplik said that diseases of the heart in adults differed very strikingly from diseases of the heart in children. The management of diseases of the heart in children seemed to be a field of work in itself. It was a rare thing to see a child suffering from myocarditis, pure and simple, such as was seen in the adult. Myocarditis was sharply divided in children into those instances complicating or immediately following acute infectious diseases of the heart. Syphilis, alcoholism, and arteriosclerosis were not met with in children as they were in adults. The heart symptoms following acute infectious diseases, such as were mentioned by Dr. Stengel, if present in children would be most serious. For instance, in diphtheria, swelling of the liver, pain in the stomach, vomiting, etc., made the condition a very severe one to deal with. In children the myocardial condition was a serious one. Dr. Stengel had mentioned swelling of the liver, which might exist for a long time, and yet the patient be comfortable; but in children this would make them face a very serious situation. Chronic myocarditis in children with symptoms referable to the liver was always serious. The nutritional disturbances mentioned by Dr. Stengel as occurring in adults must be a very rare condition in children.

Dr. Morris Manges presented specimens showing an acute ulcerative endocarditis and hemorrhage into the brain. Headache played the most prominent part in the case, and it was very natural to assume the presence of a pachymeningitis with hemorrhages. The patient was found one morning in coma. The left pupil was the size of a pin point, while the right pupil was dilated. There was a right-sided palsy and lack of tactile sense. At the base of the brain was found an enormous hemorrhage extending as far back as the cord and as far forward as the chiasm. The cut section showed the hemorrhage to be in the island of Reil and the right lateral vantricle was filled with clot. Two hemorrhages were demonstrated; the greater was in the island of Reil; this worked its way through the Sylvian fissure up to the middle line.

Dr. L. F. Bishop said a very important fact had not been mentioned by the speakers, that there were many symptoms that in the past were supposed to be due to myocardial disease, but in the light of studies of hundreds of cases were now known to be due to peripheral disease with reflex symptoms referable to the heart. A study of the peripheral circulation would often free the heart from any implication of myocarditis.

Dr. T. B. Futcher said that he knew of no instances of hemorrhage occurring in connection with ulcerative endocarditis, such as occurred in the case described by Dr. Manges.

Dr. Lawrason Brown said that among 1,300 cases there were but six of valvular disease, four mitral and two aortic insufficiency. In five cases the cardiac condition unquestionably antedated the pulmonary. There was nothing that led him to believe the tuberculous infection had anything to do with the production of the cardiac lesions. Five or six cases sent to the sanatorium with the diagnosis of pulmonary disease were really cardiac disease.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 21, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	499	148
Diphtheria	361	28
Measles	172	4
Scarlet Fever	157	5
Smallpox	—	—
Varicella	153	—
Typhoid Fever	66	6
Whooping Cough	38	2
Cerebrospinal Meningitis	6	5
Malarial Fever	—	—
Totals	1452	198

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the week ending November 20, 1908:

SMALLPOX—UNITED STATES.

		Cases.	Deaths.
Arkansas, Sulphur Rock	Aug. 25–Nov. 9	14	..
California, Cedarville	July 18–Nov. 6	5	..
San Francisco	Oct. 15–31	19	..
District of Columbia, Washington	Oct. 24–31	7	..
Illinois, Springfield	Oct. 22–29	2	..
Indiana, Elkhart	Oct. 24–31	3	..
Lafayette	Oct. 26–Nov. 2	4	..
Terre Haute	Oct. 31–Nov. 7	1	..
Kansas, Topeka	Oct. 18–24	1	..
Kentucky, Covington	Oct. 24–Nov. 7	2	..
Maine, Canadian Border	Nov. 8	12	
Montana, Butte	Oct. 20–27	4	
Ohio, Cincinnati	Oct. 23–30	1	..
Tennessee, Nashville	Oct. 24–31	1	
Stanton and vicinity	Sept. 10–Nov. 9	21	..
Washington, Spokane	Oct. 24–31	3	..
Tacoma	Oct. 18–25	1	
Wisconsin, Manitowoc	Oct. 24–31	2	..

SMALLPOX—INSULAR.

Philippine Islands, Manila	Sept. 19–Oct. 3	5	1

SMALLPOX—FOREIGN.

Arabia, Aden	Oct. 12–19	..	15
Ceylon, Colombo	Sept. 19–Oct. 3	38	10
India, Bombay	Oct. 6–13	..	2
Calcutta	Sept. 12–26	..	4
Indo-China, Saigon	Sept. 19–26	2	
Italy, General	Oct. 23–29	14	
Naples	Oct. 17–24	4	
Mexico, Veracruz	Oct. 24	1	
Peru, Lima	Oct. 19	8 cases in the lazaretto	
Russia, Moscow	Oct. 10–17	9	2
St. Petersburg	Sept. 26–Oct. 10	14	4
Spain, Valencia	Oct. 17–24	2	
Vigo	Oct. 17–24	..	1
Zanzibar, Zanzibar	Sept. 14–21	..	1

YELLOW FEVER.

Brazil, Menacs	Sept. 26–Oct. 3	..	2
Ecuador, Guayaquil	Oct. 3–10	..	1
Mexico, Veracruz	Oct. 27	1	..

CHOLERA—INSULAR.

Philippine Islands, Manila	Sept. 19–26	314	184
	Sept. 26–Oct. 3	67	33
Provinces	Sept. 19–26	1,122	745
	Sept. 26–Oct. 3	1,666	977

CHOLERA—FOREIGN.

Ceylon, Colombo	Sept. 19–26	2	..
China, Shanghai	Oct. 13–	..	Present.
India, Calcutta	Sept. 12–26	..	13
Rangoon	Sept. 26–Oct. 3	..	5
Indo-China, Cholen	Sept. 19–26	7	7
Japan, Moji	Oct. 22	..	Present.
Russia, St. Petersburg	Oct. 27–Nov. 2	142	80

PLAGUE.

Brazil, Maranhao, State	Oct. 20	..	Present.
Chile, Iquique	Oct. 6	1 case in the lazaretto	
Ecuador, Guayaquil	Oct. 3–10	..	1
India, General	Sept. 19–26	3,033	2,162
Bombay	Oct. 3–13	..	10
Calcutta	Sept. 12–26	..	12
Rangoon	Sept. 26–Oct. 3	..	2
Indo-China, Cholen	Sept. 19–26	9	8
Saigon	Sept. 19–26	12	9
Peru, General	Sept. 29–Oct. 7	28	16
Callao	Sept. 29–Oct. 7	1	1

OVERCOMING THE PREDISPOSITION TO TUBERCULOSIS AND THE DANGER FROM INFECTION DURING CHILDHOOD.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; VISITING PHYSICIAN TO THE RIVERSIDE SANATORIUM FOR CONSUMPTIVES OF THE CITY OF NEW YORK.

THAT there may be occasionally a direct bacillary transmission from the tuberculous parent to the child has been demonstrated sufficiently to permit of no further dispute. Yet the number of such cases is insignificant compared with the frequency with which a predisposition to tuberculosis in particular, and to other diseases in general, is transmitted to the offspring of a tuberculous mother or father. That this predisposition leads so frequently to a tuberculous disease can, of course, be easily accounted for by the many chances the child has of a post-natal infection as a result of the tuberculous environment it is forced to live in. The exposure to infection is, of course, greatest when the mother is tuberculous.

In the second portion of this paper we shall enter more fully into the details of exposure to post-natal infection during childhood. For the present we will devote our attention to overcoming the predisposition inherited from a tuberculous parent.

In what does this predisposition consist? It is a general enfeebled condition without a distinct pathological lesion, all the organs possessing perhaps less than the normal resisting power to the invasion of any disease. I believe the words physiological poverty are more than any others explicit of the condition of a child with a predisposition to tuberculosis and other diseases inherited from father or mother.

The child of a tuberculous mother, conceived and born while the mother is suffering with pulmonary tuberculosis in the advanced stages, has, of course, less chances for life and health than in cases where conception takes place in the incipient stage of the mother's disease. When both parents are tuberculous at the time of the conception of the child, the offspring is naturally more strongly predisposed to contracting tuberculosis. The predisposition is usually least marked in the earlier years of childhood when the mother was healthy and only the father tuberculous at the time of conception.

But whoever may be the tuberculous parent, father or mother, or whether the progenitors have been in the earlier or later stages of the disease, the overcoming of the predisposition to tuberculosis in infancy and childhood must begin with the child in utero. The mother who fears the transmission of a tuberculous predisposition to her child must throughout the child-bearing period live in the best possible hygienic environment, in the purest air obtainable, and, from the earliest recognition of her condition, refrain from the use of constricting garments. She should breathe deeply and often; in fact, she should take regular breathing exercises until the desire for deep breathing becomes natural with her. The kind of breathing exercises which a pregnant woman can take without any fear of harm in her condition, but which on the contrary will benefit her, are the following: She takes a deep inhalation and during this act raises her shoulders, rolls them backward and holds the breath for three or five seconds while in this position (Fig. 9). Then she exhales while moving the shoulders forward and downward. This exercise, which she can take from three to five times every half hour, she should, of course, practise in pure air, preferably near the open window or when outdoors.

While we will return to the subject of respiratory exercises later on, it might be interesting to note here the benefit which the lung of the mother of the future child will derive from deep breathing. Under ordinary conditions we never inhale or exhale more than about 500 c.c. of air, which represents the tidal volume, or tidal air. When we inhale deeply, we are able to take in 1,500 c.c. of air (complemental volume or complemental air), and about the equal amount of supplemental or reserved air can be expelled by making the expiratory exercises corresponding in effort to the inspiratory exercises. It must be evident that not only the respiratory, but also the circulatory system, in fact the whole organism, can be but benefited by such practise of deep breathing.

The living and the sleeping room of the pregnant woman should always be well ventilated and at least one window should be kept open in the bedroom even in cold weather. While it is hard to demonstrate that the fear so many people have of night air is indirectly responsible for a good deal of tuberculosis, I nevertheless believe this to be the case. Some people will sleep in a small bedroom, often several individuals together, with windows tightly closed, breathing the same air over and over again, and thus poisoning themselves with the toxic products of their own and others' exhalations.

It is difficult to write on the subject of tuberculosis of childhood without touching upon the social problem. How can the pregnant woman, obliged to labor in a factory, or workshop, often until the last few hours before her confinement, carry out the hygienic instructions just given which she should do in order to bear a child vigorous and strong with sufficient natural resisting power never to contract tuberculosis?

*Read before Section IV. of the International Congress on Tuberculosis; "Tuberculosis in Children; Etiology, Prevention and Treatment," A. Jacobi, M.D., LL.D., president, Washington, D. C., October 1, 1908.

There should be a law prohibiting work in unsanitary, dusty and badly ventilated environments for all people, but particularly for women and children. The pregnant woman should be obliged to cease work in a factory or workshop two months before her confinement and not be permitted to reenter until one month after her confinement and her complete restoration to health.

A typical description of such conditions where pregnant women work in factories until the very last moment can be found in Mr. John Spargo's book, "The Bitter Cry of the Children." Unfortunately, poverty compels them not infrequently to adopt most pitiful means to hide their condition so that they may not be discharged. Perhaps they do not fear so much the few weeks of absence which their condition demands. What they mostly fear is permanent discharge—"losing the job"—and then being obliged to hunt for another. But, as Mr. Spargo very tersely puts it, "the consequences are too serious alike to mother and child to justify legislative neglect."

That there is also a field for the exercise of the greatest humanitarian consideration on the part of the employer must be evident, and the philanthropists who will create an institution destined to succor during a few months after childbirth any family depending also upon the mother's earning, can rest assured that many a life will thereby be saved.

The newly born child is as much in need of pure air as the grown up person, and while in early infant life the system requires more warmth, the air the child is to breathe must be pure, free from dust and other impurities. The lying-in room and nursery should be well ventilated and their temperature well regulated. The atmosphere in such rooms should be warm enough, but never be too hot nor too dry.

As the young child grows, it should gradually become accustomed to cooler air. The habit of enveloping the child's face in a thick veil when it is taken out for an airing is absurd, and if veiling is used at all, it should be thin, permitting the air to have access to the face. As the child grows up attention should be paid to its breathing. It should be noted whether it breathes through the nose as it should, or whether the nose seems obstructed and it breathes with open mouth. It must be remembered that mouth breathing in children is a predisposing cause to frequent colds, to bronchitis and similar affections, all of which in many instances must be considered forerunners of consumption. Mouth breathing in children is caused, as a rule, by certain growths in the throat (adenoid vegetations) and sometimes by enlarged tonsils, or by polypi in the nose. Besides the deleterious influence on the child's respiratory system, adenoid vegetation may also result in difficulty of hearing, consequent impairment of the intellect and even in actual deformities of the jaw. Adenoids and all other obstructions to free breathing should be promptly removed by timely operations.

When a child, because of its delicate constitution, is susceptible to frequent colds so that one may hesitate to take it much outdoors, it should be borne in mind that fresh, pure air really does not give colds, and what are commonly known as colds are often an infectious disease due to a specific microorganism which fastens itself more readily on a delicate system. To overcome such so-called susceptibility to colds, one should resort to the judicious use of cold water.

From the tenth to the twelfth month one should accustom the child gradually to cold baths. The best time to begin is after its daily warm bath. Rub the child a few times with the hands dipped in cold water, and then wipe it rapidly. By and by one may begin with cold sponging, and later with a little douche. In the use of cold water it is absolutely necessary that the reaction should follow rapidly. This reaction, as is well known, is manifested by a pleasant warmth perceived by the child, and is made visible externally by a reddish appearance of the skin. Whenever cold water is applied to the skin one will notice at first a certain whiteness or pallor, which is caused by the contraction of the external blood-vessels. The return of the blood to the external surface causes the reddening of the skin. Whenever reaction is lacking or tardy, the advice of the physician should be sought.

Of course, it goes without saying that a child should always be properly dressed. In order that its lungs may develop to the fullest extent it must not be hindered by restricting garments, particularly not by tight neckwear (constricting collars and bands). Furthermore, it must be remembered that to dress the neck too warmly lessens the power to resist taking cold when there happens to be a change in the atmosphere. The less one is accustomed to bundle up the neck, the more freely will he breathe and the less will he be likely to take cold.

When a girl develops into a young woman, one should bear in mind that the tightly laced corset is one of the most injurious garments which can be worn. Not only is free and natural breathing interfered with by this article of dress, but indigestion and disturbances in the circulation follow excessively tight lacing. Anemia, or poverty of blood, so often observed in young girls, can very frequently be ascribed to this unnatural mode of dress, which does not permit either a free circulation or sufficient oxygenation of the blood.

I reproduce here three pictures, better to illustrate the result of excessive lacing. Figure 1 shows the

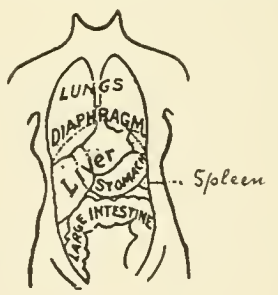

Fig. 1.

situation of the organs in chest and abdomen in a normal thorax. Figure 2 shows lungs, liver and intestines as they appear in a thorax constricted by wearing a tightly laced corset for a number of

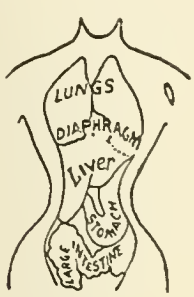

Fig. 2.

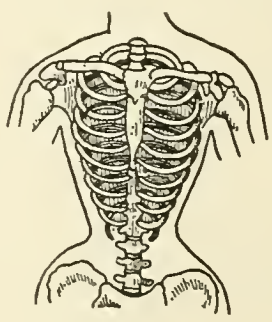

Fig. 3.

years. Figure 3 shows the skeleton of a chest deformed by tight lacing.

As soon as the intelligence of the growing child

will permit, it should be taught to breathe deeply, and later on be taught to take the following breathing exercises, which it should learn to love as the average boy or girl loves general gymnastics: In front of the open window, or out of doors, it should assume the position of the military "attention," heels together, body erect, and hands on the sides. With the mouth closed it takes a deep inspiration (that is, breathing in all the air possible), and while doing so raises the arms to a horizontal position (Fig. 4), remains thus holding the air inhaled for from four to five seconds, and while exhaling (breathing out) brings the arms down to the original position. The act of exhaling, or expiration, should be a little more rapid than the act of inspiration.

Fig. 4.—Exercise A.

The act of inhalation occupies about four, the act of exhalation about three seconds, and as has already been said, the act of retention of the air about five seconds. The child should be taught to count mentally during these three acts so as to be systematic about holding the air. One can give two upward and two downward movements of the wrist joints counting four, and on the fifth second lower the arms and begin to exhale.

When the first exercise (A) is thoroughly mastered one may begin with the second exercise (B). One places the arms one above the other, in front of the chest, giving the hands a position as though wanting to tear open the chest (Fig. 5).

Fig. 5.—Exercise B.

Then hands, arms, and shoulders make a backward movement (the fingers remaining bent) while one takes a deep inhalation, counting again four by tapping the chest four times with both hands, and at the fifth second one starts to exhale, bringing the hands and forearms into the position from which they started. This exercise has the advantage that it can be taken in the sitting position, or even when lying down on the back.

The third exercise (C) consists in raising the arms from the sides to the horizontal and then above the head (Fig. 6), taking a deep inhalation

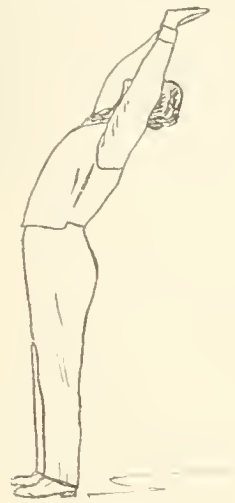

Fig. 6.—Exercise C.

during this act; then bending backward as far as one can and remaining in that position four seconds while retaining the air, counting the seconds by moving the hands alternately, twice forward and twice backward, and on the fifth second one exhales gradually while resuming the original position. During this exercise it should be borne in mind that when the arms are raised until the hands join, one should not bring the arms close to the head, but rather form a circle above the head by bending the arms outward enough so that the meeting of the index fingers and thumbs form a triangle.

The fourth exercise (D) is for the purpose of bringing the abdominal muscles also into play, or in other words, combining abdominal and chest breathing. To this end one assumes an erect position, like the beginning of all the exercises, with the hands meeting in front, with the little fingers and the edge of the palms touching the abdominal muscles (Fig. 7). While taking a deep inspiration raise

Fig. 7.—Exercise D.

the diaphragm, concentrating all attention on this act, and while doing so move the joined hands upward, sliding them along the thorax up to the chin, then turning them and continue to raise them until they are above the head, like Fig. 6. Bend backward

during the four seconds while retaining the air and then exhale lowering the arms gradually to the horizontal and to the original position of "attention."

The fifth breathing or respiratory exercise (E), which may also be called a dry swim, requires more strength and endurance. It should not be undertaken until the others have been practised regularly several times a day for a few weeks, and until an evident improvement in breathing and general well-being has been observed. One takes the usual military position of "attention" and then stretches the arms out as if in the act of swimming (Fig. 8),

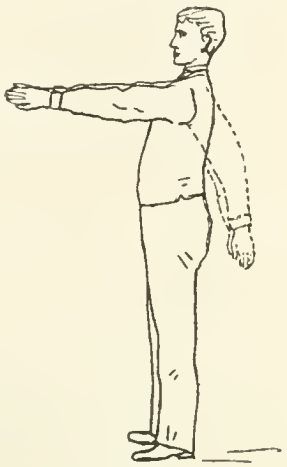

Fig. 8.—Exercise E.

the backs of the hands touching each other. During the inspiration one moves the arms outward until they finally meet behind the back; remaining in this position for the usual four seconds, counting by moving the hands while retaining the air, and on the fifth exhale bringing the arms forward again, ready to start for another swim; or if this is the end of the dry swim, the arms return to the original position of "attention." This somewhat difficult exercise can be facilitated and be made more effective by rising on the toes during the act of inhalation and descending during the act of expiration.

It will be seen that with the aid of these five respiratory exercises every muscle of the body, from the nostrils down to the toes, is put into play. The face alone is at rest and can serve as an indicator that the exercises are properly done, for it must be borne in mind that they must be taken

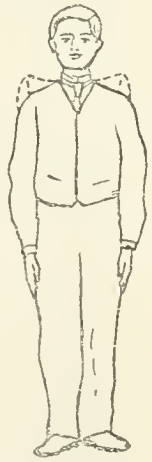

Fig. 9.—Exercise F.

with the muscular system relaxed and all unnecessary contraction of the muscles or tremor-like movements must be avoided.

Of course, when out of doors one cannot always take these exercises with the movement of the arms without attracting attention. Under such conditions one assumes quietly a position similar to "attention," raises the shoulders, making a rotary backward movement during the act of inhaling (Fig. 9); remain in this position holding the breath for four seconds, and then exhales while moving the shoulders forward and downward, assuming again the normal position. This exercise (F) can be easily taken while walking, sitting, or riding in the open air.

Young girls and boys, and especially those who are predisposed to consumption, often acquire a habit of stooping. To overcome this, the following exercise (G) is to be recommended. The child make his best effort to stand straight, places his hands on his hips with the thumbs in front and then bends slowly backward as far as he can during the act of inhaling (Fig. 10). He remains in

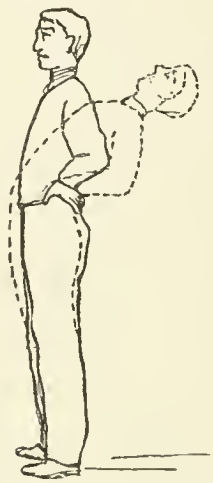

Fig. 10.—Exercise G.

this position from four to five seconds while holding the breath, and then rises again somewhat more rapidly during the act of exhalation, assuming the original position with hands on hips.

The following general rule concerning breathing exercises should always be remembered. Commence with the easier exercises (A), and do not begin with the more difficult ones until the former are completely mastered. Take from four to six respiratory exercises (one of A, B, C, D, E, or F), or when outdoors simply exercise F, four to six times every half hour or hour, or at least four to six times a day and on rising in the morning and retiring at night. Continue this practice until deep breathing has become a natural habit. These exercises should always be taken in an atmosphere as fresh and as free from dust as possible. Never take these breathing exercises when tired, and never continue so long as to become tired.

These exercises are, of course, destined for children who are not as yet tuberculous, and they should be taught gradually and according to the strength, development, and understanding of the child. It must be evident that these exercises, which I believe are of incalculable benefit as a means of helping a child to overcome a tuberculous predisposition, are not indicated in all cases. They can do harm if the child is very delicate and not judiciously advised and guided in the gradual development of its physique in general. They will never be harmful in the healthy child if not overdone. Children as a rule take kindly to these exercises, and their love for fresh, pure air and distaste for foul air becomes very strongly developed. There should be no fear that in so-called flat-chested children these exercises can do harm. It is in these

very cases that breathing exercises are indicated, for it must be remembered that in young children the bony structure yields to the pressure exercised from within. Thus with the aid of such respiratory exercises a flat or hollow-chested child can develop into a strong broad-chested man or woman.

It is for all these reasons that I plead to make breathing exercises a regular and frequent practice in all schools, so as to develop all the children's chests and bodies in general and make their systems as resistant as possible to the bacillus of tuberculosis. As will be seen from the careful study of the movements described in these exercises, all the muscles of the body are exercised, and without any violence.

As an additional means of developing the lungs of children, particularly in school children, we cannot too strongly recommend the frequent practice of singing and recitation in the open air. Many careful observers have noticed the value of such exercises, but particularly Barth, in Koslin (Germany). He has made a careful study of the effects of singing on the action of the lungs and heart, on diseases of the heart, on the pulmonary circulation, on the blood, on the vocal apparatus, the upper air-passages, the ear, the general health, the development of the chest, on metabolism, and on the activity of the digestive organs, and has come to the conclusion that singing is one of the exercises most conducive to health. Considering the fact that it can be practised everywhere (where the air is pure) or at any time, without apparatus, it should be much more cultivated than it actually is. The German military authorities, who have the reputation for instituting all exercises which tend to invigorate the soldier, have of late years encouraged singing during marches of all troops. Visits to zoological gardens, botanizing tours, geological excursions, and mountain climbing should form an important part of the curriculum throughout school life. They will tend to develop the pupils' physique and strengthen their resisting power to the invasion of the tubercle bacilli. These outdoor instructions should not be limited to the summer season only.

Besides the above described exercises there is one more which the older child particularly, after having learned all the other movements, can add to his means of developing his chest by taking in the greatest possible amount of pure, fresh air. To this end he takes exercise H, which is accomplished in the following way: He takes the usual position of "attention," then inhales deeply, rolling the shoulders upward and backward, holding the air for four seconds, as in exercise F (Fig. 9), and on the fifth second exhales all he possibly can, resuming again the original position, but before again inhaling makes a second expiratory effort while turning his arms outward (movement of supination) and pressing the inner side of the upper arms against the chest (Fig. 11). He thus, so to speak, squeezes out all the air there is left in the lungs. A vacuum, or emptiness, in the lungs is created and the patient involuntarily takes a very deep inhalation, and after that assuming the ordinary quiet position of "attention."

To show the value of this exercise let me again repeat here that during ordinary inhalation and exhalation, that is to say, quiet respiration, the amount of tidal air inhaled is only 500 c.c., the volume which can be inhaled by the first exercise is 1,500 c.c., and the volume which can be exhaled by this exercise is about 1,300 c.c. When now by the second expiratory effort, aided by the supination of the arms and pressure against the chest, 500 c.c. more of reserved or residual air can be expelled, the value of this exercise taken before going to work, at recess, and on return from work, or whenever one is environed with fresh, pure air, must be evident.

The fact that in the majority of cases the tuberculous process begins at the apices (summits of the lungs) has been explained by the supposed bad inspiratory function of this part of the lungs. Now, I agree in this respect with Hanau* and consider the almost universally adopted statement of the deficient inspiratory function of the apices erroneous. On the contrary, these portions of the lungs inspire excellently well, almost too well, for dust and all sorts of microorganisms enter there most easily and are found in large quantities in careful postmortem examinations. What is faulty is the expiratory function of the apices. A thorough exhalation followed by a forced expiratory effort, as just described, is, to my mind, the only possible way to improve this defect and prevent stagnation and congestion, which, as is well known, form excellent media for the development of bacilli.

If it would need any argument to prove the value of a well developed chest and deep frequent respiration of good, pure air, we could refer the doubters

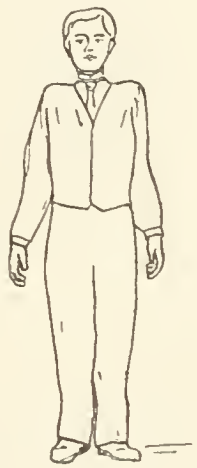

Fig. 11.—Exercise H.

to the statistics which prove that mountaineers all have deep, well developed chests and are the most immune to tuberculosis of all people. While, of course, it must be taken into consideration that the mountaineers live as a rule in less crowded regions, there is no doubt that their wonderful chest development is one of the principal reasons of their relative immunity from tuberculosis. In the mountaineers it is the physiological effect on the human body of high altitudes. The circulation is slower, often below the normal in those living constantly in the mountains, and their breathing is deeper, the inspiration longer and the expiration more complete.

That through proper breathing of outdoor air and good, sensible training, proper and regular feeding a child from tuberculous parentage needs never to develop tuberculosis must be evident. However, this is not merely a matter of belief with me, but has become an absolute conviction based on experience. I began my medical career over twenty years ago in Southern California in the city of Los Angeles. It was at that time a small city inhabited by a great many consumptives who had come there hoping that the climate would restore them to health. I was privileged to treat a goodly

*Hanau, A., Zurich: "Beitrage zur Pathologie der Lungenkrankheiten," *Zeitschr. f. klinische Medizin*, XII., 1887.

number of these patients. Some got well, some improved, and some died; but what was most interesting to me was the following observations: A number of patients brought their little children with them and some had children after their arrival as consumptive invalids in Southern California. That these parents transmitted to their children a predisposition to tuberculosis was evident. I merely practised the principles which I have just given, and it was my privilege to see many of the children develop into good, strong, healthy men and women.

In order to give the child the greatest possible opportunity to breathe fresh, pure air, and the best chances for physical development, other things must, of course, be done besides teaching the child to breathe properly. First, the child must have more years of play. A child should not go to school before its eighth year. Throughout its child life it should have more hours of sleep than most children have, and child labor should, of course, be done away with as incompatible with the solution of the tuberculosis problem. There should be more playgrounds. Every roof of a tenement house should be transformed into a playground. With the help of a good, strong wire fencing and awnings such a roof garden could be utilized the greater part of the year and for children of all ages.

Children's school farms, such as are conducted in New York under the admirable directorship of Mrs. Henry Parsons, should be multiplied by all large and small cities. Such a farm, particularly when located in a congested district, does both preventive and constructive work. The child predisposed to tuberculosis, when it has an opportunity to spend the greater part of the day doing gardening work, learns to love outdoor life and outdoor pursuits which, of course, is of the greatest advantage to its future physical welfare.

Outdoor games and temperate athletic sports should be encouraged not only in colleges, but in children's schools everywhere, and outdoor games and light sports should not be limited to the male sex alone, particularly not during adolescent life.

After the child has gone through school, and even when it has seemingly overcome its predisposition, it is well to bear in mind the possibility of a relapse into such a condition through an unwise choice of profession or calling. An occupation or profession demanding a sedentary life and exposing the individual to the inhalation of vitiated air and much organic and inorganic dust, is unsuited for anyone who is or was once predisposed to tuberculosis.

Concerning the prevention of post-natal infection, we must, of course, first think of the infection from tuberculous milk. To this end we must first prohibit the tuberculous mother from nursing her child, and secondly, see to it that the artificially fed child is provided with milk absolutely pure and absolutely free from tuberculous germs and other pathogenic microorganisms.

I will not enter here into the discussion of which method, wholesale sterilization or dairy supervision and milk inspection, is the most secure. In individual cases it would seem that proper sterilization is the safest method of rendering the milk germ-free. It goes without saying, of course, that under such circumstances a healthy wetnurse is the ideal for a child which has come into the world physiologically impoverished.

The most frequent sources of post-natal infection are perhaps the following: The consumptive mother or nurse caresses the child and kisses it on the mouth; she carries the child on her arms, coughs over it, and a drop infection from a bacilliferous spray ensues. She prepares the food, testing it to judge its temperature and flavor through the same rubber nipple or with the same spoon the child uses, and thus unconsciously conveys the germs of her disease from her own mouth to that of the child. Later on the child will play on the floor of the room, and should there be a consumptive in the family, who from carelessness or ignorance is not careful in the disposal of his expectoration, the child is indeed likely to be infected. The little one while playing on the floor may with great facility inhale the bacilli floating with the dust in the air and can thus acquire tuberculosis by inhalation, the full development of which may only take place in later years when the origin will not be thought of. Again, the little child touches everything it can take hold of, infecting its fingers thoroughly, and by putting them in its mouth tuberculosis by ingestion may result and gradually develop into consumption of the bowels. Lastly, should the child's nails be neglected it may scratch itself with the infected fingers, and thus inoculate its system with the disease. Tuberculosis of the skin, or lupus, may result from such an unfortunate accident.

To prevent these infections during childhood is certainly possible by taking the following precautions: Not only should consumptives be religiously careful with their expectoration, but they should associate as little as possible with young children, and stay away from playrooms and playgrounds. We repeat that to kiss children on the mouth should never be allowed, and the little ones should be taught never to kiss nor be kissed by strangers. They should be kissed by their own friends and relatives as little as possible, and then only on the cheeks. The floor on which the child plays should be kept scrupulously clean. Fixed carpets in such a place are an abomination; they only serve as dust and dirt collectors, and not infrequently harbor the germs of contagious diseases. The hands and nails of little children should be kept as clean as possible.

Expectorating on playgrounds should be considered a grave offense and should be punished accordingly. These playgrounds should be kept clean, as free from dust as possible, and strewn daily with clean sand or gravel.

At school the child may contract an ingestion tuberculosis from partaking of half-eaten fruit from its tuberculous fellow pupils, or by the exchange of bean-blowers, musical mouth instruments, or chewing gum.

Inoculation of the child with tuberculosis, even if it is not predisposed, happens in rare instances through ritual circumcision. I have been able to collect about twenty authentic cases; but the surgical literature of all countries, where Israelites practise this rite in the orthodox way, continue to contain reports now and then of cases of tuberculous infection through this mode of circumcision. The tuberculous inoculation following this operation manifests itself first as a local disease of the genital organs, whence it becomes generalized in a great number of cases. The operation of circumcision, when skilfully and carefully performed, is in itself trifling, but the sucking of the prepuce afterwards makes it dangerous, for it is evident that if the operating rabbi should be consumptive, inoculation becomes very possible. Since it will be difficult to stop this practice by a simple protest on the part of physicians, and as the law cannot interfere with the free exercise of a religious rite, I should suggest as a remedy that only such persons should be allowed to perform circumcision as have shown the

necessary skill before a medical board of examiners, and that every time they are called upon to perform the rite, they should submit themselves to a medical examination. Only when bearing a certificate from a regular physician, stating the absolute freedom from specific diseases, should they be allowed to perform ritual circumcision. Another reliable measure against the possibility of inoculating the child, when the parents insist upon the orthodox method of circumcision, is suction by the aid of a glass tube, as practised in France and Germany.

I feel it a duty to mention here another source of exposure of the non-tuberculous child to tuberculous infection to which benevolent societies and municipalities should pay attention with a view to avoiding it. There is in some cities a custom of giving the infant foundlings who do not improve in hospitals, to homes in the country. There those children are taken care of by families who are of good repute but in moderate circumstances. The authorities who send babies there, as a rule, never ask who is going to take care of the baby. In many instances an invalid who not infrequently is tuberculous is entrusted with this caretaking Rarely is he intelligent or overconscientious, and thus that he will give tuberculosis to the little child in his care is almost inevitable.

I cannot conclude this too meager treatise on so important a subject without mentioning here a purely philanthrophic scheme intended to overcome the predisposition which a child may have inherited from its tuberculous parents. My late and much regretted teacher, Professor Grancher, of Paris, inaugurated some years ago, by his own and Mme. Grancher's magnificent gift of several hundred thousand francs, a movement which he called "l'Œuvre de preservation de l'enfance contre la tuberculose." As the name indicates, it means to protect the children from becoming tuberculous. This society, through its agents, selects children from tuberculous parents and, with their consent, takes the children to homes in the country where they are carefully supervised and watched by the society's agents. The very best of food and outdoor life and good home hygiene is secured for the children and the society's reports for the last few years certainly show that the work is truly a work of preservation of life and gaining of health and strength which is after all the best immunity against tuberculosis.

It is to be sincerely hoped that Grancher's work may find emulators in this country and all over the world. It should be the rule in private, dispensary and hospital practice to insist upon the examination of all children of tuberculous parents.

The examination for tuberculosis or tuberculous predisposition of all children entering public, parochial or private schools and the periodical reexamination for tuberculosis should also be made a feature of an intelligent and thorough tuberculosis campaign. It is only by such means that the predisposed child can be easily discovered. The more attention we pay to avoiding tuberculous infection during childhood, the more carefully we study the early recognition of a condition predisposing the child to consumption, the more we direct our energy and whatever skill and knowledge we may possess to this end, and the more we interest philanthropic friends in the cause of overcoming this tuberculous predisposition, the greater are our chances for ultimately eradicating the disease in the adult and thus becoming complete masters of the great white plague.

TRUE NEURASTHENIA—ITS NATURE AND TREATMENT.*

By A. D. ROCKWELL, M.D.,

NEW YORK.

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL, ETC.

THERE is a true and false neurasthenia, as there is a true and false malaria or a true and false neuralgia.

The term neurasthenia is a convenient refuge in diagnosis. It is easy for the physician and most satisfactory to that large class of patients who eat too much, exercise too little, and who are simply poisoned by the unassimilated products of digestion. These people are pleased with a diagnosis which touches the nerves rather than the bowels and liver and having been duly certified to as neurasthenic ever after with a conscious air allude to themselves as the victims of nervous exhaustion. While protesting against the too indiscriminate diagnosis of neurasthenia, I am yet a firm believer in the propriety of classifying under this head a great family of symptoms. True neurasthenia is of perennial interest, for of all so-called functional diseases, it is to my mind one of the most important, because of its power to wreck completely the life of a man, the persistency of its symptoms, and the frequent futility of methods adopted for its relief, due mainly to mistaken ideas as to its nature and course. Volumes have been written about it, and if it be asked why still further discuss the subject, I reply, that until the profession at large have a truer appreciation of the reality of this condition, and get a better understanding of its philosophy, it will always deserve the freest discussion.

I have known patients to consult physician after physician without receiving any satisfactory diagnosis or advice, getting the first glimpse of the truth through a book picked up in the office of some physician or a stray issue of a medical journal. Or if told that he has neurasthenia it is in a flippant offhand way as if it was a thing to be lightly spoken of, to be taken as a half joke, instead of a reality so terrible as not infrequently to impel the unfortunate victim to choose for himself social ostracism.

One of the astonishing things in connection with neurasthenia is the infinite variety of symptoms of which patients complain. The sum total of these symptoms are by no means to be found in any individual case, but they exist, and he who comes in contact with, and studies many neurasthenics, will become familiar with them all.

Many years ago when Beard was issuing those remarkable articles which have become classic and which became and still are the inspiration of all investigations along this line, a distinguished physician remarked to me that according to Beard, if a man did but yawn or sneeze, or eructate a little wind, he had neurasthenia. And yet it is not difficult to reconcile one's self to these varied symptoms, and the explanation seems simple enough, in consideration of the probable pathology of the disease. The rapidity with which nervous force is exhausted makes possible an infinite variety of symptoms, since this exhaustion is not confined to any one center of organic or functional life, but may simultaneously or in succession influence remote centers of motor, sensitive, and emotional activity. Symptoms such as insomnia, mental depression, morbid fears, general motor enfeeblement, gastrointestinal atony, and impotence are very frequent, and many, if not all of

*Read before the Medical Association of the Greater City of New York October 19, 1908.

them may be combined in the same person. It is most important to distinguish between hereditary and acquired neurasthenia.

While a very considerable number of cases are found where the most careful inquiry fails to find any special ancestral nervous defect; yet in the majority of cases there is an undoubted hereditary tendency. Severe and prolonged mental and physical distress, acting on a nervous system endowed with normal strength, is not readily influenced to its permanent detriment; on the other hand, irritations absurdly slight, may powerfully influence nerve tracts inherently weak from any cause. The forbears of the hereditary neurasthenic may have been quite free from neurasthenia as we now understand it, but it will be found that there is a history of one or more of many neuropathic conditions such as epilepsy, hysteria, alcoholism, insanity, etc.

Indeed, when there exists a strong nervous heredity, neurasthenia may develop absolutely without any apparent exciting cause, and what is exceedingly rare in acquired neurasthenia may develop even at puberty. One seldom, if ever, sees a case of neurasthenia before the age of 25 where the heredity is good. It takes years of evil indulgence to wreck the nervous system in a strong person, and therefore most men with acquired neurasthenia are considerably older. Neurotic instability of the hereditary type is therefore the most important and frequent factor in considering the etiology and prognosis of neurasthenia. In the organic psychoses we see this hereditary instability playing an equally important part. Embolisms and thromboses of slight character and small tumors may occasion mental alienation of the most pronounced type, while in stronger physical conditions tumors of considerable size, and areas of softening may influence the mind but slightly. The effect of alcohol in different people is largely a question of nervous stability. With some, perceptible stimulation is excited only after a large amount, while with others the effects of the smallest dose becomes quickly apparent. The same susceptibility of the neurasthenic is noted in the use of various drugs.

Hysterical women are often spoken of as neurasthenic. Hysteria is not neurasthenia, and one meets with true neurasthenia in women far less frequently than in men.

Hysteria is a kindred condition but by no means the same condition, and one interesting differential point between neurasthenia in man and hysteria in woman is the difference in the degree of susceptibility to stimulation. A typical neurasthenic is as a rule more than ordinarily susceptible to alcohol, while an hysterical woman can usually greatly exceed the normal amount without perceptibly feeling its effects. Hysteria in women is undoubtedly often caused by uterine disease, but it is not probable that the nervous system in these cases is influenced in the same way as is the nervous system of man by sexual excesses. The work of the gynecologist is most important and valuable, and perhaps indispensable in many of these cases, but it is coming to be more and more understood that many cases of slight uterine and periuterine disorders in the young and unmarried should not be subjected to local treatment. Very many cases of disordered menstruation and uterine and ovarian pains are due mostly to causes that are constitutional and general, and local treatment can be of little avail.

On the contrary when the mind of the patient is constantly directed to the generative organs by the treatment of unimportant local conditions, it is conceivable that by a sort of autosuggestion the whole nervous system is made to suffer. On the other hand, with the graver forms of uterine disease we seldom see associated this peculiar instability of the nervous system that we call hysteria. The symptoms of neurasthenia and the exciting causes of these symptoms are too many to enumerate in a brief article. Of the causative factors—one only, and that the most important, do I wish to emphasize. I refer to sexual excesses—especially among the unmarried. Men who are married and are faithful to the vows of marriage rarely tend to excess in the long run. But with both married and unmarried who habitually indulge in irregular sexual relations the case is widely different. In the marriage relation as time goes on, the tendency more and more is to satisfy only a normal call of nature. He, however, whose relations are with strange women, changing from one to the other as caprice and passion dictate, enters into a realm of psychic excitation to which he must ultimately succumb.

Naturally, it is among the hereditarily weak that such excesses work the greatest havoc, and although the nervous system of the hereditarily strong is often a veritable fortress against the assaults of the most excessive dissipation, yet, sooner or later nature's reprisals are inevitable. "The mills of the gods grind slowly—but they grind exceed fine."

In regard to what is termed traumatic neurasthenia, I am more and more of the opinion that it is not a special neurosis distinct from the ordinary form of neurasthenia. In a way, all neurasthenia is traumatic. Profound mental disturbance, or the physical abuse of function, are just as surely blows as are physical strokes.

The one overmastering symptom, of symptoms innumerable, associated with the neurasthenic state, is morbid fear. What is rudimentary and natural in the healthy man, becomes in the neurasthenic, abnormal and monumental. Little by little because of his feeble powers of resistance, these fears dominate his life, gradually destroying the results of years of health and education.

And in the same way as one seldom sees hysteria associated with serious uterine disease, so one seldom encounters neurasthenia with its morbid fears in those suffering from grave organic disease. These phobias in their peculiar manifestation are pathognomonic, and it would be impossible for a malingerer to deceive long one thoroughly familiar with neurasthenic cases.

Agoraphobia (fear of open places), claustrophobia (fear of narrow, closed places), mysophobia (fear of contamination), monophobia (fear of being alone), anthropophobia (a generic term including fear of society) and gynephobia (fear of women) are only a few of the numerous phobias that to the uninitiated appear simply ridiculous, but to the unhappy victim are of fearful consequence, destroying both happiness and hope.

Treatment.—Shall a neurasthenic work or rest? Many a neurasthenic has been made worse by the rest cure, and again others have suffered by a continuance of work. In no condition is there more need of an intelligent differentiation. If there is cerebral excitement associated with physical exhaustion—rest is imperatively demanded. Rest is also to be recommended in cases of the myelasthenic type. For cases of the lithemic type—hearty eaters, who suffer from autoinfection, and whose frequent irritability and unreasonable outbursts of temper differentiates their case from the mild melancholy of the neurasthenic of an entirely different type, work and activity and plenty of it is oftentimes the saving grace.

Drugs.—Success in treatment frequently follows very little active medication, and yet at times judicious drugging is distinctly called for. While the patient is undergoing the slower process of encouragement and physical methods of treatment, it is good judgment at times and in certain cases to soothe and sustain a weak and erratic nervous system by such drugs as seem best fitted to the case in hand. In those cases where occasional medication seems to be demanded, some one of the various bromides including the bromide of zinc, either alone or in combination with belladonna—cannabis indica, etc., according to individual idiosyncrasies, serve a useful purpose.

Physical Therapeutics.—Of all physical methods of treatment I place the electrical first and regard it of the most positive value in the treatment of neurasthenia. Others and perhaps the majority do not regard it so highly, but those who would look with disfavor upon it have not, I fancy, taken off their coat, as it were, and given it a thorough and systematic trial. I have done this for many years and in a very large number of cases and my experience teaches me that no single remedy quite equals electricity. I say single remedy, yet it is really many remedies in one, for so numerous are its manifestations and so varied are its physical and physiological effects, that for all practical purposes we may say that we have many kinds of electricity.

What is lacking, therefore, most frequently to make good use of this great agent is the power of intelligent differentiation. An anomaly about a neurasthenic is that generally he appears to be well nourished. His functions are often well performed and his appetite excellent. Yet with all this we find him with a nervous system so eratic and unstable that the slightest influence is sufficient so to disturb the vasomotor equilibrium as to cause general nervous disturbance as manifested in the quickly flushed face, perspiring hands, dizziness and perverted vision.

As its name implies, neurasthenia is a disease of exhaustion and therefore of impaired nutrition, and electrization, not in one form alone, but in many forms, aids powerfully in the restoration of perverted cellular nutrition.

Phototherapy.—The influence of light and heat I have often found useful in neurasthenic cases. Fundamentally the principles on which are based the therapeutics of light and heat are very much the same as govern the application of other physical methods of treatment, and in the toxemias and the toxic neuroses the therapeutic value of light energy is beyond question. Both the incandescent and the electric arc light are valuable—the latter perhaps more than the former, since in addition to its calorific and luminous effects it imparts chemical activities of a distinctive character.

Mental Therapeutics.—While neurasthenia is no imaginary disease and no appeal to the imagination alone will overcome the profound loss of nerve tone characteristic of it, or rearrange the delicate fibrillary connection of the neurons that may have been disturbed by the constant impact of physical forces, yet mental therapeutics is without doubt an important factor in many cases. I hold that if a physician has not time or inclination to do more than drug his patient or give him the ordinary office advice and treatment, he is not quite fitted to take charge of many a case of neurasthenia. To a certain extent he should associate with his patient and by his personal presence and encouragement reinforce his feeble and wavering will.

Let me illustrate. It is quite unnecessary to tell anyone who is familiar with such cases that gynephobia (fear of women) is one of the most unnerving and distressing of all the phobias. In a patient who thus suffered to the last degree, who avoided all female society, and if he chanced to meet a lady acquaintance face to face in the street became almost paralyzed, I determined as usual on a direct method of attack. I suggested that he go with me to a department store and buy something of a saleswoman. He replied that it was impossible, but agreed to go. We walked from counter to counter, the patient suffering undeniable and uncontrollable perturbation, as evidenced by his clenched and perspiring hands, flushed and perspiring face. He finally accomplished his purpose, although avoiding the eye of the saleswoman, and then with a sigh and sense of relief, turned and asked if he had not done well. Alone and unaided he could not possibly have accomplished his purpose.

This patient is now fairly well, and I attribute his recovery as much to the personal influence that steadied his morale as to any other method of procedure. In every way the physician should treat his patient with respectful and sympathetic consideration, and while recognizing his infirmities assure him in no uncertain tone that he is by no means incurable. This he can honestly do, for in the observation of hundreds of these sufferers I have seldom met a case that I have kept track of that did not finally respond to time and treatment.

616 Madison Avenue.

THE ULTRAVIOLET RAY AND HIGH FREQUENCY CURRENTS IN NEURASTHENIA.*

By SINCLAIR TOUSEY, A.M., M.D.,

NEW YORK.

The ultraviolet light is present in sunlight, but only in small amount, because the greater part of this chemically and physiologically active radiation is absorbed by the dust and vapors in passing through the earth's atmosphere. This may partly account for the greater tendency to sunburn and to injury to the eyes resulting from overexposure to the reflected light upon mountain snow fields which are above the densest part of the atmosphere. It may also partly account for the benefit experienced by neurasthenic patients at mountain sanatoria like St. Moritz. The ultraviolet ray is produced electrically in much greater concentration than it is convenient to obtain it from natural sources. When produced by electricity its use in neurasthenia may be divided into two separate methods. First—it may form part of the combined heat and light radiation applied in local or general electric light baths; and, second—it may form according to the author's view the essential factor in several different applications of high frequency currents.

The arc light is richer in ultraviolet rays than the incandescent light and hence is preferable when practicable. The incandescent light is so much easier to handle that it is often selected for this purpose. The effect of electric light baths is due only in part to the ultraviolet rays, all of which are absorbed by the skin, producing a general tonic effect, but without a direct action upon any vital organ. More active agents in the effect of electric light baths are the visible rays, some of which penetrate considerable thicknesses of tissue and stimulate the processes of metabolism in the blood and lymph as well as in the solid tissues.

Another and perhaps the most active factor is

*Read at a meeting of the Medical Association of Greater New York, October 19, 1908.

that of radiant heat—an agent which with light, air, food, and water is essential to animal and vegetable life. It is a mistake to suppose that the air in the electric light bath need be at an uncomfortably high temperature. The room or cabinet may be freely ventilated without impairing the beneficial effect of the radiant heat and without materially lengthening the time required to produce the characteristic physiological effects of profuse perspiration and dilatation of superficial capillaries. Such an application eliminates some of the products of auto-intoxication so commonly present in neurasthenia. It is followed by refreshing sleep, and this effect may be favored by such additional applications as a cold bath or massage.

We come now to the ultraviolet ray in connection with high frequency currents. The oxygen of the air may be changed into ozone; a very unstable and, therefore, chemically a very active form. This change is most readily produced by the passage of electric sparks through the air, but only in the presence of the ultraviolet ray. Accordingly, we find that the richest production of ozone occurs in connection with electric discharges which generate the greatest quantity of ultraviolet ray. Leyden jars charged by a static machine or by an induction coil form part of the apparatus designed to give high frequency discharges which are wonderfully efficient in this regard. Glass vacuum electrodes are employed for applying these discharges directly to the surface of the body, and the odor of ozone may sometimes be detected the following day. The effect is heightened if the electrode is held at a little distance from the surface and thousands of tiny violet-colored sparks traverse the air covering the skin. This intensification is also obtained if the glass vacuum electrode is applied over thin clothing.

The ozone generated in this way penetrates the tissues and produces an effect upon the solids and liquids which make up the body. This effect is the usual one of nascent oxygen, viz., to increase the rapidity and favor completeness of oxidation. In some cases nitrogenous substances are incompletely oxidized and are found in the urine as an excess of uric acid and the same irritant substance is deposited in the region of nerves and joints. Ozonization of the tissues by high frequency currents and the ultraviolet ray favors complete oxidation and the elimination of nitrogenous substances as urea.

Autointoxication by other products of imperfect metabolism is relieved by the same application, not perhaps so much by a direct oxidation as by a stimulant effect upon the tissues which results in normal activity.

The ozonizing effect of the application of vacuum electrodes is practically the same, no matter what particular form of high tension generator is used to excite it. To this extent the static machine, the Rhumkorff coil, the Tesla transformer, and the d'Arsonval and Oudin high frequency apparatus produce similar results.

It is necessary to apply the glass vacuum electrode over a considerable part, one-fourth if practicable, of the surface of the body in order to obtain the full benefit of this effect of the treatment. And this should include the portion affected by any local symptoms; the precordia in cases of palpitation or cardiac neurosis; the abdomen in cases of dyspepsia and constipation; the spine or different nerves in case of neuralgia.

Another part of the effect from glass vacuum electrodes is dependent upon the nature of the electric current which excites the tube. High electrical tensions are obtained by connecting the glass vacuum electrode with one pole of an induction coil or with one pole of a static machine, but their discharges have not the peculiar oscillatory character observed in the high tension discharges from high frequency apparatus such as a Tesla transformer or a d'Arsonval transformer or an Oudin resonator. Comparatively low tension discharges with considerable volume, 200 milliamperes and over, may be obtained by connecting the glass vacuum electrode with the d'Arsonval or the Oudin high frequency adjusted for that purpose.

The higher tension discharges are especially useful in cases of neurasthenia with low arterial tension and the low tension high frequency discharges are a specific in cases of neurasthenia with high arterial tension. A shower of high tension sparks from a glass vacuum electrode passed rapidly along the spine is excellent in atonic cases.

In some cases of neurasthenia with high arterial tension which the author has treated by high frequency currents the blood pressure has been persistently so high as to lead to grave and threatening secondary lesions. The treatment has been by means of the d'Arsonal or Oudin high frequency, but low tension discharges applied partly by means of the autocondensation couch and partly by means of glass vacuum electrodes. The latter are applied along the spine and over the abdomen with a current of over 200 milliamperes passing through the electrode. This current is registered by a hot wire milliamperemeter and is many times greater than could be borne except for the oscillatory character of the current. Up to a certain point alternating currents produce more and more powerful effects as the alternations are increased in rapidity and the 110 volts electric light current with 60 alternations per second produces dangerous effects. More than 5,000 alternations per second rob the current of its power to produce muscular contraction and reduce the sensation to a minimum. High frequency currents have millions of oscillations per second and the nerves of motion and sensation cannot respond to them at all. The absence of a motor and a sensory effect is obtained when a direct contact is made with a metallic electrode of large size or when the high frequency current acts by induction or condensation without any charged conductor touching the body or being near enough to send sparks or a perceptible effluve to the body. This is true in spite of the fact that the d'Arsonval current has a tension of several thousand volts and an intensity of 200 to 400 or more milliamperes. The same current will give a shower of tiny sparks from a vacuum electrode held near the surface, but this changes the character of the effect produced and is more suitable for cases without high arterial tension. Even with the glass vacuum electrode held in close contact with the skin the large milliamperage results in an amount of warmth which may become uncomfortable if the electrode is held in one place for any length of time. This is prevented by moving the electrode slowly over the surface, and the latter should be thickly sprinkled with talcum powder to enable the electrode to glide smoothly over the skin. Without this precaution the perspiration excited by the application causes the electrode to stick to the surface and to pass from one portion to another by a series of jerks accompanied by disagreeable sparking.

The neurasthenic cases referred to the author for this kind of treatment have usually had some definite nervous, circulatory reproductive or alimentary disturbance, and the results have often been little less than magical.

I have endeavored to make it plain that there are several forms in which the high frequency currents

may be applied with and without the use of vacuum electrodes; and especially that the use of vacuum electrodes gives results dependent upon the exact form of high frequency current transmitted by them.

What is equally important is that other forms of electricity than the high frequency currents may be transmitted by them, with the same production of violet colored light but with radically different physiological and therapeutic effects.

One or two cases in which good results have been obtained may be of interest.

Case I.—Mrs. C., a delicate little old lady referred to me by Dr. Rushmore, had had as a most prominent symptom very severe pains in the sciatic, anterior crural, and spinal regions. She had been practically confined to the house for two years. After some fruitless inquiries at the hospital where the patient's husband is one of the trustees, he came to me, asking whether there were any possible injuries resulting from treatment and whether there was any probability of sufficient benefit to pay for the pain produced by getting into a carriage and coming to my office. I was able to encourage him in regard to both questions, and the patient came for treatment that same afternoon. Only the vacuum electrodes were used and the weakest current possible from one pole of the Oudin resonator. Application lasted 7 or 8 minutes and was made through one thickness of underclothing. I think that the term "magical" may be fairly applied to the result. The patient was able to go to one of the large retail stores after the second treatment, this having been the first time she had been inside a shop in 7 months; and after the fourth treatment she went to her son's wedding in Worcester, Mass. After the seventh treatment not a pain or ache remained. Although it is three or four years, there has never been a return.

Case II.—Mr. S., 65 years old, was referred to me by Dr. Albert H. Ely. In his case the symptoms of neurasthenia were added to those of arterial sclerosis with its usual subjective and objective symptoms including the most annoying one of hemianopsia. The treatment consisted in autocondensation by means of the autocondensation pads connected with the high-frequency apparatus which I will show in a few minutes, and the application of vacuum electrodes to the temples, where the greatest throbbing headache was felt, and to the anterior cardiac region where pain of a very severe character was almost constantly felt. The vacuum electrode was connected with one pole of the Oudin resonator and the current was of low voltage, but of as great amperage as the patient could bear. The sphygmomanometer showed a progressive reduction from 190 mm. to 140 mm. The treatment was given for several weeks one spring, and also the following autumn, and has not been required for the last year. There was marked benefit in regard to every subject of symptom. The feeling of profound mental depression disappeared and the patient became able to enjoy his favorite recreation of bridge-whist. The loss of vision in one half of the retina did not, of course, yield to the treatment. The headache disappeared simultaneously with the return of the normal appearance of the blood-vessels of the face. The cardiac pain and the palpitation also disappered.

These are only two examples selected from a large number of cases, among which were several cases of a purely neurotic type treated with equally good results.

59 West Forty-sixth Street.

THE CARE OF THE MOUTH DURING INFANCY AND CHILDHOOD.*

By WILLIAM J. LEDERER, D.D.S.,

LECTURER AT THE NEW YORK COLLEGE OF DENTAL AND ORAL SURGERY; ATTENDING DENTAL SURGEON TO THE GERMAN HOSPITAL DISPENSARY, NEW YORK.

A great deal could be written about the care of the mouth during infancy and childhood, if one were to review all the pathological conditions which are liable to occur in the oral cavity and discuss their treatment. I shall, however, not bore you with etiological, pathological, and therapeutic facts, which you are all acquainted with, but rather view the subject from a prophylactic point of view and try to point out the importance of certain hygienic measures and attempt to show the value of conservative treatment which, so far as the mouth is concerned, has not been accorded that station in medical science of which it is deserving.

Altogether, the hygiene of the mouth has been a sadly neglected factor and it is only of very recent date that the importance of a clean healthy mouth has begun to be realized. Thus since about a year the medical school inspectors not only examine the children's eyes, ears, throats, and noses, they also look at their teeth and report their findings to the health authorities who notify the children's parents and demand a visit not only to the physician, but also to the dentist.

Such action has borne good fruit already, as the reports showing the results of the treatment of tuberculous glands in children give better statistics than before dental inspection was practiced.

Stomatologically, infancy and childhood can be divided into various periods according to tooth eruption; thus we get: (1) The period beginning at birth and terminating with the eruption of the first temporary teeth about the 6th month. (2) The period of eruption of the temporary teeth, which begins about the 6th month and ends at about the completion of the 2d year. (3) The interval between primary and secondary dentition, namely from about the 2d to 6th year. (4) The period of eruption of the permanent, and exfoliation of the primary teeth, not including, however, the eruption of the 3d molars or wisdom teeth, as these come through during adolescence and sometimes not until later, in fact they may erupt at any time after the 15th and 16th year; that would end the last period about the 13th year, when the permanent eye teeth have made their appearance.

From the dental point of view these different periods are: (1) A toothless period, (2) a period of dentition, (3) a period of rest, (4) a second period of dentition.

However, the whole epoch from birth until the 13th year, and as a matter of fact, before and after that, the period is one of tooth formation and development, for the developmental history of teeth begins about the 7th week of embryonal life and does not terminate until the completion of about the 21st year.

The proper care of the mouth during these periods will not only insure a healthy buccal cavity and comfort to the little folks, but will remove the etiological factors of many pathological conditions of infancy and childhood, some of which may reflect lifelong upon the individual.

What are the lesions which occur in the buccal cavity and what measures constitute that which collectively can be termed the care of the mouth? To review individually all pathological conditions liable

*Read at a meeting of the Manhattan Medical Society, May 22, 1908.

to involve and emanate from the portal of the alimentary tract would take us too far, but all can be classed as traceable (1) to traumatism and infection, (2) to diseased constitutional states or faulty nutrition, and (3) to abnormal development.

If these factors be removed, buccal disease and its

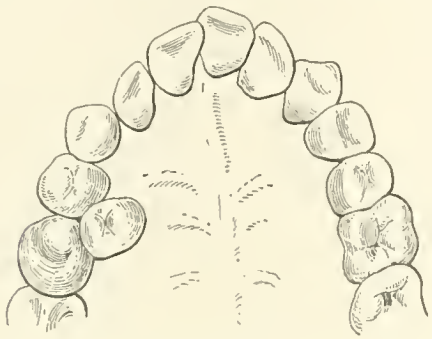

Fig. 1.—Radiograph showing the eruption of a bicuspid inside of the dental arch.

sequelæ will be greatly reduced; this would mean the establishment, as far as possible, of oral asepsis, the treatment of systemic disease, the modification of improper nutrition, and the correction if possible of developmental faults.

Little is to be said about the care of the mouth of the infant during the first 6 months. Different men have expressed different views on the usefulness of cleansing the infantile mouth. The mouth, like the rest of the alimentary tract at birth, or rather up to birth, is presumably sterile, but with the drawing of the first breath and the emission of the first cry, there are introduced into the mouth many species of microorganisms.

Certain localities of the buccal mucous membrane are especially prone to injury and subsequent infection. These are the mucous lining covering the hamular process of the palate bone and those light-colored bodies on both sides of the median line, designated as epithelial pearls of Epstein. If traumatic lesions are produced here and these become infected, the resulting ulcers which Parrot termed "plaques pterygoidennes," or which are better known as Bednar's apthæ, may become quite troublesome. This has caused many authors to abandon infantile mouth sterilization, as it is claimed that the normal buccal secretions are fully able to protect the mouth. Mikulicz and Kummel in their work on "Disease of the Mouth," say: "Experience in Maternity hospitals, quoting Epstein, Fisch, von Engel, and Baum, have shown that palatal ulcers are observed only in infants whose mouths are cleansed. If the buccal cavity is not cleansed, buccal ulcers are not observed." Ritter of Berlin, in his work on "Diseases of the Mouth and Teeth," states that: "It is of the utmost importance that the attention of mothers be directed to the careful washing of the buccal cavity of infants from birth on, and if this be observed, most of the so-called diseases of dentition will be avoided—especially among the poorer class of patients. The buccal lavage is best done by means of absorbent cotton or a very soft sponge." Koplik says: "The mouth of the breastfed infant especially should not be frequently washed. If the breast nipple is kept scrupulously clean, sprue and stomatitis will be avoided." Kilmer says: "An infant's mouth should be cleansed before and after every nursing, be it from breast or bottle." Holt advocates mouth sterilization as a prophylactic against sprue, etc.

The different authorities expressing varying views have all valid reasons for their individual practice, but summing up all, I am inclined to urge mouth sterilization, especially in children who are fed artificially. There is practically no danger of mouth infection in healthy, breastfed infants, brought up in hygienic surroundings, if the mother washes the breast nipples before and after nursing. The artificially-fed baby, however, is at a disadvantage, as its very food is but a substitute for mother's milk, and bottles, nipples, and pacifiers, unless scrupulously clean, may constitute a formidable danger.

The word *careful* as applied to the washing of the infantile mouth, should be emphasized. It is better to leave the mouth alone than to introduce roughly a finger, which is never aseptic and may wound the buccal mucous membrane. In fact, a finger should never be introduced into the child's mouth, but a swab made of cotton on an applicator or a piece of wood. This used gently will not hurt the mouth. It does not appeal to me that it can be of benefit to the child to permit remnants of starchy and other foods to decompose in the buccal cavity and be swallowed. The buccal toilet is not for the purpose of cleansing the mouth so much, as the normal secretions will probably take care of a normal oral bacterial flora. The septic materials found in the buccal cavity as the result of bacterial action upon foodstuffs and other things introduced into the infantile mouth, which have no place there, are swallowed and may become the factors of gastro-intestinal disturbances.

The mouth will not suffer unless traumatized, but the gastrointestinal tract may. Therefore, I believe careful buccal lavage, in all artificially-fed children at least, is a necessity and if done carefully will be of no harm. I advocate an alkaline antiseptic tablet, dissolved in water or saline solution as a wash for infants.

The use or nonuse of pacifiers has been the subject of considerable discussion. Some men claim that the so-called "fruitless sucking" is harmful to the child, others oppose this view. The fact remains that pacifiers are kept even less clean than nipples. I have seen a baby's pacifier on a dusty mantlepiece, in the bed wet with urine, on the floor, in brother's trousers pockets, and in other places which were far from clean; for this reason a pacifier becomes a danger. There are, however, other reasons which cause me to look with disfavor upon these "pipes of peace." I contend that the pacifier may become the first source of mouth breathing and lay the foundation of the thumb-sucking habit.

A very pernicious custom of grave danger to a

Fig. 2.—Radiograph of a boy of about 10 years of age, who has cut his permanent teeth as well as his sixth year molar; he has *in situ* his temporary eye teeth and the temporary molars.

child is the habit of the nurse moistening the nipple or pacifier with her own lips before giving it to the child. Sometimes a stranger is asked to mind the child for a short time, and indulging in this common practice may cause luetic or other infection of the infant's mouth if there be abrasions in the child's

mouth or about its lips. Too much stress cannot be laid upon this point.

If an infant has a cleft palate or hare lip, or both, the care of the mouth becomes an even more important factor. Fortunately, however, these malformations are rare, and in many cases do not inter-

Fig. 3.—The arrow points to the temporary cuspid.

Fig. 3.—Radiograph of a jaw wherein the permanent bicuspids are in position; the temporary eye tooth is about to be exfoliated, its permanent successor is about to erupt.

fere with the taking of nourishment of the child Brophy of Chicago advocates a very early operation, that is, when the infant is a few weeks old Brown of Milwaukee, and others, wait until the child is 3 years or older. A hare lip is better operated upon early, as the scars and deformed lip resulting will be less visible. A staphylarrhaphy, however, is indicated in very young infants only when the cleft interferes with nutrition that there obtains the danger of starvation, otherwise I would deem it more advisable to postpone the operation until a little later.

Primary dentition brings us to the second period.

A great deal has been written about dentition and some of the concomitant conditions. Older writers spoke of teething diarrhea, teething convulsions, teething coughs, and in fact there are few diseased states which have not at one time or another been brought in relationship with the eruption of the teeth. Some have advised to lance the gums freely to help the teeth come through, others advised the opposite.

Dentition is a physiological process, but if there are severe symptoms attending, they may be brought on by the eruption of the teeth, as the period of dentition is one of great physiological activity and growth, but this only constitutes the last drop in the bucket which causes the overflow, and the real cause is always some other underlying abnormal or pathological condition, as the symptoms vary in different cases and we have not even a temperature chart characteristic of dentition.

It may be of interest to quote Prof. R. Parreidt of Leipzig from a paper "Upon the Influence of Primary Dentition Upon the Infantile Organism." He writes as follows: In a holy book of the ancient Indians, dating from the 17th century B. C., there is found an incantation addressed to the milk teeth, to spare the body of the infant. Archigenes advocated the local appliances of harebrain and dog's milk, Paulus of Aegina old herrings, meat, etc. Also the rubbing of the gingivæ with hard substances was practised, the nurse beginning to rub the gums from the 3d month on. Mesue used hard bacon, rings, and other articles. which we know to be employed in the nursery even now.

These processes, although exposing to the danger of infection, are not as bad as the notorious scarification of the gum.

Hunter boasted of having used the lancet 10 to 20 times during the eruption of one tooth. Hurlock, in 1742, incised the gums of children 10 days old, and to carry this nonsense to extremes lacerated the gum tissue after all the primary teeth had erupted to protect the child against eruptions and other diseases. A great deal could be written about the various absurd methods of treating dentition symptoms; however, time and space forbid it.

To illustrate the care of the mouth during dentition, I should like to frame a set of "Don'ts."

Don't rub the teeth through, as this will only open an avenue of possible infection, particularly as the resistance of the little body is somewhat lowered during this state.

Don't rub the gums (as a rule), for the abovementioned reason, and especially if the erupting tooth is well covered, the incised wound will heal up very rapidly and the operative procedure has to be repeated.

Don't poke dirty fingers into the child's mouth to find out if the tooth is through, but keep the mouth clean. Most of the attending symptoms of difficult dentition can be avoided by carefully looking after the digestive apparatus.

After the first teeth have made their appearance, many begin to modify the infant's diet, giving the child other food than milk. A soft tooth brush should now be used, but particular care must be exercised to use a brush which does not lose its bristles. The mouth should be washed after every feeding and before retiring. A mild antiseptic like liquor antisepticus diluted, to which a little bicarbonate of sodium is added to make it alkaline, can be used, or an alkaline antiseptic tablet, dissolved in water. If a child is under medical care and takes medicine of any kind, the mouth should be washed, so as to neutralize any acid drug given and to cultivate the habit for the future. Regular dental inspection should be instituted from the time that all temporary teeth are fully erupted.

The care of the mouth consists first in keeping the mouth clean; that means to remove by means of a brush, floss silk, and tooth pick any particles of food. The mouth should be washed after every meal and the teeth brushed. It is most important, however, to brush the teeth before retiring, for otherwise there remain in the mouth remnants of food, etc., over night, a period of about ten hours, during which time, in normal conditions, little or no saliva is secreted and fermentation goes on without disturbance, which prepares the path for dental caries.

If dental caries is established, the early filling by proper dental care, which can be obtained by regular dental examination, in order to avoid untimely extraction, is important.

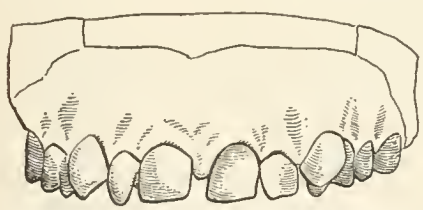

Fig. 4.—A deformed jaw, produced by the too early extraction of the temporary eye teeth; this patient could not shut her mouth, she was a mouth breather, and had hypertrophied tonsils and adenoids.

The belief that the first or milk teeth can be extracted at random, inasmuch as they are replaced by the permanent teeth, is erroneous, as dental irregularities are thus produced which may alter the shape of the dental arches so as not only to be unsightly but to induce abnormal breathing. It is almost

more important to retain the temporary teeth until certain periods, than it is to retain the permanent denture intact, as the latter can be replaced by artificial organs. The functions of the temporary teeth are not only to assist in buccal digestion, but also to assist in the development and shaping of the jaws

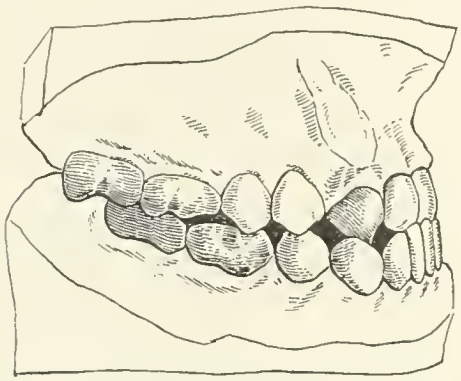

Fig. 5.—An irregularity, produced by the too early extraction of a temporary eye tooth; the upper arch is too small for the lower jaw.

or dental arches proper. The permanent teeth are larger in size and number than the first or temporary dental organs and, therefore, require more room, which is created by the enlargement of the dental arches. This enlargement is brought about by the eruption of the permanent molars behind the temporary teeth. By the eruption of the permanent molars, the temporary teeth are, so to say, pushed forward and the dental arches are lengthened anteroposteriorly. If one of the temporary molars is extracted prematurely, the erupting permanent molar will exert its pushing influence only upon the teeth posterior to the gap made by the extraction and not only will the anterior temporary teeth not be affected by the wedging of the erupting permanent tooth, but the bicuspid which was to take the place of the external temporary molar may erupt inside or outside the dental arch. (Fig. 1.)

The next temporary tooth to be exfoliated is the first molar, to be followed by the eruption of the first permanent bicuspid. This is followed by the shedding of the second temporary molar, whose place is taken by the second permanent bicuspid tooth. After these are in position the temporary eye tooth will be shed and its place be taken by the permanent canine. If for some reason the temporary eye tooth be extracted too early, the permanent bicuspids being nearer the gum than the permanent eye tooth, the bicuspid may come down (the temporary molars being shed) and, advancing towards the blank space created by the extraction of the temporary canine, leave no room for the permanent eye tooth, which coming down will erupt outside of the dental arch and what is popularly known as a buck tooth is the result. This condition also determines a small arch and a facial deformity results, which frequently is the cause of the institution of mouth breathing.

Just as it is wrong to extract the temporary teeth too early, it will be an error to retain them beyond a certain period. Sometimes temporary teeth are retained longer than their normal period, brought about by the failure of root absorption, which is produced by a dead pulp or other conditions. In such cases the permanent tooth is deflected in its course and will erupt either inside or outside of the arch.

The thumb, tongue, or lip sucking habits frequently found among children also deserve mentioning here, as these practices are the cause of malformations which also induce not only faulty articulation with resulting inefficient mastication, but are often the cause of incorrect breathing (mouth-breathing) with its sequelæ.

Fortunately thumb-sucking is usually broken before much damage is done, as these habits rarely cause displacement of the temporary teeth. If, however, the practice is kept up the upper front teeth (incisors and cuspids) are always pushed outward and to one side, according as the thumb of the right and left hand is used. The lower teeth, however, from the pressure of the back of the thumb are crowded back. The pernicious habit of biting the lower lip, or pressing the occlusal edges of the upper incisors against its outer surface, has a tendency to move the upper central incisor teeth forward, thus lessening their natural resistance to the narrowing of the lateral halves of the arch. This is shown in Fig. 7.

The habit of resting the tongue between the upper and lower teeth will produce the effect shown in Fig. 8.

Careful dental inspection and examination are necessary to avoid such irregularities. Irregularities produced by the untimely extraction of teeth take months of treatment for reduction. A temporary tooth should never be extracted prior to its period of exfoliation only if its presence in the mouth is harmful and its pathological state cannot be overcome.

No intelligent physician will tolerate a focus of infection anywhere. Tuberculous glands are excised most promptly. The mouth, however, which is a perfect breeding ground for microorganisms, offering heat and moisture and endless nutrient material for the development of a bacterial flora, extraordinary in number and variety, the mouth, which is the most abused part of our anatomy, being constantly irritated, stabbed, cut, torn, and otherwise injured, is absolutely, or almost, ignored. Purulent conditions are permitted to exist here without care for years and microorganisms are allowed to gain entrance to the system by inhalation, swallowing, and through abrasions of the mouth and through necrosed tooth pulps.

I shall submit only a few facts and let you make your own deductions. During my service at the German Hospital Dispensary, I saw during one month 22 children with enlarged glands; all of these had badly decayed teeth.

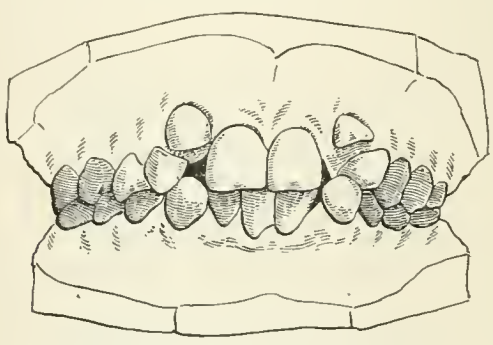

Fig. 6.—Deformity showing the result of too early extraction of the deciduous incisors (Angle).

Case I.—Breast-fed child. Age 5 years, had had only measles. Left side of face was swollen, toothache. Lower temporary molars were badly broken down, the pulps being septic; the gingivæ were inflamed. The tongue presented markings of lingua geographica. Cervical glands were enlarged and painful to the touch. The anterior pillars of the fauces were slightly reddened. Temperature, 100.1°. A diagnosis was made of buccal infection from septic teeth and absolute neglect of oral hygi-

ene. Treatment consisted in the extraction of badly decayed septic teeth, mouth wash of liquor antisepticus, and a laxative magnesium sulphate.

Case II.—Breast-fed child, age 5 years. Right side of face swollen, no previous disease. Several badly broken down septic temporary lower molars.

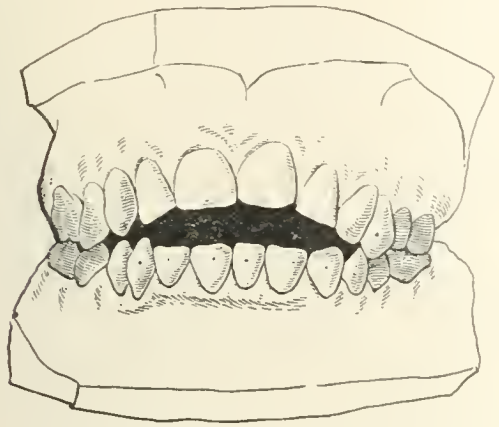

Fig. 7.—Deformity produced by biting lower lip and pressing occlusal edges of upper teeth against outer surface of lower lips.

Ulcer below the lower right gingival border in the molar region. Cervical glands enlarged on right side. Bacteriological examination of pus from gingival ulcers shows a pure culture of Vincent's spirilla. Diagnosis: Buccal Vincent's angina due to infection from septic teeth. Treatment: Extraction of decayed teeth, mouth wash of bichloride of mercury 1:10,000 in saturated sodium boric acid; mild laxative. Gingivitis and ulcer cleared up in 5 days and the glands were reduced in 10 days.

Looking up the literature, I find that Odenthal of Bonn has investigated the relationship between chronic enlargement of the cervical glands and dental caries. He examined 987 children, 429 had carious teeth and of these 424, or 99 per cent., had glandular swelling. Hoppe of Leipzig examined 269 cases and found in 73.9 per cent. glandular swellings, in nearly all instances associated with carious teeth. Sexton, who examined the teeth and ears of the inmates of a large charitable institution, they being almost exclusively within the age of second dentition, found that over 6 per cent. were suffering from otitis media purulenta. In 30 children there were frequent attacks of earache; in some cases there were earache and toothache simultaneously. In many cases, he writes, where inflammation cannot be directly traced to dental irritation as its cause, it is certainly aggravated by the latter and a cure is seemingly impossible until the dental irritation is removed.

Dench writes that it is quite possible that carious teeth may cause middle-ear inflammation, either directly by the introduction of germs into the tympanum through the Eustachian tube or indirectly through the nose.

Mouth breathing, as is well known, is a very potent and common contributary cause of phthisis, and in many cases this pernicious habit is formed as the results of carious teeth in early life. An exposed nerve or tender gum, or a dental periostitis renders mastication painful and the child is afraid to close its jaws, and not only acquires the habit of bolting its food, but also to avoid painful contact of the teeth, keeps them open sufficiently to part the lips and commences to breathe through the aperture thus formed. Mouth breathing will also be produced by dental irregularities as previously shown. Thumb-sucking is also productive of this pernicious habit. It is hardly necessary to point out the deleterious results of mouth breathing; too much is not said, if it is stated that the upper half of the head does not develop properly in mouthbreathers. The upper respiratory apparatus also becomes predisposed to disease, as well as the faucial and Lushka's tonsils. The part played by oral sepsis in enlarging the tonsils will itself favor this dangerous habit.

Whatever may be said in regard to specific septic infection, taking place through the mouth and teeth, there is no doubt as to the existence of secondary anemia, associated with lowered vitality and great foulness of the whole alimentary tract resulting directly from buccal infection. In such cases not only is there local absorption of toxins through the mucous membrane of the mouth and the alveoli of the teeth, but the infection with staphylococci is a continuous process throughout the alimentary canal. Just as the remedy for chlorosis is said to consist in the cleansing of the lower end of the intestine, so it may be claimed that the cleansing of the mouth is of equal importance. It is a safe aphorism: Look after the ends of the alimentary canal and the middle will look after itself.

All that has been said in reference to the part played by oral sepsis in the production of phthisis in adults, may be repeated with greater emphasis in the case of children. They are more susceptible to diseases of the respiratory organs and of tuberculosis in particular. In 586 children examined during an outbreak of diphtheria, in London, 458 showed signs of buccal disease, ranging from simple hyperemia of the mucous membrane of the mouth and throat, to hypertrophy of the tonsils with adenoids, etc.; 88 per cent. of the children had carious teeth.

A great deal of indisputable evidence has been gathered to show the connection between oral sepsis and general infection. Pedley in his book, "Diseases of Children's Teeth," quotes among many others the following cases supplied by Dr. Wainwright, House Surgeon at the Evelina Hospital, London:

Mary Banton, 7½ years old; stomatitis and diarrhea of 5 weeks' standing; nearly all the teeth were carious and very foul. Four were removed and a mouthwash of permanganate of potassium was ordered and was also used with a toothbrush. The mouth became clean and diarrhea ceased in a week.

Carolina Willcocks, 3 years old; extreme stomatitis and diarrhea with great emaciation. Pus oozing from all of the teeth which were carious. They

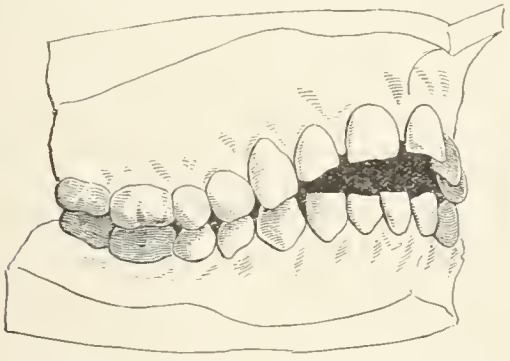

Fig. 8.—Deformity produced by continually thrusting the tongue between the teeth, and thumb sucking (after Angle).

were removed. The child became quite well at once, grew fat, and is still so, though toothless.

Ellen Burns, aged 6½; bronchopneumonia and diarrhea. Three lower molars were removed opening up an abscess cavity. The diarrhea ceased and in four weeks the child's weight increased from 2 stones 3 lbs., to 3 stones 4½ lbs.

Many other cases could be cited. The diarrhea in all these cases was of the same nature. About three motions each day, which were frothy and intensely offensive. In most cases the offensive character disappeared for some days before the diarrhea ceased.

The effects of swallowing quantities of putrid material are often associated with other symptoms besides disturbances of the alimentary canal.

The toxins are taken up by the lymphatics of the stomach and intestines and pass into the blood stream. Headache, nausea, and vomiting may follow, sometimes accompanied by a rise of temperature, showing the symptoms of sapremia (due to the absorption of chemical substances and in no sense of the word an infective condition).

In view of all this, why is it that the mouth is not cared for in the manner necessary to reduce the oral sepsis and its sequelæ? The reasons are that the busy general practitioner does not realize the importance of oral hygiene, the lack of knowledge of parents and guardians regarding these matters; and the remedy which will overcome these conditions is collaboration of the general practitioner, the specialist, and the parents. The first step I think has been taken, in that the Board of Health has the mouths of children examined, now let the family physician take up this work and the results will be of inestimable value to humanity at large.

The care of the mouth can be outlined in one sentence, namely, "Keep the mouth clean," which means: (1) To reduce oral sepsis as much as possible; (2) to render the buccal cavity alkaline; (3) to reduce dental caries, to avoid this as much as possible by frequent oral examinations and early filling; (4) to reduce inflammatory conditions and remove their local and systemic causes; (5) to avoid the untimely extraction of teeth; (6) to induce normal bodily functions to establish and maintain a physiological balance.

This applies to adults as well as to children, but the earlier it is instituted the better the results. Another factor important to the reduction of dental caries and its sequelæ, namely, the proper development and calcification of the teeth, is the rational mode of living of the mother during pregnancy and the rational feeding of the infant and child.

A very important step towards the reduction of buccal sepsis and its innumerable sequelæ would be the appointment of a stomatologist on every hospital staff whose duty it would be not only to attend to emergency cases (as it is in a few hospitals), but also to make his regular rounds and create and maintain clean, healthy mouths. I believe it is of great importance that a patient who is to be operated upon, whether the operation be a laparotomy or any other surgical procedure, should not only, as is customary, have his bowels cleansed, but the other end of the tube, his mouth, should also be rendered as clean as possible.

The first step necessary would be an elimination of inflammatory processes and suppurative foci which exist so frequently. We all know what an ideal incubator, abundant in material favoring the production of sepsis, the mouth is. How many patients confined to bed with typhoid fever and other diseases of long duration have their mouths cleansed? How many sanatoria for the treatment of tuberculosis have a regularly attending dentist? This is not dentistry, but prophylactic medicine and, after all, the greatest triumph of medical science is not the curing, but the prevention of disease.

SPECIAL PROVISIONS FOR MANAGEMENT OF CERTAIN FORMS OF MENTAL DISORDER.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

ASSOCIATE IN NERVOUS AND MENTAL DISEASES, JEFFERSON MEDICAL COLLEGE; NEUROLOGIST TO MOUNT SINAI, NORTHWESTERN GENERAL, AND DOUGLASS MEMORIAL HOSPITALS.

The fundamental and at the same time imperative indication in management of mental cases is *isolation*. The reason of it lies chiefly in the necessity of removing the affected individual from his usual surroundings where the delusional conceptions and faulty interpretations originated. By this method any cause that is apt to revive and accentuate the already developed delusions is thereby removed and the patient whose mental operations are disturbed and who is therefore incapable of appreciating fully the reality of things, can be properly taken care of. Isolation is the essential therapeutic principle in mental diseases.

The varieties of cases with mental deviation from normal are legion. The question is whether all cases should be treated uniformly with respect to isolation or not. Otherwise speaking, should all cases of mental disorder be indiscriminately committed to special asylums for the insane?

During a very long time an asylum was considered as the sole means of treatment of lunatics who were gathered there pêle-mêle. Gradually a necessity had arisen for division and subdivision of the institution in separated quarters for various types of insanity. Continuous study and clinical observation in mental diseases led to a further discrimination of forms of psychic disorders and in the light of our present knowledge of the causes, course, and prognosis a question naturally arises: "Are we justified or is it beneficial to direct all cases with mental derangements to special insane institutions?"

Commitment of a patient to an asylum is accompanied by certain inconveniences. Independently of a request made and signed by a member of the family, the law requires a medical document certified by a public officer. These formalities have been found necessary in order to avoid arbitrary commitments, but they have the inconvenience of stamping the patient in the eyes of the community with a neuropathic stigma of an hereditary nature. In the present state of our ideas and customs such a condition is bound to have its effect upon the patient's future social life and interfere with his obtaining a position for his livelihood. The unfortunate victim of an accidental delirium or of another curable mental disturbance of brief duration, committed to an insane asylum, may in the future be disqualified socially.

Although nowadays physicians and the laity are sufficiently enlightened on the subject of psychiatry as to consider a lunatic a diseased person but not as one possessed by "the devil," yet the humane ideas of Pinel and Esquirol concerning insanity are far from being understood by all. The prejudice existing in regard to commitment is still in full vigor. An individual once treated in an asylum, even for a very short period and though fully recovered, is branded as an unsafe person and will meet with great obstacles in his life. Since such views exist and it is beyond our power to alter the prevailing prejudice, it is our solemn duty to endeavor at

*Read by invitation at the meeting of the Pennsylvania State Medical Society, Cambridge Springs, September, 1908.

least to ameliorate the existing condition in an indirect way. Apart from purely sentimental consideration of the question, let us see if our scientific knowledge of mental disorders will enable us to find some means for obviating the necessity of committing all persons suffering from mental derangements.

It is a common occurrence to witness episodic attacks of delirium or confusion in the course of infectious diseases, such as pneumonia, grippe, typhoid fever, etc. Confusional or delirious states are also observed in uremia, in the puerperium, also immediately or shortly after surgical operations. Acute morphine or cocaine poisoning and acute alcoholic intoxication of short duration are accompanied by confusion, delirium, or else stupor. An epileptic seizure may be followed by a delirious state which is transitory in character. An hysterical paroxysm may be accompanied or preceded by delirium with hallucinations and illusions.

Should all these mental disorders which are essentially temporary in nature and most frequently recoverable without the least tendency to permanency—be a sufficient reason for commitment of individuals thus afflicted to asylums and thereby place the latter and their families in difficult positions?

When we turn our attention to the true classical psychoses, we will also find certain forms for which asylum treatment is equally unjustifiable.

While melancholia with its pronounced mental depression, delusions, and evident tendencies to suicide, should be treated in special institutions, there are nevertheless varieties and subvarieties of the same affection to which forceful commitment would be injurious. In fact these milder forms are by far more numerous than the typical form. There are a great many individuals who in their life pass through a number of mild attacks of genuine depression characteristic of melancholia and repeatedly recover. Should such individuals be placed in insane asylums, the surroundings of the latter will doubtless have a deleterious effect on their mental condition. Having sufficient amount of reasoning power they will be worried over their confinement among the insane and over the fact that the laity views insanity from a very prejudiced standpoint.

Very frequently an attack of delirium is taken for mania and the patient is hurried to an insane institution. Paretics in the early stage, when only neurasthenoid symptoms are present, should not be placed in such an institution. It is well known, speaking generally, that the sooner the diagnosis is made and the earlier the general treatment is instituted, the later the second stage will make its appearance. The same remarks can be made in reference to dementia præcox. The numberless cases of mild dementia observed in senility or in cerebral softening are equally not subjects for lunatic asylums.

There is a series of mental cases by far larger than the true forms of insanity, which belong to the so-called "borderland cases." They are composed of all varieties of obsessions, doubts, phobias, of cases with deficient inhibition, as for example kleptomania, of the hypochondriacs who are walking pathological museums, of the large number of neuropaths who episodically exhibit peculiar psychic manifestations of an unclassifiable nature.

Are we justified in advising commitment of such individuals? The rich among them seek relief in private sanatoria for nervous diseases, but what about the less fortunate psychopaths? Should they not be given analogous facilities and escape the insane asylum?

This brief discussion is sufficient, I believe, to indicate the urgent advisability of a careful discrimination among the overwhelming multitude of mental disorders with reference to the method of management.

The insane asylums, as they are organized at the present time, are suitable for incurable psychic infirmities, but do not meet the material or moral requirements of recoverable maladies. This truth was recognized even by Esquirol. There are two ways to remedy the existing state of affairs. One is either to create special asylums for the acutely insane or else to divide the existing institutions into departments for acute and chronic insane. The other remedy is to create either special hospitals or special services in the already existing general hospitals.

As to the first, it doubtless presents considerable conveniences from the standpoint of treatment, but it does not remove the above-mentioned substantial objection, viz., the stigma which accompanies every individual who even once in his life had been placed in an asylum.

Special hospitals for the acutely insane or recoverable cases of insanity present grave objections as they are and always will be considered by the laity as analogous to the old asylums for the insane. Alienists of distinction in France, Germany, Switzerland, England, Denmark, and the United States, solicitous about the proper treatment of the acutely insane, moved by justifiable expectations of curing such individuals, penetrated by the sense of justice due to them and their relatives in abstaining from commitment, have initiated a propaganda for the creation of special services in the general hospitals. The benefit derived from such an organization is manifold.

If a patient in a surgical or medical service of a hospital suddenly develops a delirium with or without hallucinations, he will be certainly a source of great disturbance to his fellow patients. If he remains in the same service, all sorts of measures will have to be taken to restrain him. These measures are not without danger. The usual means of coercion, such as the straight jacket, are decidedly injurious to acutely agitated and delirious patients, as for example alcoholics, cardiac, pneumonic, or typhoid cases. He will then be immediately transferred to the special psychopathic service supplied with a sufficient number of attendants and nurses, and be treated without forced restraint until recovery follows. When the latter takes place, he will be returned to the service from which he came. If an individual irrespective of any organic visceral lesion should develop suddenly a confusional state with or without delusions, the nature of which can be appreciated only after a prolonged observation, the special service in question will undoubtedly be of enormous help under the circumstances. When after a reasonable period of observation, the diagnosis is definitely established and the patient is recognized to be incurable and dangerous, commitment to an asylum is advisable. In case improvement is noticeable, the treatment will be continued, and finally, when recovery takes place, the patient is discharged with the thought that he was treated in a general hospital. He will encounter no difficulties in obtaining a position.

Enormous benefit will be derived by those melancholiacs whose chief symptom is only various degrees of mental depression. Besides the purely moral effect from being kept away from an asylum,

the therapeutic applications will be followed by the most favorable results. We know from experience that when an appropriate treatment is given in such cases upon early manifestations of the disease, the improvement may be rapid and tendency to extreme despondency and consequently to suicide may not develop.

If we consider legions of the neuropaths with their various obsessions and impulses, a special isolation service in a general hospital instead of an asylum may bring the greatest amount of good. Such patients must be isolated and treated vigorously by hygienic and dietetic measures which can be applied only in a well organized service.

Every practicing neurologist is well aware of the fact that the suggestion alone of an institution, be it even a private one, to this class of patients is repulsive. The name sanatorium is identified by them with an insane asylum. Having sufficient intellect to reason, they believe themselves affected in their mental faculties and therefore view with horror the placing in special institutions. When placed there forcibly, they naturally abandon themselves to progressive self-analysis with the most disastrous results. Being naturally inclined to mental disturbances by reason of their peculiar make-up, they will be placed in the most unfavorable conditions when sent to special institutions. Their "borderland condition" may thus be overstepped. When on the other hand the doors of general hospitals are open to them with all the appliances, medical and surgical, known to every lay person, no objection from our special patients will ever confront us and the greatest facilities will be then offered to us to accomplish a great amount of good for those unfortunate victims. We all know from experience that when patients of that character are given complete or partial rest in bed, the rules of intelligent hygiene and dietetics strictly observed, regularity of life maintained, all sources of irritation and annoyance removed; finally when these patients come in daily contact with intelligent nurses and attendants who are especially trained in the manner of handling and speaking to them, and with all this a continuous, kind, and skillful suggestion on the part of the physician in charge—when all these means are at our command, our patients, speaking generally, improve rapidly. This is a daily observation with our wealthy patients. If this is the case with rich people, does not the community owe a similar debt to the less fortunate hypochondriacs and neuropaths who crowd our offices and dispensaries for months and years without appreciable results?

The creation of special wards in general hospitals will necessarily involve an economic problem, but when we consider the enormous expense of the crowded asylums with very little or hardly any result, so far as the treatment is concerned, and therefore an aggravation of the mental condition of some patients and consequently an increase in the insane population; when all this is considered, I say, the economic objection loses ground.

The special service under discussion will require no special arrangement distinguishing it from other services of the general hospital, except an increase in the personnel and a separate hydrotherapeutic outfit. A sufficient number of nurses and attendants is necessary and they must be especially trained in management of various nervous and mental disorders.

So far the interest and welfare of the patients have been considered. There is also another great advantage in creating special psychopathic wards in general hospitals. I mean from an educational standpoint.

The study of mental diseases, generally speaking, has been neglected or ignored by the average man. It is true that the treatment of patients with chronic delusional ideas is not the province of the general practitioner, but the latter *volens nolens* will meet cases with acute delirium developing in the course of toxiinfectious or other diseases for the management of which he was primarily called upon. It is essential for him to be able to discriminate between an ordinary accidental delirium which is only transitory and temporary and a beginning delusional state which is to become systematized and prolonged. It is essential for him to distinguish between a delirious or confusional state caused by a cardiac or renal condition and a similar state in a beginning genuine psychosis. It is also highly practical to be able to distinguish a case of a neurasthenia or hypochondria from melancholia and their intermediary stages. Errors due to a confusion of these various mental states are continuously being repeated. The responsibility of committing patients to insane asylums is enormous and errors caused by want of elementary knowledge of psychiatry are not infrequent. Special services when created in general hospitals will give resident physicians an excellent opportunity to observe and study various mental disorders and their treatment under the guidance of their expert chief. It is true that courses in psychiatry are now given in the majority of the medical schools, but no teaching will ever take the place of an active participation which internes attached to a service are obliged to take. Whoever became interested in mentally affected persons knows that one must live in their atmosphere to be able to understand them.

These few considerations permit us to draw the following conclusions.

The greatest advantages would accrue to both patients and the community if ordinary hospitals would undertake to treat mental disorders. By these means a certain group of acute mental diseases and some other mental disorders would be placed under the same conditions as other maladies in which so much progress has been accomplished from a scientific and a therapeutic standpoint. The principles of scientific prophylaxis cover a large field: they can bear fruit also in mental and nervous disorders, when the patient and neurologist are placed under favorable conditions. Finally the most important feature in the new service I am pleading for lies in the demonstration of the truth that insanity is a disease, which is not repugnant nor to be ashamed of and which develops like any other malady.

Foreign Bodies in the Eye.—Mr. Bishop Harman says that the after-treatment of an eye from which we have removed a foreign body will be varied, as we consider sepsis likely or unlikely. If sepsis seems unlikely, we may merely cover up the eye with a soft pad and bandage and let the patient go, with the caution to return if the eye be red next day. If there be much abrasion of the cornea, we should instil atropine as a further means of putting the eye at rest. Should we deem the injury septic, it is our duty to sterilize the wound, and that we can readily accomplish by touching it with pure carbolic acid. This may sound drastic treatment, but it is painless and efficient; the acid anesthetizes the part, and can be applied so as to reach only the point to which it is applied. Cocaine should be instilled. The lids should be held well open, and the tears sopped up with a pledget of wool held in the lower fornix; then, after drying the cornea by touching it with a piece of filter paper, press the sharpened end of a wooden match soaked in the acid into the wound, and gently move the point over the whole area of the abrasion. The part on which the acid has acted will turn white, but the discoloration is transient; the next day, in a successful case, no sign may be detected of the application.—*The Clinical Journal.*

New York, December 5, 1908.

HEREDITY AND DISEASE.

THE question as to whether disease is transmissible from parents to children is a fascinating subject of study, and one which is by no means definitely settled. Few ordinary persons will be found to deny that mental traits and characteristics are handed down from parents to their offspring, and the matter of the amount of influence that disease exerts upon the next generation has not been finally decided. At one time the belief was more or less common that certain diseases passed on from father or mother to son or daughter. Now that view has been greatly modified, and the current theory seems to be that no disease can be directly transmitted, but that there are maladies to which, if parents suffer therefrom, their children are likely to be susceptible; that, in fact, an individual may inherit a distinct susceptibility to a disease, or at least a weakened power of resistance to it. Furthermore, there would appear undoubtedly to be some diseases which transmit manifest traces to a succeeding generation, a legacy of ill, which it is difficult to explain without embracing the theory of heredity of disease to some extent.

In the Harveian Oration delivered recently before the Royal College of Physicians of London, Dr. J. A. Ormerod took as the subject for his address "Heredity in Relation to Disease." Naturally it is not easy to say anything new on such a subject, and Dr. Ormerod made no original remarks but stated in a plain common-sense manner the opinion of probably the majority of scientific men. Learned authorities such as Weismann, Galton, Pearson, and others have put forth their theories with no uncertain voice, but it must be borne in mind that they do not all agree on certain important points, and that learned as a man may be he may yet be led astray.

Dr. Ormerod says that there appears to be a glaring instance of transmission of disease by heredity in the case of syphilis, but that this is explained as follows: "Either the child imbibes the virus *in utero* by the placenta from an infected mother—this is evidently an antenatal infection rather than an inheritance—or else the virus is introduced by the sperm cells of the father at the very moment of conception; this again, whatever it may appear to us, is to the biologist not inheritance but an infection of a still earlier date. Similarly it is denied that there can be a true inheritance of any microbic disease whatever. Suppose we assent to that, yet susceptibility to such diseases, in either a plus or minus direction—that is proclivity to them or power of resistance to them—may be inherited. And may not such susceptibility be first acquired and then transmitted?" This last sentence really puts the whole question in a nutshell. If no diseases can be inherited, nevertheless it is possible that acquired susceptibility to them may be inherited.

Again, how far does the prevalence of a disease among a race for a continued period confer immunity? When pulmonary tuberculosis attacks a people who have hitherto been free from its ravages it spreads like wildfire and is fearfully destructive of life. The same may be said of syphilis when it encounters a virgin soil. This would appear to show that in the case of nations who have had these diseases with them for hundreds of years, some degree of resistance has been acquired and then perpetuated. That is to say, that the taint in the blood, so to speak, which confers immunity has been transmitted.

In the sphere of the nervous system the study of heredity in disease is of the greatest interest. Here most certainly, as the speaker showed, heredity is an agent of great power, for it ranks with injuries, infections, and intoxications as one of the principal causes of chronic nervous degeneration. So far as the neuroses are concerned, including such affections as epilepsy, insanity, hysteria, neurasthenia, tics, alcoholism, etc., the manifest influence of heredity can be easily traced. In addition, there are some diseases, such as Friedreich's ataxia, Huntington's chorea, and periodic paralysis, which crop up, either in successive generations or in one generation; periodic paralysis, indeed, has been traced back for five generations. These have been called familial diseases, to avoid the distinct assertion that they are hereditary, but this seems to one very like verbal hair splitting. As to acquired characters being transmissible, Dr. Ormerod truly remarks that in answer to this question "the plain unlearned man would certainly say 'yes,' and so did the learned up to a short time ago." Weismann's theory of heredity, so widely held nowadays, has overturned this view, and the theory of the continuity of the germ plasm is the one which now holds sway.

Our views on heredity may have been wrong and needed revision, but possibly at the present time we are progressing too rapidly in the opposite direction. The biologists have arrogated to themselves the position of laying down the law on the subject to the scientific world, and scientists appear to have recognized the assumed superior knowledge of the biologists, albeit they have not been able to fit in all the parts of their theory. They may be right, but until they have proved their points more conclusively than they have proved them up to now, the ordinary man is quite justified in exhibiting some degree of scepticism on the subject.

HOSPITAL MANAGEMENT.

IT goes without saying that the value of a hospital is mainly dependent upon the manner in which it is managed. If a hospital is badly managed, then its sphere of usefulness is greatly limited. This statement, however, is so obvious that it is not worth while to waste time in discussing it. Many hos-

pitals are not so well managed as they might be. This also is an obvious statement, but it leads to the matter in point. How should hospitals be managed so as to be wholly successful? Undoubtedly there are a large number of hospitals in this country and in New York itself which are excellently managed and which therefore give most satisfactory results, but there are also some of which the reverse may be said.

It is not the intention here to criticise the management of the hospitals of America, but to note what has been recently stated in regard to the management of hospitals in Great Britain by one of the greatest authorities on the subject. Sir T. Clifford Allbutt delivered an address on hospital management at the opening of the Medical Department of Victoria University, Manchester, on October 1. In Great Britain the control of hospitals is invariably in the hands of both laymen and medical men Frequently the lay managers are more numerous than their medical confederates, which often leads to a large amount of friction. There have been in recent years several regrettable controversies between the lay governors and the hospital staff and medical members of the board of control. Allbutt, referring to this subject, said that a prevailing error in hospital government was the failure of the lay managers to act in frank and equal partnership with the medical managers, whereby the full cooperation and best results of money and knowledge were more or less sacrificed. In this matter the lay governor was a little apt to be arrogant, a little purse-proud. Yet, after all, money was but the raw material, to be worked up with knowledge. The speaker proceeded to say that the belief that money was of more value than knowledge was vulgar and erroneous. Yet in the medical and lay partnership too often the lay manager presumed that the physician or surgeon was not his partner in hospital management, but in some sort his servant. The partners should not be, and, in fact, are not master and servant, but comrades; and even if the great healing engine is created by banknotes the principle of frank and open partnership should not be modified. Of course, there are often faults on both sides. Sometimes the scientific expert is prone to allow his imagination to carry him into the realms of extravagance, but on the other hand the layman is just as likely to be narrow-minded, domineering, and unduly meddlesome. He looks upon the whole affair from the standpoint of economy alone, and is apt to be cheeseparing at the expense of scientific progress. Unless, indeed, medical and lay managers work in unison and keep in touch, little mistakes and large blunders are continually being made.

The argument of the lecturer was that scientific research and the proper treatment of patients should not be hampered by laymen who were necessarily ignorant of scientific and medical matters. Of course there is another side to the argument. Physicians are proverbially bad business men, and if the whole management of hospitals were left in their hands it is to be feared that unsatisfactory results from the point of view of economy would occur. Good business men are absolutely needed in the management of hospitals and therefore it is eminently fitting that a certain number of laymen possessing the commercial instinct should be found on the boards of hospitals. But there would seem to be no reason why medical men and laymen should not work together amicably with good results to science and in the best interests of the institutions concerned.

Kefir in Malnutrition of Infants.

It is now generally recognized that neither drugs nor general hygienic measures play any great rôle in the therapy of chronic malnutrition of infants; the whole problem is that of feeding, and where breast milk is unavailable and modified cow's milk unsuccessful, this problem becomes very difficult indeed. Of late the administration of soured milks, that has won a recognized place in the therapy of the gastrointestinal disorders of adults, has been tried in the nutrition of infants, and has proved to be of distinct value in well selected cases. Dresler has experimented with the use of milk prepared with the kefir ferment and in the *Münchener medizinische Wochenschrift* for November 10, 1908, Tollens reports his results with the ferment obtained from Dresler. Freshly boiled milk was used, the ferment being allowed to act for eighteen hours, the necessary dilution being made with six per cent. sugar solution. The children very quickly lost their dislike of the sour-tasting food and the good effects of it were observed in a surprisingly short time; the appetite improved, the appearance of the skin became much more healthy, the increase in weight was constant and satisfactory, and the stools assumed a normal consistency and odor. The improvement soon allowed a transition to the usual milk modifications and the "kefir children" of the hospital were then safely sent home to the care of their mothers. A number of illustrative cases reported by Tollens give good evidence of the success of the method in individual children. There seem to be no contraindications to the use of the ferment so far as chronic cases of indigestion and malnutrition are concerned. Acute cases are probably ill-adapted for the use of such milks, the experience with milk soured by the Bulgarian lactic acid bacilli having been discouraging in this class of patients. Kefir fungi are obtainable in America and may well be tried in connection with hospitals for infants where the effects of such diet may be properly observed. The paper of Dr. Tollens noticed above and the original article of Dresler in No. 27 of the *Medizinische Klinik* for 1908 give the necessary details for the preparation of the food in question; proper attention to these details is, of course, a *sine qua non* of success, for fermentation of milk not controlled in the right time may easily result in products that will prove highly injurious to the sensitive gastrointestinal tract of the infant.

"Healed" Lesions in Tuberculosis.

Both clinicians and pathologists are fond of describing and demonstrating tuberculous lesions in which calcification has taken place as "healed lesions," which have become free from danger to the organism, and, indeed, it would seem as if the chalky nodules could not be suspected to harbor virulent bacilli. Some experiments of Schmitz, however, made under the direction of Lubarsch and reported in the *Deutsche medizinische Wochenschrift* for November 5, 1908, cast grave doubt upon the seeming innocence of these lesions. Inoculation of

guinea-pigs with the chalky material obtained from such lesions was followed by the infection of the animals with tuberculosis in seventy-five per cent. of the cases, while nodules that had assumed stony hardness proved to be infective in over thirty-five per cent. of cases. That the process of calcification is not necessarily of equal significance in all animals was shown by the fact that chalky nodules taken from tuberculous cattle and pigs proved much more frequently infective for guinea-pigs than similar material obtained from human lungs; calcification in human beings, therefore, seems to be of greater conservative significance than an anatomically similar process in the lower animals. The important conclusion to be drawn from these results is that great care should be exercised in considering any appearances in tuberculous lesions as signifying that healing has taken place. Careless induction of this nature when applied to the condition of tuberculous foci in living patients that clinically have apparently conquered the disease may lead to very unfortunate results if the patient follows his usual mode of life or unnecessarily exposes his lungs to some injuries. To look upon any appearances as indicative of "healing" in tuberculosis is little warranted in the face of the above experimental results; at most we should look upon calcified lesions as quiescent foci, and this attitude is certainly safest for the patient.

Antidiphtheritic Serum in Post-diphtheritic Paralysis.

Although antitoxin is universally used in the acute and early stages of diphtheria it is still considered as of doubtful value in the paralytic sequelæ of the disease. G. E. Schneider and L. A. Vandeuvre, in the *Progrès Médical* for August 29, 1908, state their belief that we may prevent these complications and may cure them when they have occurred by the use of large doses of antitoxin. In cases in which these injections have been successful the tendency has been to say that the disease tends to recovery, and that nature could have accomplished a cure if let alone. The authors cite a very interesting case, that of a young adult, who after an attack of diphtheria of moderate severity, from which he recovered, after injections of antitoxin, and remained well for five weeks, was suddenly attacked with paralysis involving all of the muscles of voluntary motion except those of respiration. He was unable to swallow and became emaciated from lack of food. Atrophy of all the muscles was extreme so that he had the appearance of a living skeleton. His heart was irregular and he was somnolent. Injections of antitoxin of twenty cubic centimeters each were given, five in all, and improvement began after the first. He recovered entirely and was able to attend to all of the duties of a soldier. Even an isolated instance, when so striking as this, is at least suggestive and would warrant a further trial of the serum in the late complications of diphtheria.

News of the Week.

Tuberculosis Exhibition.—The International Tuberculosis Exhibition brought to New York from Washington largely through the efforts of Dr. Alfred Meyer, opened at the Museum of Natural History on November 30. At the opening meeting addresses were made by Mayor McClellan, Mr. Robert W. De Forest, Mr. Edgar J. Leavey, Dr. Darlington, Dr. Meyer, Dr. Abraham Jacobi, and Prof. H. F. Osborn of the Museum. The exhibition will be open daily from 10 A. M. to 11 P. M. and on Sundays from 1 to 5 P. M., and no tickets are required. Besides the exhibit work on the three floors of the museum there will be a number of special conferences for the medical profession, churches, Y. M. C. A.'s, labor unions, telephone operators, street railway employees, and others. These conferences taken in connection with 40,000 posters to be displayed, street car cards, and more than one million pamphlets to be distributed or mailed, will, it is believed, interest nearly one million people in the subject and constitute the greatest battle against disease ever waged in an American city.

Physicians are taking an active part in the campaign and will hold a series of conferences as follows:

Dec. 4.—Mass Meeting of Physicians. Speakers: Drs. Lawrence F. Flick, Edward L. Trudeau, Simon Flexner, Joseph D. Bryant, and Mr. Edward T. Devine.

Dec. 8.—Mass Meeting of Medical Students. Speakers: Drs. G. F. Laidlaw, H. M. Biggs, W. B. James, Woods Hutchinson, W. Gilman Thompson, John B. Huber, and S. A. Knopf.

Dec. 18.—General Mass Meeting under auspices of the Homeopathic Medical Society of the County of New York. Dr. George F. Laidlaw, presiding. Speakers: Dr. Thomas Darlington, Hon. Robert Hebberd, Hon. Eugene H. Porter, and Dr. H. D. Pease.

Dec. 11.—Special Medical Meeting, under auspices of Public Health Section of the Academy of Medicine, Dr. John A. Wyeth, presiding. Dr. Walter F. Wilcox will be one of the speakers.

Monday, December 21, has been set apart as "New York State Day." The responsibility for organizing the meetings and exercises of New York State Day, at the request of the authorities of the Exhibition, has been accepted by the State Charities Aid Association, which will have the cooperation of the New York State Department of Health. The Hon. Joseph H. Choate, President of the State Charities Association, will preside over the general public meeting to be held in the evening. Among those who have been asked to speak are Hon. E. H. Porter, State Commissioner of Health, under whose administration that Department has carried into effect comprehensive and far-reaching educational campaigns for the prevention of tuberculosis; Hon. James W. Wadsworth, Jr., Speaker of the Assembly; Hon. Horace White, Lieutenant Governor Elect. Hon. John Williams, Commissioner of Labor, who is to speak on the Medical Inspection of factories with special reference to tuberculosis; Bishop Nelson of Albany, who is chairman of the local sub-committee on pubulicity, and has done most effective work in this line: Dr. William M. Gibson of Utica and Dr. Herman N. Biggs of New York City; John Mitchell of the National Civic Federation; Hon. Joseph T. Alling, President of the Rochester Health Association; Hon. Martin E. McClary, President Board of Managers of Ray Brook State Hospital.

Vanderbilt Clinic Day Camp.—The roof of the Vanderbilt Clinic, which has been prepared for the open-air treatment of tuberculosis, received its first quota of patients on November 30. On the Saturday preceding, the camp, which is to be known as the Red Cross Day Camp of the Vanderbilt Clinic, was open to inspection by those interested in the maintenance of the work. The entire roof over the laboratories, about 110 feet in length, has been covered with a waterproof flooring, and

along the northern wall a shelter has been erected which is completely open to the south. In the center there is a small but complete diet kitchen where a luncheon will be served to the patients, who will also be supplied with milk and eggs twice during the day. About forty or fifty patients will be accommodated, and steamer chairs and rugs are provided for them. The Ladies' Auxiliary of the Vanderbilt Clinic, which has recently been formed, is taking an active interest in the work and will assist in providing amusements, games, clothing, and such other extras as may be needed. The camp is under the direction of the Professors of Medicine, Diseases of Children, and Applied Therapeutics of the College of Physicians and Surgeons, and the attending physicians are their respective Chiefs of Clinic, Dr. L. R. Williams, Dr. E. La Fetra, and Dr. H. S. Patterson. Two other physicians will also be in attendance during the day, as well as several nurses.

Tuberculosis Sunday.—In response to a request made by the Committee on the Prevention of Tuberculosis of Brooklyn, many Brooklyn ministers set apart Sunday, November 22, for a discussion of means of preventing the spread of the disease in the borough. In some of the churches addresses were made by speakers sent out by the Committee, and collections were taken up to assist in carrying on the work. There is a great need for more dispensaries for the treatment of the disease and for nurses to reach the sick in their homes. New York clergymen have been requested to observe Sunday, December 6, in the same way.

Labor Men and Tuberculosis.—The Central Federated Union has decided to hold its regular meeting on Sunday, December 13, in the Assembly Hall of the Museum of Natural History, and to follow it with a mass meeting in connection with the Committee on the Prevention of Tuberculosis. Addresses will be made by physicians and by labor delegates from trades in which there is a danger of tuberculosis, and opportunity will be given to view the exhibition which is to open on November 30.

Health of the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission for September, 1908, shows that the sick rate per thousand is considerably less than that for September, 1907, although the usual decrease from the August rate did not occur. As compared to September, 1906, the decrease in the sick rate is very marked, being about 12 per thousand; that is, there was saved in the working force, in September, 1908, over September, 1906, 16,200 days of sickness. There has also been a notable decline in the death rate, particularly among the negroes. In September, 1908, the total death rate was 12.78, and the total number of deaths, 48; in September, 1906, the rate was 57.34, and in September, 1907, 28.63. The death rate among negroes has fallen in the past three years from 67 per thousand to 10.65 per thousand, and during the last six months has several times been lower than the rate among the whites. For some reason the whites seem to be much more exposed to death by accident than do the negroes. For example, of the 19 deaths among the whites during September, 12 (more than half) were due to violence; of the 29 deaths among negroes but 5 were violent. Dr. Gorgas, Chief Sanitary Officer, suggests that under present conditions, the number of cases of malaria may be considered an index of the conditions of sanitation. In September, 1907, 1,811 cases of malaria among employees were admitted to the hospital; in August, 1908, 1,525, and in September, 1908, 1,410, showing a decrease of 401 cases from last year. No case of yellow fever or plague has occurred in the Canal Zone within the last two years.

Cholera.—An increase in the number of cases of cholera in St. Petersburg occurred during the last week in November, most of them among the better class of families. The expectation that the cholera would die out entirely with the advent of cold weather has not been fulfilled. In Manila the situation has so greatly improved that Admiral Sperry reversed his decision not to allow the men of the Atlantic fleet shore leave during their stay there, and this was accordingly granted from November 26 to November 30.

Foot and Mouth Disease.—With the disease already reported in four States, and reaching almost to the source of New York City's milk supply, the situation has become alarming. Michigan and Maryland are the two last quarantined and traces of the disease have been reported elsewhere. Both England and Canada are maintaining a strict quarantine, and President Roosevelt has forbidden the exhibition of any cattle from the infected areas at the International Stock Show in Chicago.

Death Rate in New York.—For the week ending November 21, the death rate in New York was 14.58 per 1,000, with a total of 1,236 deaths. During the same week in 1907, the death rate was 16.09, and the total number of deaths 1,322. The statistics show a decrease in deaths from pneumonia and tuberculosis, and an increase in those from heart disease.

Our Falling Birth Rate.—During a lecture on Births and Birth Rate in the course in Sanitary Science at Cornell University recently, Prof. Walter F. Wilcox stated that from 1860 to 1900 the proportion to each 1,000 women of child-bearing age in the United States has decreased by 152, or an average of about 30 in each decade. If such a change, he pointed out, were to continue unchecked for a century and a half, there would be no children left. Prof. Wilcox said that the true reason for this fall, is that in modern times births and the birth rate have come to be the control of human will and choice to a larger extent than ever before. Under these conditions modern societies are apparently showing a tendency to increase from the classes with less prudence of self-control than the average, and thus to eliminate the most desirable lines of descent, somewhat as the monastic system has been said to do. He pointed out, also, that among men who were graduated from college probably one-fourth and among women two-fifths remain unmarried, a much larger ratio than in other classes.

Newark Water Supply.—The residents of Newark, N. J., have recently complained of the condition of the city water, which has had an oily or fishy taste and a pronounced odor, nauseating to those who attempted to drink it. Chemical examination has shown that the trouble is caused by the growth of the organism asterionella, the development of which is favored by low water in shallow reservoirs. The city engineers have begun to treat the lakes in the watershed with copper sulphate as a means of killing the organism. As a result of the city water becoming unpotable, Newark has very nearly experienced a famine in bottled waters.

Medical Reserve Corps.—Several leading physicians and surgeons were recently appointed First Lieutenants of the Medical Reserve Corps of the United States Army, among them Dr. Wm. T. Bull,

Dr. Roswell Park, Dr. Alvah H. Dotay, Dr. Simon Flexner, Dr. Thomas Darlington, Dr. Frank Foster, and Dr. Alexander Lambert of New York. All passed with "distinguished standing." They are liable to be called upon in an emergency for professional services, and when they are, they will be rapidly promoted to a rank more in keeping with their stations in civil life.

Hospital Ship in Storm.—The hospital ship *Relief*, which sailed from Manila on November 15, bound for San Francisco, was badly damaged by a typhoon which was encountered on November 18, during which the engines were disabled and fire broke out on board. This, however, was controlled by the crew, which showed splendid discipline. After being five days overdue at Guam, the vessel was reported, on November 25, from Southern Luzon, P. I. The *Relief* is under the command of Surgeon Charles F. Stokes, and during the anxious five days in which she was overdue, the question of the advisability of putting a medical officer in command with a civilian sailing master was acutely to the fore. The result proved that a capable surgeon is as fit to command a ship at sea as any other man of sound judgment and nautical experience.

Philadelphia Clinic for Home Treatment of Chest and Throat Diseases.—The Board of Trustees of this institution has recently purchased the property, 2114 Lombard street, and has made application to the State Board of Charities for an appropriation to adapt the building for the work of the Clinic. Until these alterations are completed the Clinic will continue to be held in the temporary rooms, 519 South Fifteenth street, Mondays, Wednesdays, and Fridays at 3 P. M. The work of the Clinic has been very satisfactory. Dr. Frank Read is President of the Board of Trustees, and Dr. Thomas J. Mays is Medical Director.

German Hospital, Philadelphia.—On Donation Day on November 26 the German Hospital received, in addition to nearly $8,000 in cash and $750 in useful articles, two donations of $5,000 each for free beds, one for the benefit of the members of the First Regiment, N. G. P., from Mrs. Bessie McClure in memory of her son, Dr. Sorden McClure, the other from Mr. George W. Bremer in memory of his parents, Lewis and Catherine Bremer.

Beth Israel Hospital.—At the graduating exercises of the Beth Israel Hospital Training School for Nurses (New York) on November 24, gifts to the amount of $60,000 for a new building for the hospital were announced. It is planned to locate the new institution on the East Side somewhere between Houston and Fourteenth streets. The graduating class of the school numbered eleven.

Hospital of the Rockefeller Institute.—At a recent meeting of the Board of Directors of the Rockefeller Institute for Medical Research, Dr. Rufus I. Cole of the Johns Hopkins Medical School, Baltimore, was appointed Director of the Hospital of the Rockefeller Institute for Medical Research and Dr. Christian A. Herter was appointed one of the Physicians to the Hospital. Work on the hospital buildings is in progress and it is expected that they will be completed and the hospital be ready for opening in November, 1909.

Hospital for Nervous Diseases of the City of New York.—An examination for the appointment of two internes in this hospital will be held on December 15. Application should be made to Dr. E. L. Hunt, secretary of the Medical Board, 54 W. Fiftieth street, Manhattan.

Dr. Daniel R. Brower of Chicago was recently appointed a member of the State Committee which is to have in charge the investigation of conditions at the Cook County Insane Asylum, Dunning.

Dr. E. C. Dudley of Chicago was recently elected an honorary member of the American Medical Association of Vienna. He is the third physician to receive this distinction. The other two honorary members are Dr. Politzer of Vienna, and Dr. W. W. Keen of Philadelphia.

Mme. Curie, the widow of Prof. Curie and with him joint discoverer of radium, has been appointed Chief Professor of Physics in the Faculty of Sciences of the University of Paris. Mme. Curie succeeded her husband in the professorship which he held in the Faculty before his death.

Athletics in the Public Schools.—Dr. C. Ward Cramptom, the new director of physical training in the New York public schools, is taking an especial interest in developing athletics among the boys of the elementary schools. The Board of Education has recently made official the practice for class athletics and the athletic badge test hitherto conducted in a few of the schools. The Public Schools Athletic League offers trophies for the class in each borough making the best record in each of the events.

Nobel Prize Awards.—It has been officially announced that the Nobel prizes for 1908 are to be awarded as follows: For chemistry, Prof. Ernest Rutherford, Director of the Physical Laboratories of the University of Manchester, England; for literature, Algernon Charles Swinburne; for physics, Dr. Max Planck, Professor of Physics in the University of Berlin; for medicine, divided between Dr. Paul Ehrlich of Berlin and Prof. Elie Metchnikoff of the Pasteur Institute of Paris. Prof. Metchnikoff is quoted as saying that as Theodore Roosevelt and other recipients of the prize in other fields have devoted the money to continuing the work in which they were interested, he intends to do the same "in continuing his efforts to discover how the body can get its chance, so to speak, and how it can be prevented from being needlessly sacrificed in early youth—comparatively, that is—at 70 or 80 years of age, when it ought to hold out until it is 150."

Publicity Pays.—The report of the management of the Mount Morris Plains (N. J.) Insane Asylum shows that the innovation which was made there last year in advertising for all supplies and making contracts therefor with the lowest bidders, has been successful. The result has been a saving of nearly $2,500 for the year.

Health of Montclair.—The rumor of an epidemic of scarlet fever in Montclair, N. J., has been met by the publication by the Board of Health of statistics for the month ending November 20. The report shows that during that time there were but nine cases of scarlet fever in the town. But one case of diphtheria had occurred among the four thousand school children since the schools were opened in September.

Harvey Society Lecture.—The fifth Harvey Society Lecture will be delivered on Saturday, December 5, at the New York Academy of Medicine, at 8:30 P. M., by Dr. M. J. Rosenau and Dr. John F. Anderson of the United States Public Health and Marine Hospital Service. The lecture will be on "Anaphylaxis."

New York Pathological Society.—At a joint meeting of this Society with New York Surgical Society on December 9, 1908, Dr. John Howland

and Dr. A. N. Richards will present a paper on "An Experimental Study of the Pathology and Metabolism of Delayed Chloroform Poisoning." The discussion of the paper will be opened by Dr. Gideon Wells of Chicago, Dr. James Ewing, and Dr. Charles G. L. Wolf. A discussion of the clinical aspects will be introduced by Dr. George E. Brewer.

American Association for the Advancement of Science.—The sixtieth meeting of this Association will be held in Baltimore, December 28, 1908, and January 2, 1909, under the presidency of Dr. T. C. Chamberlin of the University of Chicago. The permanent secretary is Mr. L. O. Howard of the Smithsonian Institute, the general secretary, Dr. J. Paul Goode of the University of Chicago, and the secretary of the Council, Dr. D. C. Miller of the Case School of Applied Science, Cleveland, Ohio.

American Society of Sanitary and Moral Prophylaxis.—A regular meeting of this Society will be held at the New York Academy of Medicine, on Thursday evening, December 10, at 8:30 P. M. The subject for discussion will be "The Lecture Work of this Society." Papers will be presented by Thomas M. Balliet, Dean of the School of Pedagogy, Prof. F. N. Seerley, Dr. Emma E. Walker, and others; followed by a general discussion.

The Eastern Medical Society.—The annual dinner of the Eastern Medical Society was held at the Hotel Astor, New York, on Thanksgiving night, November 26. Dr. Abraham Jacobi was the toastmaster, the speakers included Dr. Wolf Freudenthal, Rabbi Stephen Wise, and Dr. William K. Polk.

The Penobscot County (Me.) Medical Association held its 55th annual meeting on November 17, at Bangor, and elected the following officers: *President,* Dr. Harry Butler; *First Vice-President,* Dr. J. E. Lethiecq; *Second Vice-President,* Dr. H. P. Clough; *Secretary,* Dr. J. B. Thompson; *Treasurer,* Dr. H. H. Crane. The following standing committee was also appointed: Dr. W. C. Peters and J. O. Bemis of Bangor, and Dr. C. M. Thomas of Brewer.

Obituary Notes.—Dr. Thomas M. Wilson of Chicago died on November 19 in the Presbyterian Hospital in that city, after a three weeks' illness from glanders, aged 38 years. Dr. Wilson was graduated from the Rush Medical College in 1906, and has served as an interne in the Presbyterian Hospital and as instructor in pathology in the Chicago Veterinary College. For some time past he had devoted his spare hours to the study of glanders, in an effort to produce a serum to counteract the effects of the bacillus. His death adds another name to the list of martyrs to research.

Dr. A. J. Gibbs of Denison, Texas, died at his home on November 12, aged 72 years. Dr. Gibbs was graduated from the Pennsylvania Medical College in 1857, and had served as city physician and as a member of the Board of Health of Denison. He was a member of the American Medical Association, and of the County Medical Society, a veteran of the Civil War, and formerly editor of the *Eureka Springs Medical Journal.*

Dr. Walter M. Jackson of Stamford, Conn., died suddenly on November 15, aged 56 years. Dr. Jackson, who was a graduate of Harvard Medical School, after a few years of practice in Providence, R. I., settled in Stamford about seventeen years ago, and devoted himself largely to laboratory experiments. He had taken out a number of patents on various devices.

Dr. Charles Dexter Noble of Norway, Maine, died at his home, on November 9, after a long illness, aged 65 years. After serving during the Civil War in the 17th Maine, until wounded in the spring of 1864, Dr. Noble took up the study of medicine at the Louisville (Ky.) Medical College, graduating in 1867. In 1869 he settled in Oberlin, Ohio, where he remained in practice for nearly thirty years. During the Spanish War he served as surgeon in the 5th Ohio, and from 1900 to 1902 served in the Philippines. Here, however, his health gave away, and after his return he was unable to resume practice.

Dr. Armand Mignault of Salem, Mass., died at his home, on November 13, aged 53 years. Dr. Mignault was a native of Canada, and was graduated from the Victoria Medical College, Montreal, in 1886. He had since practised in Lowell and in Salem. He was a member of the Massachusetts Medical Society.

Dr. Hanley Nelson Bushnell, for many years a practitioner in northern New York, died at his home in East Orange, N. J., of old age, on November 28. Dr. Bushnell was born in 1827, and was graduated from the medical department of New York University in 1848. He retired from practice several years ago.

Dr. Gabriel P. Reeves, a well-known citizen of Yonkers, died at his home, on November 25, aged 99 years. Dr. Reeves was graduated from the medical department of New York University in 1845, and had practised in Yonkers from 1857 until his retirement a few years ago.

Obituary.

ANDREW J. McCOSH, M.D., LL.D.

NEW YORK.

Dr. Andrew J. McCosh, a prominent surgeon of this city and a man of many friends, died on Wednesday of this week, as a result of fracture of the base of the skull received last Saturday in a runaway accident. Dr. McCosh was born in Belfast in 1858, and came to this country with his parents when his father was called to the presidency of Princeton College in 1868. He studied at Princeton, and was a member of its first football team. Being graduated in 1877 he began the study of medicine at the College of Physicians and Surgeons, New York, receiving his degree with the class of 1880. After a year of postgraduate study in Vienna, he began practice in this city in the office of Dr. T. Gaillard Thomas. Dr. McCosh was surgeon to the Presbyterian Hospital and professor of clinical surgery in the medical department of Columbia University. He was a member of the American Surgical Association, of the Medical Society of the County of New York, of the New York Academy of Medicine, and of the American Medical Association.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

KING'S BIRTHDAY HONORS—BRADSHAW LECTURE—TUBERCULIN BY THE MOUTH—LISTER AND WEST HAM—MRS. GARRET ANDERSON A MAYOR—PLAGUE IN LIVERPOOL—OBITUARY—THE CENTENARIAN AND OTHER AGED MEMBERS OF THE PROFESSION.

London, November 13, 1908.

The list of honors conferred on the King's birthday will both please and disappoint. Of course, the politicians and supporters of the Government and free trade run off with the chief. But science and medicine get a few crumbs. Alfred Russell Wallace, F.R.S., has the Order of Merit, although this may be due to his chairmanship of the Land

Nationalization Society as much as to his great scientific position. Sir G. A. Critchett is promoted to the baronetage. Dr. Percival Hartley, Secretary of the Committee of the King Edward Sanatorium, has a step in the Victorian Order. Jonathan Hutchinson is given a knighthood. Such a title is scarcely appropriate for a veteran whose fame has penetrated every civilized country. I am sure the King would have fully realized his work if it had been explained in the weakest terms. The Premier and his cabinet have served him badly. If hereditary title was not desired His Majesty would have selected an appropriate distinction had he been properly informed. Dr. Thomas Oliver also gets a knighthood, largely, no doubt, in recognition of his excellent work in hygiene, especially on the White Lead Commission and the Madrid International Exhibition, and as Medical Expert in Dangerous Trades; but he has done good work as a physician, too. Dr. Donald Macalister enters the Order of the Bath. Dr. Stewart Woodhouse, who has served on the Irish Prisons Board, receives a knighthood. So does Dr. J. J. Thomson, Cavendish Professor of Experimental Physics, who received the Nobel Prize in 1906.

The Bradshaw Lecture at the Royal College of Physicians was delivered on the 3d inst., by Dr. W. Pasteur, of the Middlesex Hospital. He took for his subject, "Massive Collapse of the Lungs," treating at length of those cases which depend on imperfect power of expanding the thorax. Our knowledge about this may be chiefly derived from cases of paralysis of the diaphragm, the latest advance being due to the advent of radioscopy. Since the introduction of the orthodiograph, which eliminates the error due to the magnification of the shadow, accurate records of the size and position of the thoracic viscera in different phases of respiration have been obtainable, and by it Dr. Halls Dally has carried out a series of observations to which the lecturer referred in appreciative terms, and stated that during the last year he had obtained confirmatory results. He added that there are strong reasons for believing that the central tendon of the diphragm, contrary to former belief, moves freely in respiration. Dally, among others, has found that its curvature undergoes little change in its descent. Supported below by the viscera, it acts somewhat like a piston, pushing them forward and downward, and expanding the lower ribs. If the descent of the viscera is prevented by contraction of the abdominal muscles, the force is chiefly expended on the lower ribs. The expanding force of the diaphragm accordingly is for the most part exerted on the portion of the lungs below the great fissures—that is to say, on the lower lobes—and the study of cases of diaphragmatic paralysis shows what happens to the lungs when this force is removed. The lecturer then mentioned a series of 64 cases of diphtheritic paralysis observed by himself, the diaphragm being involved in 28. Clinical evidence is not so definite in cases of massive collapse. The physical signs may be due to compression, consolidation, or collapse, and the state of the patient may not permit careful examination. Curiously, too, when these signs have been most marked the patients have recovered, but they were mostly those of affections of the upper lobes from paralysis of the intercostals. Those form a group with apical signs for the most part. In another group—diaphragmatic—the signs point to the bases. Rarely the two groups seem combined with physical signs all over one lung. The lecturer had noticed a paradoxical symptom which he would not at present explain: That was exaggerated action of the lower ribs as an early indication of diaphragmatic failure, most obvious when the paralysis is well marked, disappearing as soon as the function is restored. In intercostal paralysis no sign is of greater value than flattening of the chest wall unilateral or bilateral. Another feature of importance is rapid onset of symptoms and equally rapid improvement on restoration of function. Massive collapse differs from the patchy or lobular form in being due to muscular weakness, and it may occur in the absence of bronchial obstruction, although the two may co-exist. Any degree of inflation of the lung may promote lobular collapse when there is any obstruction in the air-way, but the mode of production is different. Massive collapse is an active process; lobular, passive. The former is brought about by the active exercise of the elasticity of the lung, the latter, as usually held, by a passive removal of the air from portions of the lung, cut off by bronchial occlusion from the external air.

So far as to diaphragmatic paralysis. In contrast to it costal paralysis throws upon it all the work of respiration. The lecturer had seen two cases of this in the last ten months, and described them. In each there was duirng inspiration a definite diminution in girth of the upper part of the chest in striking contrast with the expansion of the lower ribs by the diaphragmatic action. Still, it is not easy to account for the further falling in of the ribs in this condition, except on the supposition that the root of the lung moves freely in respiration, and is not fixed, as it was thought to be. It would appear, then, that in complete paralysis of the upper ribs the expanding power in the diaphragm is not sufficient to prevent collapse of the upper lobes and in complete loss of that expanding power the costal breathing cannot maintain the expansion of the lower lobes.

The observation that pulmonary lesions may be caused by diaphragmatic failure led the lecturer to ask whether the same agency might not be sometimes responsible for the chest complications after severe operations. These are most often abdominal and the bases of the lungs most liable to be affected. Sepsis, anesthetics, cold, irrigations, aspiration of secretions during insensibility, and other things have been invoked to explain the post-operative lesions. Thinking that interference with the action of the diaphragm might be a cause, the lecturer had examined some patients under *x*-rays shortly after gastroenterostomy and had hoped to be able to bring forward some conclusions on this occasion, but the cases were not at present sufficiently numerous. He, however, exhibited some orthodiagrams and hoped to obtain tracings to throw further light on the subject. He had also seen 4 cases of massive collapse in the post-mortem room. The condition, he thinks, has been overlooked or neglected. It may lead to entire deflation of one or more lobes, is generally caused by the muscles which are the direct distenders—the diaphragm and intercostals—but there are strong reasons for thinking the reflex inhibition of diaphragmatic movement may lead to the same result. This, too, may throw light on post-operative lung complications.

Ever since the use of tuberculin was introduced one has heard at times the question casually put, What would be the effect of giving it by the mouth? I have on many occasions joined in a little speculation on the question when started among friends, but I had no definite facts to go upon until Drs. Arthur Latham and A. C. Inman communicated to the Royal Society of Medicine (*Proceedings* No. 6) a paper stating that administration by the mouth or the rectum would elicit a satisfactory immunizing response. They showed that the effect was to reduce fever, diminish the daily fluctuations of temperature and the curve of the opsonic index in tubercle, etc., was almost the reverse of the temperature curve. Since that preliminary paper (April last) they have continued their research, with the result of confirming their previous work and perhaps of also extending it. One cannot forget how at the earliest trials of tuberculin in this country the effects were so often disastrous that its use was speedily discontinued. In Germany it was held to be useful, and our ill-success attributed to improper doses or methods. One of the results of Sir Almroth Wright's work is a reconsideration of this matter. Doses are now given that only serve to raise the opsonic index, the aim being to keep the patient as long as possible in the "positive phase." Meantime Drs. Calmette and Breton have shown that tuberculin given by the rectum produces the same effect as when injected under the skin, on the announcement of which fact early this year it seemed that many patients might prefer the method. This is also confirmatory of the report on which I am commenting on administration by the mouth. Drs. Latham and Inman state definitelv that the same effects on both the temperature and opsonic curves are produced by the mouth as by injections, and further, that as far as they can judge, the dose by the mouth is about equal to half that by the skin. The effect of a dose on an empty stomach is rapid, often within an hour—an excessive dose is followed by undue intoxication in from one to two hours.

The point of most difficulty and yet of most importance is the determination of the dosage. It is desirable to do this before beginning the treatment, and it is best done by the opsonic index. But in acute pulmonary tuberculosis that should be determined three times a day—a demand to be met in the research laboratory. Within limits it appears that the correspondence of the clinical symptoms with the curve may be utilized for practice, but the initial index ought to be taken and then the official observations. But even so the opsonic index should be taken from time to time as a safeguard, for it must never be forgotten that tuberculin is a dangerous thing to be introduced hy any method, and its use demands as much care as the most active poisons. It is of little use while successive autoinoculations occur. To arrest these or limit them absolute rest is the only resource. The Germans continue the plan of giving gradually increasing doses at stated intervals, but the plan is not advisable, and is only satisfactory in a limited class of cases. Mr. Oliver Bruce in the laboratory of the hospital greatly assisted in the research, and the authors express their gratitude, as they do also to the physicians whose beds were placed at their disposal.

The freedom of West Ham has been conferred on Lord

Lister at his country house, and he has written thanking the citizens of his birthplace, with regret that his health had not permitted him to receive the distinction in public.

Mrs. Garrett Anderson, the first English lady doctor, has been elected Mayor of Aldeburgh, of which town she and her family have been benefactors. She was proposed on this account by a doctor, who said that on principle he objected to women presiding over assemblies of men, but this was an exceptional case. Mrs. Anderson in accepting said the mayoral robe had no terrors for her. She would have worn a mortar board, but when she once appeared in that headgear it made His Majesty smile, so she had had a black velvet bonnet specially made.

Three cases of plague have occurred at Liverpool, as probably you have heard by cable. Two have died. The origin of the first has not been traced. It is not expected to spread further.

Our medical centenarian passed away on the 16th inst. Sir Henry Alfred Pitman, who reached his one hundredth birthday on July 1, and who was for so long Registrar of the Royal College of Physicians (from 1858 to 1889), when he was named Emeritus Registrar, was born on July 1, 1808, entered Trinity College, Cambridge, in 1827, and took his B.A. in 1831. He was elected F.R.C.P. in 1845, assistant physician of St. Georges' Hospital 1857, and remained on the staff until 1886. From 1876 to 1886 he represented the college in the General Medical Council. His Knighthood dated 1883. On attaining his one hundredth birthday in July the King telegraphed his congratulations, and his friends presented him with a silver gift bowl. The funeral, on Wednesday, was attended by many old friends, including the president of the college he had served so well.

Some other aged members of the profession have also passed over to the majority.

John Briscoe, F.R.C.S., many years surgeon to the Radcliffe Infirmary, Oxford, and to the prison, has died at the ripe age of 87. He had retired from active work for twenty years or more. He qualified in 1842, and was elected to the fellowship of the college in 1875.

Dr. John Tudor, J.P., of Dorchester, died on the 19th inst., aged 85. He qualified in 1847. He was many years surgeon to the County Hospital, and had been surgeon also to the Seaman's Hospital. He contributed to the Medical Chirurgical Society on excision of the elbow as long ago as 1858.

Dr. Ben. F. Popham of Kensington died on the 10th inst., in his 83d year.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 19, 1908.

Acute Gonorrheal Epididymitis, with Special Reference to the Operative Treatment.—Under the general headings of definitions, pathology, prognosis symptoms, and diagnosis, J. H. Cunningham covers familiar ground. When he takes up the question of treatment he claims for operation that it shortens the suffering, arrests the course of the acute process, lessens the period of confinement, and shortens convalescence and after-treatment. The general principle involved is the surgical one of drainage to an infected organ. It is only within the past two years that operative treatment in this affection has received serious consideration. The author describes the Hagner method of operating, and summarizes his personal experience with it in seven cases. In some of these the vas deferens was drained by the Belfield method. Following operation it is advisable to use massage and to give deep instillations of 10 per cent. argyrol. Induration in the epididymis remains after operation, but it is not of the discreet nodular type generally observed in an epididymis previously the site of gonorrheal infection. Instead, it is the induration commonly observed after drainage of any inflamed structure. The sensitiveness so often noted in the testicle after epididymitis, and which often lasts seven months, has been absent. In conclusion, there is no question in the mind of the writer that the operation advised by Hagner greatly lessens the suffering and diminishes the duration of the disease. Whether or not the epididymis is left in a better condition to serve as a conduit for the testicular secretions cannot be determined. It is a notable fact that recurrent epididymitis has not taken place in any case in which the operation has been performed.

New York Medical Journal, November 21, 1908.

The Nature of Carcinoma in General, and the Early Diagnosis of Gastric Carcinoma.—J. M. Anders gives a general description of this disease, dwelling particularly on the matter of early diagnosis. He adds that this is, by medical methods, in our present knowledge out of the question, but it is practicable save only in cases marked by extreme latency, to assume the existence of strong suspicions by weighing the available facts and data. Under these circumstances, delay in the matter of requesting the application of surgical means is inexcusable, in view of the amenability of incipient malignancy to surgical art, in some cases, at least. As to the actual indications for surgical intervention he says that in the presence of the following grouping of features and conditions, or even a majority of the same, an exploratory operation should be advised, to be followed by radical extirpation in case the new growth be encountered: (1) If the patient's age is between the forty-fifth and seventieth years, the period of life in which carcinoma develops in the majority of cases. (2) If slight or moderate indications of secondary gastrectasis exist, confirmed by *x*-ray and physical examinations. (3) If the chemical examination repeatedly during the course of three or four weeks shows marked subacidity or absence of hydrochloric acid and particularly if lactic acid be also found. (4) If there is wasting without other assignable cause or causes, and moderate anemia with low color index and possibly leucocytosis. (5) If the condition resists treatment for several weeks. (6) If epigastric rigidity is present. (7) If a constant positive blood reaction is given by the stools with good motor functioning on the part of the stomach and neither free hydrochloric nor lactic acid is present.

Lipoma of the Kidney.—O. W. H. Mitchell reviews the recent literature of the subject, and discusses current views as to the pathology of this class of renal tumors. He appends a report of the case of a colored woman of 32 years who died from uterine carcinoma. The kidneys were dark colored, and their capsules stripped readily. On the surface of the left kidney, just beneath the capsule, situated entirely within the cortex of the organ, was a yellowish-white area measuring 6 x 8 x 7 mm. Microscopically the tumor consisted of fat and connective tissue cells. Many capillaries found in the tumor were distended with blood. The tumor was surrounded by a hyperemic zone. No pigmentation was found. The tissue of the kidney was congested and was in a condition of moderate catarrhal nephritis. The capsules of the tufts, which were in close proximity to the tumor mass, were much thickened. The preponderance of connective tissue in certain parts of the tumor would place it in the class of fibrolipomata of some investigators. No portion of kidney tissue was seen to be entirely surrounded by tumor tissue. The tumor presented an encapsulated appearance, the capsule being formed by compressed kidney tissue. Fat droplets were to be seen in some of the connective tissue cells which lie in close proximity to the tumor. Several glomeruli were to be seen adjacent to the tumor tissue. A body very similar to a glomerulus was seen within the connective tissue area surrounding the tumor, and fat droplets were found in some connective cells external to it.

Pulsation of Large Aneurysms Nonexpansile but Transmitted.—S. Lange has made a study of aneurysms with the fluoroscope, and says that he has repeatedly found that large tumors proven by autopsy to have been aneurysms failed to show on the screen any trace of pulsation. Yet some of these cases, in which the tumor pressed against the anterior or posterior chest wall, gave to the palpating hand the sense of an expansile pulsation, undoubtedly a transmitted one. On the other hand, small aneurysms and nonaneurysmal dilatations of the aortic arch have invariably shown fairly active pulsations upon the fluorescent screen. The smaller the aortic tumor, the more active the pulsations were. In this latter type of cases it was assumed that such active pulsations could occur only in the fluorescent screen, would almost disappear during diastole, only to swell out prominently during absence of accumulated blood clot, which presupposes an unbroken endothelium, hence the diagnosis of simple aortic dilatation was advanced. But when the aortic wall gives way and thrombosis occurs (a true aneurysm resulting) the pulsation becomes less active and the diastolic recoil less marked. When the tumor mass and its blood clot (the mass of which usually increasing with the size of the aneurysm) reaches considerable proportions, there is no longer any pulsation or diastolic recoil visible to the *x*-ray, although the palpating hand upon the chest may still feel a transmitted impulse.

Journal of the American Medical Association, November 21, 1908.

Cardiovascular Drugs.—J. L. Miller describes the characteristics of the more important remedies, dividing them into two classes: those which act chiefly on the heart, such as digitalis and strophanthus, and those which act chiefly on the vessels, such as the vasoconstrictors and the vasodilators. They are to be used when there is imperfect distribution of blood, due to cardiac insufficiency or lack

of vascular tone. The special cardiac remedies, the digitalis group, are to be employed when the imperfect distribution depends on cardiac insufficiency from valvular or muscular defect. The idea that such are not indicated in myocarditis is incorrect though greater care in dosage should be observed. Nor are they contraindicated necessarily in cardiac trouble with marked arteriosclerosis or high blood pressure. Heart insufficiency associated with slow pulse is often relieved by digitalis, which favors better emptying of the heart in each systole, better circulation in the coronary vessels, and consequent better nutrition of the heart muscles. There is still much difference of opinion as to the value of digitalis in aortic regurgitation. It should be remembered that it increases the systolic output which compensates in a measure for the greater amount returning during diastole, and Stewart has shown that, after all, the amount of regurgitating blood is small and prolonging the diastole is not a serious matter. The various members of the digitalis group have practically the same action, the difference is mainly one of degree. It is unfortunate that such a valuable drug as digitalis should have its objectionable features. These are chiefly its variable strength, its irritating action on the gastrointestinal tract, and cumulative effects. As regards the first there is no reason why a standardized preparation of digitalis should not be made. The cumulative action and the gastrointestinal irritation cannot be entirely overcome, and the daily secretion of urine and character and frequency of the pulse need to be watched during the administration. When an increased secretion of urine is observed, usually occurring within 48 hours, the dosage should be lessened and the lessened dose may be continued often for a considerable period without danger of cumulative action. The patient must be seen daily while taking full doses, and too much stress cannot be laid on arrhythmia as an evidence of intoxication. With a preparation of known strength and careful watching, it should not occur. The resort to intravenous medication is mentioned as proper in certain cases, but it is reserved for those cases in which prompt action is required and when administration by the mouth is prevented by gastric irritation. Strophanthus differs from digitalis in its less powerful action and somewhat less cumulative action. The second class of drugs, the vasomotor ones, is next taken up. First, the vasoconstrictors of which the most important are adrenalin, caffeine, camphor, and strychnine. These are described in detail, the most active is adrenalin, but its action is very transitory, lasting only from five to ten minutes; it should be given subcutaneously or intravenously, the dosage is from ten to fifteen minims of the 1 to 1000 solution. Caffeine holds the first place as a vasoconstrictor in the acute infections and camphor has similar effects though less constant. In ordinary doses strychnine can hardly be considered a vasomotor drug, and it is only when the dose approaches the toxic one that the blood pressure is increased. The vasodilators have a rather uncertain position in cardiovascular therapy. With our present knowledge, nitrites and nitroglycerin in physiological doses are absolutely contraindicated in the heart failure of acute infection. The value of alcohol as a cardiac stimulant has been much disputed, but Miller thinks that its dilating action on the external vessels renders it useful in shock and when there is engorgement of the splanchnics with insufficient filling of the peripheral vessels. The use of vasodilators in hypertension is discussed and the conflicting results of experiments noticed. Miller thinks, however, that we may safely use vasodilators in cases of extreme hypertension (over 200 mm. of mercury), and in headaches which are relieved by lowering pressure. The treatment of angina pectoris is especially discussed and Miller thinks, from certain experiments made by himself and Dr. Matthews, that it is possible that the forcing of blood through the coronary vessels by digitalis may be useful, the drug being given intravenously or subcutaneously. As regards the treatment of arteriosclerosis, only the iodides can claim to be efficient.

Infant Feeding.—D. E. English criticises the modern scientific feeding of infants, as not calculated to favor the proper development of the infant's stomach into the complex organ of the adult. What is wanted is an elastic muscular organ and this, he claims, is not so likely to be produced by regular frequent feeding, which, moreover, disturbs the infant's rest. He advises instead, allowing the baby to feed till it is full, without regard to the amount. This stretches the stomach and gives its muscle the exercise it needs to develop it. Then let the infant sleep as long as it will, under the most favorable conditions, and when it wakes don't feed it at once but wait till it is hungry. If it is thirsty or fretful give it water and soothe it, but do not mind mere crying—it does the baby good. This exercise of crying somehow prepares the stomach for its next load of food. When the crying threatens to change to a sickly wail, then feed the baby and feed him full. The intervals of feeding will be irregular. During the first month they may sometimes be as short as two hours, sometimes as long as four hours in the day and six or eight at night. The feedings for the first three weeks will average for the twenty-four hours, seven or eight, rarely nine. General hygienic treatment is inseparably connected with the success of any method of feeding. Under this plan of feeding and general treatment, it is astonishing, English says, how easy it is to modify the milk to suit the baby. Fed in this way, kept out of doors and not overclothed, it soon develops surprising digestive powers. The foundation principle of the method is that a healthy infant cannot always digest the same amount of food in the same number of minutes. The amount he can digest depends on how much he has used up and how much he has earned by exercise, crying, etc., since the last feeding.

The X-Rays in Epithelioma.—G. E. Pfahler divides the epitheliomas, as regards their treatment by the Roentgen rays, into five classes: 1. Superficial epitheliomata of the exposed surfaces of the hands and face, which should yield practically 100 per cent. of cures. They are usually small in area, of slow growth and comparatively painless. They will usually require ten or twelve treatments and from two to three months for a cure; the results are more likely to be permanent than with any other treatment. If untreated there is a possibility of this form passing into the deep ulcerating type. 2. Superficial epitheliomata associated with senile keratosis also yield to the Roentgen rays very similarly to those of Class 1, but recurrences are much more probable. These patients also seem to have exposures at short intervals on account of the risk of dermatitis. 3. Pearly epitheliomata. These include a small group of cases in which there is a circle of pearl-like elevations forming a ridge and surrounding a central area much resembling healthy skin. The ridge spreads, often irregularly, while the center heals. They are of slow growth and not very malignant, but they yield to treatment less readily than the other superficial forms. Best results will probably be obtained by protecting the soft center and treating the border strongly with a very soft tube. 4. Under the class of deep ulcerating epitheliomata, Pfahler groups those cases that involve the deeper tissues and present large ulcerating surfaces, with indurated edges and often with an indurated base. They may involve any part of the body and are at times associated with enlargement of neighboring lymphatic glands. They often consist of recurrences of superficial epitheliomata of Class 1 after treatment with caustics, curettement or excision. These cases do not yield readily to the rays and should be excised when possible. 5. Epitheliomata on mucous surfaces, including those on the lips and inner surface of the cheeks, the vagina and the penis. In these cases no time should be lost by *x*-ray treatment, but the growth should be excised at once, and this followed by a thorough course of treatment with the rays over the glandular area.

Ruptured Tubal Pregnancy.—Hunter Robb thinks that there is room for conservative treatment in ruptured tubal pregnancy and that it is indicated in the majority of cases. When the diagnosis of the condition is certain, operative measures are indicated, but in most cases the danger is not so imminent as to demand immediate interference unless the condition of the patient is otherwise satisfactory. Many women not only survive tubal abortion or rupture, but even recover without operation. Not more than 5 per cent. die at the time of rupture, whereas the statistics that he has collected of immediate operation show a mortality of 8 per cent. In cases in which there is collapse or shock the operation should be deferred until this is tided over. Loss of blood rarely causes death and it is rarely sufficient in these caes; and he asks why we should add to the existing condition the additional shock of immediate operation. Clinical operation has shown that patients whose abdomens are filled with bloody fluid may survive, and dogs when experimentally subjected to like conditions do not succumb. In most cases we fail to find any bleeding vessels and the danger of restarting a hemorrhage is to be considered. Some reasons for not believing the hemorrhage to be so great as has been supposed are: (*a*) The great majority of ectopic sacs are ruptured between the first and third week of gestation. (*b*) The point at which the impregnation takes place is in a small area formed by a diverticulum in the tube, and the chorionic villi have only a feeble attachment. (*c*) From 75 to 78 per cent. of the ruptures occur through the fimbriated end of the tube, and are tubal abortions, not more dangerous as far as hemorrhage is concerned than those occurring through the cervix. (*d*) The next most frequent place of rupture is the isthmic portion of the tube which is free from any large blood vessels. (*e*) The point of rupture in the gestation sac practically never involves the ovarian or uterine artery. (*f*) As a result of the inflammation preceding the ectopic gestation there is a relative

increase in the connective tissue in the tube, decreasing its vascularity. (*g*) The placenta is generally attached to the posterior wall of the tube and as the rupture is generally through the anterior or lateral wall it is not lacerated, but retains its firm attachment to the wall of the tube and is subjected to pressure. Physiologists teach us that a woman weighing 130 pounds must probably lose four pounds of blood before succumbing to the hemorrhage *per se*. So much blood as this is rarely found in the abdomen. The bloody fluid is partly a serous exudate. Its sudden removal before the vessels have had a chance to adapt themselves is dangerous and may be fatal. When the bleeding would be enough to cause death the patient is rarely seen in time to be saved by ligation of the bleeding vessels and the best operators lose from 40 to 50 per cent. of their patients after immediate operation during shock. The results obtained by some who have waited are certainly worth considering. Robb reports experiments on dogs which suggest that hemorrhage may be determined from the hemoglobin readings and that the subcutaneous injection of physiologic salt solution usefully stimulates the patient and does not start up the hemorrhage again. They also suggest the use of proper bandages or the application of weights to the lower abdomen as hastening the stoppage of hemorrhage, rendering the pulse slower and of better quality and improving the general condition. He holds that it is better to leave something to Nature when there is any possibility that the immediate operation may be the wrong procedure.

The Lancet, November 14, 1908.

Seven Cases of Cheese Poisoning.—All the patients of W. B. Evans were young, the ages running from 3 to 16 years, and they were grouped in families, all of whom were evidently purchasers of cheese from the same source. Some of the adults in the same families who had eaten the cheese complained of nausea and epigastric pains. The younger the patient, the more severe were the symptoms. In all the children the symptoms were of the same type, pain, vomiting, and collapse of varying severity. In all a mustard emetic was given, with brandy and water in the cases collapsed. This was followed by a bismuth mixture, and in one case with diarrhea a dose of castor oil was given. All were well inside of 48 hours. The reporter says that the cheese had a strong odor and a somewhat crumbly consistency, but was not discolored or offensive, and had nothing suspicious about it to either seller or purchaser. He considers that it had developed tyrotoxicon, and that this alkaloid was the cause of all the trouble.

Quinine Poisoning.—The patient of A. C. Parsons was an American man of 35 years, who had lived in various countries, but had never contracted malaria as far as was known. On several occasions he had been upset by small doses of quinine taken for various purposes. When traveling from England to Nigeria he was advised by his fellow voyagers to begin taking quinine. He took five grains, which made him sick. On admission to a hospital two and a half grains of the bisulphate of quinine were given him in solution. In the course of an hour (at 9 A.M.) he had a sinking at the abdomen and flushing of the face. Intense irritation and discomfort then began in the feet and gradually spread throughout the body. This was quickly followed by a rapidly spreading rash, erythematous rather than urticarial in character and most marked on exposed portions of the body. His appearance had by now undergone a complete change; the face was flushed, and the skin everywhere was hot, hyperemic, and dry; the temperature, however, was subnormal. There were distracting tinnitus and frontal headache, but no amaurosis. The heart's action was seriously weakened, and the pulse was feeble, accelerated, and irregular; there were palpitation and shortness of breath. The patient looked and felt ill, the flushed appearance, restlessness, and general pruritus producing a picture of severe anguish. At noon he had a syncopal attack while trying to rise from his bed. At about 2 P.M. the pruritus and erythema began to pass off, but nausea and severe headache remained. At 3 P.M. the temperature had risen to 101° F., and he was perspiring profusely. By dinner-time he felt better, all the symptoms had cleared up with the exception of headache. At 10 P.M. he was sleeping quietly, with a normal temperature. Subsequent examination showed a marked anemia, with hemic heart murmurs. No malarial parasites were found in the blood. He set out for England, but died from some kind of "fever" on the voyage. The author says that it would be a sound practice if all officials and others who contemplate residing in malarial districts were examined as to their capability of taking quinine before they ventured out into unhealthy lands.

Recent Investigations into the Pathology and Treatment of General Paralysis and Tabes Dorsalis.—W. F. Robertson says that bacteriological, histological, and experimental evidence has been obtained bearing out the opinion that tabes dorsalis is dependent upon an invasion from the genitourinary tract by special diphtheroid bacilli. There is good reason to believe that as a predisposing factor gonorrhea is of greater importance than syphilis. One part of the evidence in support of the conclusion that a diphtheroid invasion is the essential element in the pathogenesis of tabes consists in successful therapeutic experiments. Certain cases under the author's recent care confirm his opinion that this disease if not accompanied by serious secondary infections can be combatted by serum and vaccine methods. Under such treatment the lightning pains, which in both cases were very severe, have virtually disappeared, the progress of the disease has been arrested, and the general health of the patients has undergone a very striking improvement. He adds that the facts recently observed have served to establish more securely the conclusions that general paralysis and tabes dorsalis are dependent upon the presence of specific infective foci, primarily localized in the nasopharyngeal and oral mucosa in the one case, and in the genitourinary tract in the other, and that in both diseases the bacterial and toxic invasion is essentially lymphogenous.

Novel Methods of Operation in the Removal of Malignant Tumors.—H. Manders exploits the "fulguration" method of treatment, which is a combined surgical and electrical procedure. Its novelty consists in the application of oscillatory electricity. The steps in a given operation are about as follows: (1) The surgeon divides the tissues and lays bare the neoplastic masses without separating them; (2) the tumor is "fulgurated" by the strongest sparks, so as to produce the greatest possible effects in the shortest time (maximum, ten minutes); (3) the growth is excised, and (4) the "fulguration" is repeated. The last step continues for about 45 minutes. The tissues become ischemic and the cut capillaries cease to bleed. No actual scab is formed, but a fine layer of clot, which eventually becomes detached, as happens in burns. The wound is then closed, provided with thorough drainage, and covered with gauze plentifully sprinkled with sodium biborate, over which is placed a large pad of cotton wool. This dressing, which is changed after 24 hours, is often very painful. Cicatrization is rapid after the slough separates, but complete healing is slower than after an ordinary surgical operation. The paper contains full details as to the electrical devices employed and their mode of application. Manders says that if "fulguration" has in any way reduced to a minimum the recurrence of cancer after operation the combined operation is fully justifiable, and must be regarded as a distinct gain in treatment. The demerits of the new operation are: (1) That the length of time during which the patient must be kept under anesthesia is much prolonged; (2) that the anesthetic must be chloroform, because the more volatile ether is apt to catch alight from the sparks; (3) that anesthesia, besides being prolonged, must be deep, because the fulguration, especially in the second stage of operation, when the biphase method is used, is very painful; (4) the disadvantage during the operation of having to change from one instrumentation to another; (5) the difficulty of managing and controlling a rush of violent sparks; and to these must be added (6) the uncertainty of being able to reach every part of the incised area with a series of sparks which are not continuous but intermittent, as will be explained immediately.

British Medical Journal, November 14, 1908.

Arteries, Normal and Pathological.—The paper of J. A. McWilliam and A. H. Mackie gives a series of illustrations of cross-sections of arteries in both health and disease, especially after pneumonia. In making their investigations the authors have found that in the majority of cases in which dissolution has been a gradual process of an exhausting nature preceded by high temperature, etc., the arteries have shown no sign of contractility when they came to their hands from the post-mortem room twelve to twenty-four hours or later after death. They presented all the characters of dead relaxed arteries when tested in various ways—the application of stimulating and relaxing agents, tracings of elasticity, etc. On the other hand, they found that in many instances, especially in cases of relatively sudden death, the vitality of the arteries may not be so readily lost, and contractility may persist for very considerable periods. Thus the renal artery of a man who had died suddenly from cerebral hemorrhage showed decided contraction in response to stimulation (chemical) twelve hours post mortem. After stimulation it gave the elasticity curve characteristic of contracted as contrasted with relaxed artery—a transverse strip when weighted did not give the maximum elongation with the first weight, but increasing elongations (with equal increments of weight) up to a maximum followed

by decreasing elongations. A portion of this artery put into the usual fixing and hardening fluids contracted markedly and showed a caliber and thickness of wall notably different from those of the same artery fixed in the relaxed state after vitality had been extinguished. In many other instances, both in the case of normal and pathological arteries, marked contraction has been seen to occur especially in response to chemical stimulation (chloroform vapor, alcohol, formol, etc.) as long as thirty hours post mortem. Full details are given of the methods employed in hardening and straining the sections.

A Case of Stokes-Adams Syndrome Observed for More Than Eight Years.—The patient of W. J. Turrell and A. G. Gibson was a man of 70 years, formerly considerable of a walker, and during his last ten years of life a gardener. He was first seen in 1899 for digestive troubles. His heart was weak at the time. Later he began to have series of convulsions of an epileptiform character. Later these seizures were accompanied by giddiness or fainting, but no convulsions. Later, mild attacks were brought on by the taking of food and by voiding of urine. A firm grasping of some solid object would at times ward off an attack. So the man went on for a term of years. His pulse was slow, even down to 16 at times, and had the habit of dropping beats. This occurrence seemed to be more marked with a relatively quick rate, but with the slower rate it seemed to be of more consequence to the patient, for when the pulse beats dropped to the slow rate he was more liable to an attack. He stated that the dropping of one beat did not incommode him, but if two beats in succession were dropped it was hard for him to remain conscious, and he often had an attack. A rate of 25 per minute seemed most comfortable for the patient. When it reached or exceeded 30 it became intermittent or irregular. Treatment seemed of little avail. In unusually severe attacks, large hypodermics of strychnine with small internal doses of brandy gave relief. He was finally found dead in bed, his livid appearance indicating a convulsion. Autopsy showed no gross change in the regions of His's bundle, or its branches, but the microscope showed a tendency to fibrosis in the region of the central fibrous body of the heart, extending downwards and encroaching especially on that region occupied by the bundle. The bundle in the fibrous body itself was represented only by a few isolated strands of muscular tissue.

Tuberculosis in Lime Workers.—W. J. Burns Selkirk has made some interesting observations as to health conditions among this class of workers. He finds the health of workers in lime kilns above the average. There seems to be far less than the normal amount of consumption and bronchitis. It is believed that the lime inhaled is dissolved by the carbonic acid in the lungs and absorbed. Calcium in the intestinal canal prevents fermentation. Lime dust particles may, however, be deposited in the lungs. It may be that continual absorption of calcium from the lungs and intestine may maintain an abnormally high percentage of it in the blood. The author asks, does this occur in the lime worker, and is it preventive of tuberculosis in him? Or is his freedom due to the external lime dust being unfavorable to the life and growth of the bacillus outside the body? It seems curious to suggest an atmosphere of dust for the treatment of tuberculosis; it would have been as curious some generations ago to have suggested fresh air. At the least have we not in this lime and cement working an occupation which we may recommend to the workingman predisposed to tuberculosis or already in the early stages of it? Or could the neighborhood of a lime-kiln be organized as a curative tuberculosis colony?

Influence of the Nervous System on Infective Processes.—G. L. Cheatle divides the relationship between the nervous system and infective processes into neurovascular and neurotrophic. It must be admitted, he says, that in most cases the nerovascular system is normal immediately before the actual moment of inoculation, and that in most cases the changes which occur in the neurovascular system after inoculation are due to the presence of the infective processes. On the other hand, it is obvious that, if abnormal vasoconstriction or abnormal vasodilatation were present at the time of the inoculation, then the infective process might be modified by either of these conditions. However this may be, my object now is to point out that there is a marked change in the neurovascular system associated with some processes of infection. Concerning the neurotrophic relationship, one of two things or a combination of both must be operative. Either there is a positive or negative influence of a neurotrophic nature in the normal areas which repels the onset of the disease, or there is a positive or negative influence of a neurotrophic nature the operation of which limits the disease to the whole of the neurotrophic area affected. Discussing a case of tuberculous lesions in the head and neck the author adduces, as pertinent, the following argument. The presence of the disease in the affected area is alone sufficient to account for its spread within and final limitation to that area, for the simple reason that presence of the disease lowers the immunity of the area in which it is operative. This may be an important factor, but it is impossible to assume that, with the disease on their boundaries, the surrounding areas have not been attacked by it; and if they have been attacked, then they must have repelled it; and as they have repelled it, then the neurotrophic affairs cannot have been in identical states on the two sides of the boundaries even before the inoculation of the tuberculous area occurred. For if the neurotrophic conditions had all been the same before infection, there would not have been any limitation to a nerve area, but the spread of disease would have been equal in all directions except for mechanical obstruction. Hence the area diseased was more susceptible to the *Bacillus tuberculosis* than were the surrounding parts before inoculation occurred. There appears to me no doubt that there is a neurotrophic factor to be taken into consideration in the consideration of the process of immunity.

Berliner klinische Wochenschrift, November 9, 1908.

Transplantation of Vessels and Organs.—Capelle reports results of extensive experimental work in this subject. Implantation of pieces of arteries for artificial defects in other arteries was followed by good functional and anatomical results when the same animal species was used for the operation and for procuring the material. When other species of animals were used the sections of the vessels functionated properly, but after a time showed various stages of degeneration. Sections of veins were found to serve as good substitutes for arterial defects; slight dilatation of the vein section was soon followed by increase in the thickness of its walls and approach to the character of arterial structure. Very encouraging results were obtained in the transplantation of the thyroid gland with the suture of vessels supplying it. One dog lived for fifty-one days, and the gland proved to be quite normal in appearance. Another animal lived for 245 days; the gland was then removed and proved to be normal; the dog died after the removal of the transplanted gland, showing all symptoms of tetany. Transplantation of kidneys proved to be more difficult, because infections were very frequent. In two cases, however, the transplantation of the kidney into the peritoneum and into the neck of another animal was followed by the cantinuation of kidney function for several days. Death resulted from hemorrhage and infection. The kidney transplanted into the neck showed the phenomena of secretion very well, the ureter having been sewn into the external wound; chemical examination of the secretion showed it to be normal urine. The writer thinks that the sewing of vessels and the use of sections of arteries and veins to fill out defects can be safely adopted for operations in human beings at the present state of technique; the future must show how far transplantations of organs will prove successful in this connection.

Duodenal Ulcer in Children.—Kuttner reports a case of duodenal ulcer in an infant one month old and another in a child of four years. Neither case was diagnosed during life. The ulcers were situated in the "unprotected" part of the duodenum above the papilla of Vater. No etiological factors could be found in the previous history or in the physical examination of the patients; one of them suffered from a light nephritis which could not be brought into any relation with the origin of the duodenal lesion. The older child suffered from a pseudo-membranous colitus and its stools contained an overabundance of colon bacilli; some recent experimental work in the production of gastric and duodenal ulcers suggests that this organism may play an active part in the production of ulcers. Kuttner thinks that many cases of so-called idiopathic pyloric stenosis of infants is really caused by the existence of duodenal ulcers; frequently, comiting of blood is reported in such cases, and even the absence of such vomiting does not exclude an ulcer, as the affection may be quite latent. The treatment of duodenal ulcer of infants and children consists in procuring as much rest as possible for the stomach. Food is to be given in small quantities, should consist mainly of milk, and should be administered cool or cold. In case vomiting persists, rectal feeding must be temporarily carried out; among drugs, alkalies are most serviceable. The author holds that operation is especially indicated if internal medical treatment has not been successful. When the surgeon is called to see the patient while the latter is suffering from a very severe hemorrhage, operation is usually hopeless.

Book Reviews.

Text-Book of Nervous Diseases and Psychiatry. For the Use of Students and Practitioners of Medicine. By Charles L. Dana, A.M., M.D., LL.D.; Professor of Nervous Diseases in Cornell University Medical College; Visiting Physician to Bellevue Hospital; Neurologist to the Montefiore Hospital; Neurologist to the Woman's Hospital; Consulting Physician to the Manhattan State Hospital; ex-President of the American Neurological Association; ex-President of the New York Academy of Medicine; Corresponding Member of the Société de Neurologie, etc. Seventh Edition, Illustrated by 261 Engravings and 3 Plates in Black and Colors. New York: William Wood & Company, 1908.

The fact that Dr. Dana's book has now reached its seventh edition is a good index of its popularity and also its best advertisement. Following out the author's original intention "to present the science of neurology in a concise yet as far as possible complete form," the present edition has not been materially enlarged. While additions to the sections on histology, psychasthenia, hysteria, neuritis, tabes, multiple sclerosis, tics, brain tumors, etc., have been made, and in some instances the articles on these subjects rewritten, considerable of what is now old or unimportant has been at the same time eliminated. The book occupies an extremely useful place between the larger treatises and the smaller textbooks, and will continue to be found a helpful and reliable guide in the study and practice of this most difficult branch of medicine, and a credit to American neurology. Valuable additions to Part II. on Diseases of the Mind are noticeable in the shape of case histories, etc., and the writer has overcome his well-known prejudices sufficiently to review the methods of psychotherapy. The book retains its handsome dress and typographical excellence.

The Sanitation of Recreation Camps and Parks. By Dr. Harvey B. Bashore, Medical Inspector for Pennsylvania Department of Health. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1908.

A pocket volume of something over one hundred pages, well illustrated and containing much that cannot fail to be of value to the summer camper—brief and readable chapters on location and construction, water supply, waste disposal, and environments, with a supplementary chapter on the sanitation of public parks—intended as a sanitary guide, particularly for inexperienced vacation campers.

Consumption, How to Prevent It and How to Live with It; Its Nature, Its Causes, Its Prevention, and the Mode of Life, Climate, Exercise, Food, Clothing Necessary for Its Cure. By N. S. Davis, A.M., M.D.; Professor of Principles and Practice of Medicine, Northwestern University Medical School; Physician to Mercy and Wesley Hospitals; Member of the American Medical Association, American Climatological Association, Illinois State Medical Society, Chicago Medical Society, Chicago Pathological Society, Chicago Neurological Society, Chicago Academy of Sciences; Fellow of the American Academy of Medicine; Author of a Handbook on "Diseases of the Lungs, Heart, and Kidneys" and a Treatise on "Diet in Disease and Health." Second Edition, Thoroughly Revised. Philadelphia: F. A. Davis Company, 1908.

In this book the author has attempted to put forth in a simple untechnical manner the elementary principles with which a layman who has contracted tuberculosis should familiarize himself. The original edition has been considerably enlarged and some of the chapters rewritten. It is a book intended almost wholly for the laity, and is comparatively free from some of the objectionable features which characterize so many works of its kind.

The Age of Mental Virility. An Inquiry into the Records of Achievement of the World's Chief Workers and Thinkers. By W. A. Newman Dorland. New York: The Century Co., 1908.

The greater part of this little book appeared in the *Century Magazine* last spring. It was written in disproof of Osler's rash statement that "the effective, moving, vitalizing work of the world is done between the ages of twenty-five and forty," and the facts offered in refutation of this pessimistic utterance are indisputable and convincing. Dr. Dorland cites the life histories of four hundred of the world's greatest thinkers and workers—philosophers, inventors, painters, musicians, physicists, novelists, etc., and shows that all of them did effective work, and often their best work, after the age of forty. His conclusion, with which his readers are forced to agree, is that the age of the acme of mental activity lies between forty and sixty, and that, provided health and optimism remain, the man of fifty can command success as readily as the man of thirty. Every man of forty or over should keep this interesting book on his shelves and turn to it whenever he is tempted to feel that his age of usefulness is passing. A glance through its pages will be like a whiff of oxygen to the tired runner.

Neurological and Mental Diagnosis; A Manual of Methods. By L. Pierce Clark, M.D., Senior Attending Physician, Hospital for Nervous Diseases, New York; Visiting Neurologist to the Randall's Island Hospitals and Schools, New York, etc., and A. Ross Diefendorf, M.D., Lecturer in Psychiatry in Yale University; Assistant Physician and Pathologist, Connecticut Hospital for the Insane, etc. New York: The Macmillan Company, 1908.

This little volume on methods in neurological and mental diagnosis ought to be an excellent aid to the medical student, both in and out of college. A definite method of procedure is laid down in each line of examination, and the authors have had the courage to omit those newer signs and phenomena, yet unproven, which would tend to bewilder and confuse the physician studying in this special field of medicine. The illustrations are for the most part original, and are excellent. It is gratifying to note that the work includes a glossary of mental items, an addition much desired in these days of modern psychiatric cant.

Diseases of the Eye. By M. Stephen Mayou, F.R.C.S., Late Hunterian Professor, Assistant Surgeon, and Pathologist, Central London Ophthalmic Hospital, etc. (Oxford Medical Publications.) With 119 Original Illustrations and 8 Color Plates. London: Henry Frowde, Hodder & Stoughton, 1908.

This is an elementary work designed for the use of students and to give the "general practitioner" a cursory glance at the subject of ophthalmology. It is written by one who is well versed in regard to the subject, is brief, lucid, and somewhat dogmatic. The illustrations, which are original, are generally excellent. The author has been particularly fortunate in depicting pathological changes. The greater part of the work is devoted to the consideration of diseases and conditions affecting the external parts and the anterior segment of the eye. The rather obscure affections of the fundus are very briefly described. The chapter on operations occupies about fifty pages, and is very practical. An appendix containing a formulary and setting forth the visual requirements for entrance to the British military and civil services completes the text. It is one of the very best works of its kind and scope, and is recommended especially for undergraduates in medicine.

Therapeutics: Its Principles and Practice. By Horatio C. Wood, M.D., LL.D.; Emeritus Professor of Materia Medica and Therapeutics in the University of Pennsylvania; Member of the National Academy of Science. Thoroughly Revised and Rewritten by Horatio C. Wood, Jr., M.D.; Associate Professor of Pharmacology in the University of Pennsylvania; Assistant Physician to the Philadelphia General Hospital. Fourteenth Edition. Philadelphia and London: J. B. Lippincott Company.

The author states that the changes in this edition are more extensive than in any previous edition for many years, and among them is to be noted a complete rewriting of the chapter on cathartics, giving the latest conceptions of their modes of action and a more orderly rearrangement. In the article on diuretics more space has been assigned to the effects of water and the mineral salts of the system. There are also articles on the opsonic and ion theories, together with graphic tracings portraying the effects of drugs.

Generally the drugs are treated scientifically and thoroughly, but the author still looks upon alcohol as a cardiac stimulant, although acknowledging the different experimental results. He also classifies sparteine as a cardiac stimulant, a drug at present being closely questioned as to its right place.

The absence of material on the physical methods of therapeutics is a distinct weakness in a volume otherwise so complete. Drugs which are printed more often in textbooks than written on prescriptions occupy full space, while methods which need description and explanation and which are often of great efficiency, are calmly ignored.

The plan of the author in printing the important facts in large type, leaving the more intricate details in smaller type, is excellent. In these days of student life, when so much is to be learned, concise statements are most important.

It is to be regretted that the senior Dr. Wood, on account of ill health, has not been able to take active part in the preparation of the present volume, his long, painstaking, and scientific work having reflected such honor on American medicine.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Second Annual Meeting, Held in Poughkeepsie, Wednesday, October 21, 1908.

THE PRESIDENT, DR. S. W. S. TOMS, OF NYACK IN THE CHAIR.

President's Address.—Dr. S. W. S. TOMS of Nyack in making this address said that the county medical society must heed the voice of the times. It should take the initiative in each community in matters that presented themselves regarding public health and the problems of sanitation. Our nation had its canal zones and its New Orleans cesspools at its doors. The recent International Congress of Tuberculosis reminded us that there were 200,000 deaths annually from a preventable disease. The speaker asked what was being done outside a few large cities to lessen this scourge. The infant mortality per thousand, according to the last census of the United States, was as follows: Michigan, 121.3; Connecticut, 156.8; New York, 159.8; Massachusetts, 177.8; District of Columbia, 274.5. Were these figures not sufficiently appalling to stir all to activity in preventing the slaughter of the innocents? The principal cause for this high death rate was so well understood and could be so efficiently prevented that it became almost criminal for a community to allow it to exist. The giving of poisons to these defenseless infants in their food could not be laid to criminal intent, but to the ignorance of their mothers. The term "cholera infantum" should be supplanted by the term "acute milk poisoning"; this would appeal to the mind and comprehension of the most ignorant. What mother would continue to give a food known to be poisonous to her infant? Every mother who was feeding her infant artificially on cow's milk, or other food of which it was a part, should be told of the danger of continuing to do so while the child was suffering from a putrid diarrhea. Many a mother had never suspected for a moment that the diarrhea from which her child was suffering was caused by the germs in the food that had hitherto perfectly nourished the child. She did not realize that such milk, originally pure, if allowed to remain for twenty-four hours in a warm room, would contain more germs than sewage. Mothers should be more thoroughly instructed regarding these matters. Another problem deeply concerning the public welfare was that of school hygiene. During the year just ended 17 per cent. of the school children of New York City were excluded from attendance at school for varying periods of time, on account of contagious diseases, and out of 141,908 children examined 108,329, or 76 per cent., were found to be suffering from non-contagious physical defects. It was generally conceded that contagious diseases of childhood could be absolutely controlled were it not for the schoolhouse. Gonorrhea, next to measles, was stated to be the most prevalent malady of civilized countries, and it was estimated that from 75 per cent. to 90 per cent. of all males had been infected, and that it was the cause of from 50 per cent. to 65 per cent. of the capital operations on women in public hospitals, and one of the chief causes of sterility. The county medical societies should take more interest in the questions which were constantly presented to municipal boards of health. There were the problems of milk supply, water supply, ice supply, pure foods and drinks, as well as the control of contagious diseases.

A Successful Demonstration of the Problem of Obtaining Sterile Cows' Milk.—Dr. JOHN T. HOWELL of Newburgh said that five years ago the proprietor of a dairy farm consulted him regarding the best means of securing germ-free milk from his dairy. He laid down for him certain well-known principles of aseptic surgical technique, emphasizing the importance of attention to detail, and these principles were applied in the management of the dairy work. The stables and milk houses were made models of construction, providing all necessary ventilation, cleanliness, sterilization, refrigeration, etc. The cows were most carefully selected. One and a half hours were spent in the preparation of the cows and the milkers before the operation of milking was undertaken. The results of these painstaking methods were apparent from the first, and a record had finally been made which had, as yet, not been equaled, one which included the first specimen of sterile milk ever recorded, and the only sterile specimens taken from the bottles delivered in New York City. Of nine samples taken by the inspector who visited the farm, six plates contained no growths, and the other specimens contained but 100, 200, and 300 colonies per cubic centimeter. The average bacterial count for the years 1906 and 1907 was below 1,000 per cubic centimeter. The average bacterial count for the year 1908 (eight months) was 126.1 colonies per cubic centimeter. An examination of seven specimens of foremilk from the teats showed three sterile plates. The keeping powers of the milk from this dairy were demonstrated by the fact that a bottle of milk sent to Copenhagen, Denmark, was found sweet after fifteen days; one sent to Panama was found sweet after eighteen days.

A Campaign Against Tuberculosis.—Dr. S. E. GETTY of Yonkers said that four years ago an anti-tuberculosis campaign was begun in Yonkers, and the tangible results thus far were a dispensary for consumptives, a nurse who devoted her whole time to visiting and instructing consumptives, an annual appropriation from the city of $3,000, a sanatorium for incipient cases, located on a tract of land away from the built-up portion of the city, with a present capacity of twenty patients. The relief committee was well organized, and distributed milk and eggs. Some educational work had been planned and executed. For the full details of this campaign he referred to Dr. Oscar H. Rogers' monograph on "The Fight Against Tuberculosis," published by the State Charities Aid Association Bulletin No. 103. The death rate from tuberculosis had shown a substantial and continuous decline since the beginning of the campaign. The total decline in the death rate in the fifteen years previous to the beginning of the campaign was from 24 per 10,000 to 21 per 10,000 population. In each of the last three years there was a decline from the previous years, so that the rate for the last year was 17.5 per 10,000 population. There had been a larger decline in the last three years than in the previous fifteen years. The dispensary had been treating patients for nearly two years; there were treated there 112 persons, of whom 103 were undoubtedly suffering from tuberculosis; 28 patients either refused treatment or removed from the city, leaving 75 cases. Of these 26 died; 31 per cent. of the remainder gained in weight; 29 showed improvement in the physical signs, and there were six apparent cures. The dispensary was filling a large place in the campaign. To bring to a successful issue this fight against tuberculosis there should be established in all cities of medium size hospitals or camps for the care and treatment of advanced cases of tuberculosis. In urging the municipalities to build and maintain hospitals for the care of advanced cases of consumption, he said that he was not unmindful that, if under political control the best interests of all could not be served, the objects of these institutions would possibly be defeated. The suggestion had been made, and it seemed feasible, that they be placed under the care of trustees or commissioners with a long tenure of office, say five or seven years, one to be appointed yearly. The appointing power should rest in the hands of the mayor. This method would tend to insure the continuance of a definite policy which would not be subject to the vicissitudes of party defeat or victory. There was no necessity for the erection of monumental buildings.

The Control of Ophthalmia Neonatorum.—Dr. John T. Wheeler of Chatham read this paper, from which he deduced a corollary the logic of which it seemed hard to escape, namely, that the practice of midwifery was responsible for one-third of all the blindness of children and of from one-tenth to one-eighth of all blindness from all causes in the world. In the city of Buffalo several years ago the births for the year numbered 8,500, and among these there were 102 cases of ophthalmia neonatorum, making a ratio of rather more than one case of ophthalmia to every 100 births. By following up these cases it was found that one in every twenty resulted in blindness; in other words, the ratio of blindness from ophthalmia neonatorum to the number of births was as 1 to 2,000. The statistics of London, though on a larger scale, gave practically the same ratio. Recently there had been about 60,000 births reported annually at Albany for 4,000,000 up-State population, not including New York, Buffalo, Albany, and Yonkers. If these reports were complete the number of births would probably be near 100,000. With a ratio of one case of blindness for every 2,000 births there would be, in New York State alone, 50 cases of blindness caused every year by the neglect of accoucheurs to employ the Credé method. Every individual doctor who habitually or occasionally neglected to use the Credé method was in a degree guilty of a share in the perpetration of this crime. Undoubtedly the largest proportion of the cases of ophthalmia neonatorum came from the lower classes, and midwives were responsible. Gonorrhea was responsible for 60 per cent. of the cases of ophthalmia neonatorum; the remainder were mainly due to the streptococcus. Dr. Wheeler said that it was his privilege to form a part of the machinery of a large movement in which every member of the medical profession was expected to do his share, toward which intelligent lovers of humanity were looking with eager interest. He then presented to the society an outline of the proposed campaign against ophthalmia neonatorum. This recommended the adoption by the entire profession of the practice of instilling a solution of silver salt into the eyes of the newborn child, which would reduce the number of cases of blindness occurring every year by one-third. A circular would be sent to the members of the profession which would make two important announcements: First, that all birth returns would hereafter contain the inquiry, did you employ a preventive for ophthalmia neonatorum? If not, why not? Secondly, that in order to facilitate this procedure all health officers, of which there were 1,260 in the State, would be supplied with small containers of silver solution of suitable strength for use in the toilet of the newborn, for free distribution among doctors and midwives.

Dr. Herman J. Boldt of New York said that he was one of the men appointed to carry out this undertaking in the State of New York, and he moved that this branch of the Medical Society of the State of New York form a resolution which would embody the features contained in Dr. Wheeler's outline. He also moved that a committee be appointed to bring this matter before each county society. It was decided that this matter should be acted upon later.

Dr. Joseph Price of Philadelphia, in discussing this paper, said that all the statements made regarding the gynecological affections which resulted from gonococcus infection were correct. The intelligent lay people were now beginning to consider the advisability of instituting such measures as were proposed.

Poliomyelitis Anterior Acuta.—Dr. M. W. Barnum of Ossining read this paper. He told of the methods and theory of treatment in the study of seven cases. In the summer and fall of 1907 there were probably 3,000 cases of this disease in New York City and its vicinity; it had left in its track many hundreds of helpless little human wrecks with which the future would have to deal. Two vitally important points remained to be cleared—first, the exciting cause of the disease and, second, a well-defined plan of treatment. The symptomatology of the disease was naturally divided into two parts—the acute stage, or the cyclone, and the chronic, or the wreckage. The clinical manifestations of the first stage he subdivided into three types—the mild, the neuritic, and the cerebral or bulbar. It seemed to be conceded by all authorities that during the acute stage, in the absence of any possibility of specific therapeutics, the line of treatment should be the one generally applicable to fevers of childhood, namely, rest, quiet, light nourishment, baths, cold applications, vascular sedatives, elimination, and counter-irritation of the spine. During the stage of regression there were three therapeutic propositions to be dealt with: the establishment and maintenance of a high state of general nutrition and blood efficiency; maintenance of nutrition and warmth in the paralyzed muscles; prevention of contraction and wabble-joints during the paralytic stage, and convalescence by proper orthopedic treatment. None of the seven patients reported upon lived within a mile of any of the others. In no instance was there any personal contact of one with another case. Never was more than one child affected in the same house, although, in four instances, several other children were present. Every case had improved unquestionably under treatment, and had continued to improve under electrical and mechanical stimulation, even after the lapse of one year. The mildness or severity of the onset seemed to have no bearing on the amount of residual paralysis; the mild initial symptoms left as permanent a paralysis as the severe ones. It was evidently important to keep the children under surveillance in order to see that home treatment was carried out, because parents got tired of the long routine and neglected instructions, and consequently improvement ceased. It was important to apply carefully fitted braces as soon as a joint showed signs of weakness in walking or standing. The backbone of the treatment was the galvanic current, together with manual and mechanical massage; but whatever method might be used, there should be change and interruptions from time to time to make continued progress secure and to avoid the nervous irritability which often came from overtreatment. As soon as a group of muscles could be used, even feebly, they should be trained and encouraged to voluntary use as rapidly as possible by any expedient that the physician's ingenuity could suggest.

Dr. Wisner R. Townsend of New York said that these cases were treated by the general practitioner, unless the specialist was called in for some reason. The prevention of deformities should be looked to, because it was well known that every case in which deformities occurred resulted from a complete paralysis of the anterior group without paralysis of the posterior group. These deformities could be prevented by the simplest of means. He asked the profession to make greater endeavors to prevent these deformities. He especially emphasized the fact that he was not asking that these cases be turned over to the orthopedist; if the general practitioner did what was required of him the orthopedic surgeon would see fewer cases that required his attention.

Some Nose, Throat, and Ear Symptoms of Significant Interest to the Practitioner.—Dr. D. S. Dougherty of New York read this paper. Of all the subdivisions of the general system of medicine none was more closely allied to the others collectively and individually than that of rhinology and laryngology. The intimate connection between nasal and nasopharyngeal conditions and ear disease rightly added otology to this division. Many symptoms observed in the upper respiratory tract were but local manifestations of general systemic disturbances and were frequently passed over with but scanty recognition of their significance. The nose, throat, and ear conditions in systemic disease might be prodromal, indicative of an incipient

or latent stage, complicating or merely concomitant. They were many in number and differed widely in character. Epistaxis or nosebleed might be due to trauma, morbid pathological changes, vicarious hemorrhages, or constitutional disturbances. In grave disturbances of the circulatory system, the hemorrhage was more likely to be found in the lateral walls, generally in the folds covering the turbinate bodies. Spontaneous epistaxis occurred in cases of plethora, scorbutus, purpura hemorrhagica, pernicious anemia, and hemophilia. Disturbances of the circulatory system were common causes of epistaxis. Cirrhosis of the liver, Bright's disease, and chronic alcoholism might have nosebleed as a concomitant symptom. Nosebleed in the aged, seemingly without cause, might be an indication of incipient arteriosclerosis. Epistaxis was a premonitory symptom of typhoid fever. It influenced the prognosis in the latter stages of purpura, malignant disease, and diphtheria. In scarlet fever and measles it indicated a very severe type of infection. In children a unilateral hemorrhage mixed with a mucous discharge usually pointed to the presence of a foreign body. In children nosebleed was often indicative of adenoids. Nasal hemorrhage was the commonest form of vicarious menstruation. The importance of earache was apt to be minimized or exaggerated. While suppuration was probably the most frequent cause of earache, this symptom accompanied various other conditions. Especial stress was laid upon the importance of earache in children. Hoarseness might arise from any cause that directly or indirectly affected the functional or pathological properties of the larynx or that modified in any way the resonating qualities of the voice. Hoarseness complicated or accompanied many general diseases, among which were tuberculosis, syphilis, typhoid fever, rheumatism, gout, diabetes, uncompensated valvular lesions, malaria, scurvy, purpura, chronic nephritis and hepatic cirrhosis, as well as vasomotor conditions. The continued hoarseness in children usually indicated adenoids. Overuse and faulty use of the voice was a common cause of hoarseness. The chief and most dangerous complications of chronic suppurative otitis media were infections of the brain and its membranes, of the intracranial sinuses, and of the jugular vein. General septicemia and pyemia might occur through the agency of suppurative otitis. Septic conditions and pericarditis, septic pneumonia, and pleurisy, abscess of the lungs, infractions of the spleen or kidneys, metastatic abscesses of the joints were all conditions in which at times the primary infective cause could be traced to the middle ear. Arthritis and synovitis might likewise occur. All cases of purulent otitis should be regarded as serious, and in such patients any sudden rigor, rise of temperature, insistent headache or vomiting, vertigo or photophobia should arouse suspicion of a complicating infection.

The Prevention and Preoperative Treatment of Mastoiditis.—Dr. W. Sohier Bryant of New York recalled a few anatomical and physiological facts about the ear and said that the protection of the patient from mastoiditis depended upon a perfect physiological condition of the upper air tract, and this was best maintained by good hygiene. This desirable condition might be attained, when any structural or functional defect was present, by operative or medical interference. When the functions alone were at fault local applications would be found of benefit. In general diseases the preservation of a healthy state of the upper air tract would safeguard against mastoiditis. In order to be effective, the preoperative treatment should begin before the signs of mastoiditis had become marked. The sooner the operation was performed the better for the patient with mastoiditis and osteitis. As soon as infection of the middle ear appeared, or was even suspected, preventive treatment was in order. Under the head of preoperative treatment should be included cupping and bloodletting and Wilde's incision. In summarizing his paper Dr. Bryant said that the preventive treatment of mastoiditis should be directed to the nasopharynx and its preservation in normal condition. Preoperative treatment was a question (1) of general systemic treatment with saline laxatives and rest in bed; (2) of the application of heat for the pain; (3) of drainage of the middle ear; (4) of treatment of the nasopharynx. He emphasized the fact that nasopharyngeal treatment was the best treatment for the prevention and abortion of mastoiditis.

The Prognosis and Treatment of Abnormal Blood Pressure.—Dr. Egbert Le Fèvre of New York read this paper. He said that in order to interpret the true prognostic significance and therapeutic indication of abnormal blood pressure it was necessary to have a clear conception of the factors that normally controlled the circulation. Normally the vascular system protected itself against sudden variations in pressure by the coordination that existed between different parts of the system; changes in the blood supply of one organ or set of organs were met by an opposite change in other organs or sets of organs. In this way an optimal level was maintained. This coordination of different portions of the circulation was carried out through the widening and narrowing of the lumen of the blood-vessels by contraction or relaxation of the muscular fibers in the walls of the arteries, capillaries, and veins, and the action of the muscle was largely controlled by the vasomotor nerves. While the normal tone of the blood-vessels was maintained through the action of the vasomotor nerves on the muscle tissue in the blood-vessels, this action was favored or inhibited by the secretion of certain glands in the body. The suprarenal glands added to the blood certain substances which increased the blood-pressure, while a secretion of the thyroid had the opposite effect. The prognostic significance of abnormal blood-pressure depended (1) on its cause, (2) on the changes that its long continuance had produced in the vascular system itself, and (3) on the dangers of accidents as hemorrhage, etc., from too high pressure, and subnutrition from too low. The peripheral resistance in abnormally high pressure had been ascribed to (*a*) an increase in the amount of blood contained in the vascular system; (*b*) increased viscosity of the blood; (*c*) changes in the blood-vessels themselves which might be of two kinds, diminished elasticity of the vessels from fibrous or atheromatous change, or increase in the tonicity of the muscle tissue in the arteries and arterioles. Conditions that caused increased peripheral resistance through the contraction of the arteries and arterioles might be due to increased irritability of the vasomotor system, or of the arterial muscles; both of these conditions might be due to primary toxic or primary nervous influences. Regardless of cause, the changes induced by high arterial tension could be divided approximately into three stages according to the extent that the high blood-pressure was due to the contraction of the arterial muscle or the fibrous change in the blood-vessels which made them more or less inelastic tubes. The first stage was characterized by persistent high tension due to hypertonicity of the muscular coats of the arteries and arterioles. This stage had been called that of presclerosis by Huchard, angiosclerosis by v. Basch, and chronic hypertension by Cook. The second stage was that of progressive hypertrophy of the muscular tissue of the cardiovascular system associated with degenerative changes in the intima and fibrosis of the external coat of the arteries. The third stage was that of diminished muscular control due to progressive fibrosis which caused increased obstruction in the arteries and arterioles of certain areas and a tendency to cardiac exhaustion and insufficiency. The treatment should take into consideration not only the stage, but also the cause. The first stage was the curable one. He did not think that the necessity of controlling the use of tobacco in these cases was sufficiently appreciated. Mental and nervous excitement was an important factor in causing the arterial spasm and hastening the occurrence of the second and third stages. Those who practised

in financial centers had had this fact impressed upon them during the past year. The influence of psychic and mental states on high blood-pressure had not been sufficiently estimated and the curative effects of the treatment at Spas were largely due to the patient's frame of mind. There everything tended to raise his hopes. One of the most difficult therapeutic problems was the proper use of the vasodilators, and he was thoroughly convinced that the present inordinate use of them to control arterial tension was not altogether free from danger. He could find no justification theoretically or clinically for the continued use of these drugs permanently to lower blood-pressure.

The Detection of the Treatment of Abnormal Blood Pressure.—Dr. Louis Faugères Bishop of New York said that the measurement of the quantity known as blood-pressure had introduced a new factor in the diagnostics of internal medicine and one which was bound to become more important as it was better understood. At the present moment it was in the position that the measurement of fever was at the time when the clinical thermometer was first introduced. Physicians had gone such a long time without the measurement of fever with thermometers that many considered it an unnecessary refinement, and not a few were chagrined to find that their former opinion as to the existence or absence of fever was not confirmed by the thermometer. Then there were quibbles as to the inaccuracy of temperature measurement because it was found that thermometers were not always accurate and that there was a difference as to whether the temperature was taken on the surface of the body, in the mouth, or elsewhere. Because the findings were difficult to interpret and did not always coincide with presupposed opinion, and because there was some variation in the findings according to the method by which they were sought, many rather objected to this new refinement of internal medicine.

They were still in the period of accumulating experience and it was for the medical profession in general to take up the measurement of blood-pressure and record in their own minds and otherwise, the findings so that they would gradually work out an understanding of its significance. It was unfortunate that the word blood-pressure, signifying in the minds of physicians the pressure of the blood inside of the artery, should have been so securely fastened on this quantity. The quantity was really the force required when applied in the form of a tourniquet to overcome the circulation of the blood through the vessels under examination. We applied an elastic pressure to a vessel and then determined how much force was required to overcome the circulation in this vessel. This force was known in clinical medicine as blood-pressure, sometimes as systolic blood-pressure, and it was a very significant quantity in diagnosis. In studying the methods of making this measurement, for clearness, we divided the procedure into two parts: first, the method of applying the pressure to the vessels, and, second, the method by which the amount of pressure applied to the vessel was measured.

This was illustrated by several instruments which were exhibited. First as to the part of the instrument that was applied to the body. In Gaertner's tonometer we had a band that went around the finger. The blood was driven out of the finger and the rubber band was inflated to a tenseness so great that the finger remained bloodless. Then the pressure was gradually relaxed until the blood returned to the finger. The pressure at the point when the blood returned to the finger was measured. The best instrument was the Potain. This consisted of a small rubber sack that was pressed over the radial artery until the circulation was stopped in the radial and then the pressure inside the sack was measured to see how much force had been required. The third method was that now almost universally used, particularly in this country. A four-inch-wide arm-band was placed around the arm and dilated until the circulation in the brachial artery was stopped. These were the principal methods of applying the pressure to the vessels. The measurement of the amount of pressure applied was made by some form of manometer. In general manometers were correct except that the aneroid manometers had the universal reputation among the scientists of changing their readings with time. The simplest form of manometer was that which consisted of a column of some fluid that balanced the pressure that was to be measured. The mercury manometer was used with many different instruments in many ways and had been called by different names, the Riva Rocci being the best known. Another method which had come into use a good deal now in the new instruments devised by Oliver and others consisted of a tube closed at the end and containing air in which the measurement was made by the amount of air compression caused by various degrees of pressure. A small drop of mercury or other fluid was placed in the tube as an index and traveled back and forth as the pressure was applied or released. This form of manometer was open to objection, as the slightest variation in temperature vitiated the readings, but like all other instruments it was good in the hands of those who had become skilled in its use. The last form of instrument was the aneroid manometer. This had long been known in the form of von Recklinghausen. The chief objection to these manometers was that they did not hold their readings and they were very expensive. The last instrument shown was one that the speaker had devised and consisted of an arm-band in which the pressure was made by the water, and in which a column of water falling from a rubber bag was used both to make and to measure the pressure. It consisted essentially of a rubber tube connected with an arm cuff at one end and a rubber bag at the other. Inside of this arrangement was placed twelve ounces of water without any air. The arm-band was applied in the usual way and the tube and bag containing the water elevated until there was sufficient pressure to stop the circulation in the arm. The distance of the top of the water column above the heart was read by means of graduations on the tube and that gave the systolic pressure.

There were two or three other methods of measuring blood-pressure that he could not mention for lack of time. He was working on several interesting problems which he hoped would make the measurement of blood-pressure a much more convenient matter clinically. Particularly was this necessary for the simple measurement of diastolic pressure. As regarded the treatment of abnormal blood-pressure Dr. Bishop said he would touch only upon one point that he considered his own discovery, namely, the treatment of high blood-pressure by means of physical fatigue. He found, as a matter of clinical experience, that patients suffering from high blood-pressure who were subjected to physical fatigue early in the day by means of exercise, that was divorced from all nervous excitement, underwent a distinct modification of all their high blood-pressure symptoms and apparently escaped the three terminal catastrophies of this condition. They escaped paralysis, they escaped dilatation of the heart, and they escaped progressive kidney disease. The treatment of abnormal blood-pressure must always be a matter of art as well as science. Science must be brought to bear to furnish elaborate and complete data as to the physical condition of the body and its chemical activities, but art must be brought to bear to control the habits, mentality and diet of the patient, and he ventured to assert that there was no class of patients who gave more brilliant results than those who were suffering from functional circulatory disorder.

Officers Elected.—The election of officers resulted in the choice of the following to serve for the ensuing year: *President*, Dr. Charles E. Townsend of Newburgh; *Vice-President*, Dr. Theodore D. Mills of Middletown; *Secretary*, Dr. C. E. Denison of New York; *Treasurer*, Dr. J. E. Sadlier of Poughkeepsie.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held October 19, 1908.

The President, Dr. Robert T. Morris, in the Chair.

Two Cases of Glandular Tumors of the Neck Treated with X-Ray and High Frequency Currents.—By Dr. John Herman Branth. These were two of five cases, the speaker said, of glandular tumors of the neck, more or less chronic in character, which he had successfully treated by means of *x*-ray exposures and the application of the high frequency current. In one of the cases shown there was a tumor, about two and a half inches in diameter, hard and somewhat flattened, which had disappeared after 46 treatments with the *x*-ray and high frequency current. In the other cases, 72 exposures had been given, and the patient was still under treatment, although marked improvement had been noted. In all of his cases, Dr. Branth said, the tumor was on the right side of the neck, and was evidently glandular in character.

Dr. Edward Wallace Lee said these cases of more or less acute enlargements in the neck, or glandular tumors, as Dr. Branth had called them, were comparatively common. Just what the origin of the infection was in the cases shown was of course problematical—whether they were due to a tonsillar or other throat infection, or something more remote. The question was whether they would have subsided as soon or even sooner without the applications of the electricity and *x*-ray. Dr. Lee said he had seen many of these glandular swellings in the neck subside without any special treatment, or under treatment directed to the particular source of the infection, if that could be ascertained. No proof had been advanced that the method of treatment described by Dr. Branth had any specific effect on these acute glandular enlargements. In the case of the young woman, the enlarged gland could still be felt in the neck. In the case of the young man, the condition was apparently an acute one, and would probably have subsided coincidently with the infection that gave rise to it.

Dr. Charlton R. Gulick, who had sent one of the cases to Dr. Branth for treatment, said that in that case, contrary to the patient's own testimony, the glandular enlargement had existed for a number of weeks, and its presence was associated with much debility and considerable loss of weight, which was rapidly regained after the disappearance of the swelling. Its appearance and consistency, Dr. Gulick said, was entirely different from the acute glandular enlargements of the neck due to an acute infective process of the tonsils or elsewhere, to which Dr. Lee had apparently referred, and which were very common in the practice of all general practitioners. The duration of treatment—7 months—seemed further proof that acute infection was not the cause of this growth.

The President, Dr. Morris, said it was the experience of many to have seen these glandular enlargements disappear under the use of the *x*-ray and high frequency current, and personally he was inclined to believe that these agents formed a valuable addition to our therapeutic resources in cases of this kind. Of course, if these enlargements were due to a tangible source of infection, our therapeutic efforts should be turned in that direction.

Dr. Branth, in closing, said that in his treatment, he applied the *x*-ray for a period of from eight to twelve minutes, according to the susceptibility of the patient, and followed this by an exposure of from six to eight minutes to the high frequency current with the vacuum tube. In reply to Dr. Lee, the speaker said he would be quite willing to trust to nature to cure some of these cases, but in others more energetic treatment was apparently necessary. In the case of the gentlemen, the enlargement gave rise to some difficulty in breathing. In none of his five cases was any special point of infection made out. One case presented by Dr. Branth had been under treatment since December 21 (ten months), and was still under treatment, though at long intervals. In some of these cases, surgical intervention was considered, and some surgeons advised that immediate action was preferable, owing to the growing danger in the triangles of the neck. These tumors had no relation to goiter or tuberculous conditions, but should be considered in a class by themselves. At present the personal opinion of Dr. Branth placed greater value in the high frequency current application as a curative agent, yet he added *x*-ray treatment because past experience had achieved satisfactory results.

Etiology, Pathology, and Course of Neurasthenia.—Dr. Edward D. Fisher, in taking up this phase of the symposium in "Neurasthenia," defined neurasthenia as exhaustion of the nervous system, characterized by marked functional inefficiency. Its principal symptom was functional disturbance of nervous activity, shown in incapacity for continuous mental action, with loss of control over the emotions, added to which was loss of physical endurance. Being an affection of the nervous system as a whole, we naturally found symptoms referable to brain, spinal cord, and the peripheral and sympathetic nervous systems, some cases being more marked in one direction, others in another. This being the case, its multiform variety of symptoms had led to multiform plans of treatment. Of late, psychotherapy had been most in evidence. Too much emphasis could not be laid on the physical side of neurasthenia, in contradistinction to the purely psychical side. Neurasthenia was not a disease peculiar, as it had so often been said, to Americans: it belonged to all countries and peoples under like conditions of stress. There was no race which would not succumb to it if the conditions were the same; no individual who was not subject to it if exposed to excessive strain. It might be the professional man, the mother at home, the explorer, the inventor—especially, in fact, any one who used his brain powers to excess if he combined therewith physical exhaustion. Neurasthenia was much more frequent in men than in women; in the latter, hysteria was more common, a disease which clinically was closely allied to neurasthenia, some writers, indeed, classifying the two diseases under one head. It was essentially an adult disease, but not infrequently observed in children, even under the age of five years. Heredity was present in 40 per cent. of all cases, according to Zieber. It was certainly an important factor in the predisposition to nervous breakdown. One found a family history of nervous instability, alcoholism, insanity, syphilis, and tuberculosis not infrequently. The exciting causes were alcoholism, syphilis, trauma, shock, and mental strain. Occupation entered largely as a causative factor, especially among those who did night work, such as clerks and editors, telegraphers, etc. The cause here was probably insufficient rest. Exhaustive disease, such as typhoid fever, grippe, or pneumonia, left as sequelæ malnutrition of the nervous system. Excitability and exhaustion were the most marked symptoms; slight causes excited these patients to anger, anxiety, or depression. Any irritation of the special organs, as the eye, ear, stomach, heart, sexual organs, *et al.*, caused irritation and exhaustion. There was often a fear of insanity, although rarely was the intellect involved. There was, however, an actual incapacity for continual mental effort from early mental fatigue. Physically, the signs were those of headache of the pressure type, especially at the base of the skull, vertigo, and sleeplessness. There was a general feeling of discontent, unhappiness, and unrest, and inability to forget one's self, with marked self-consciousness. The vertigo was more of the subjective than the active form. Sleeplessness in all its varieties was one of the most trying symptoms, but it was not always present. The tendon reflexes were usually exaggerated; ankle clonus was exaggerated; the patellar reflex and the Babinski sign were present. It was different from that found in organic lesions of the cord, involving the lateral tracts, in that there was flaccidity of the muscles rather than spasticity. The

pupil reflex to light was normal, and this was important to remember, as the multiple character of the mental symptoms in neurasthenia might suggest general paresis. The absence of the Argyll-Robertson pupil enabled us to make the differential diagnosis. It was not to be forgotten, also, that the early symptoms of general paresis might be of the neurasthenic type. Neurasthenia was accompanied by many subjective disturbances of sensation, tingling, numbness, itching, and vasomotor disturbances, rushing of blood to the head, erythematous manifestations, urticaria, etc. There was usually palpitation or intermittence of the cardiac action, associated with pain, and it was difficult at times to differentiate the cardiac symptoms from those of true angina pectoris. There might be actual loss of consciousness for many hours, with marked tachycardia and all the appearance of impending death. These attacks had been compared to epileptic seizures. Intestinal disturbance was almost always present, and colitis was present usually if there was digestive trouble. In neurasthenia, the restoration to normal conditions was slow, if ever complete. The nervous system was the last to show evidence of exhaustion from excessive physical and psychical stress; it was also the last to show complete restoration of function. The course of the disease was often a prolonged one. Recovery was always possible and generally probable in time under proper management. Often some great exciting motive or desire might be the cause for a sudden and complete disappearance of all symptoms of the disease. It was not possible to speak of any definite plan of treatment, but rest and nutrition were the keynotes.

True Neurasthenia; Its Nature and Treatment.—By Dr. A. D. Rockwell. (See page 955.)

Treatment of Neurasthenia by High Frequency Currents and the Ultra Violet Ray.—By Dr. Sinclair Tousey. (See page 957.)

Treatment of Neurasthenia by Static Electricity.—Dr. John Herman Branth said the deeper one delved into the physics of electricity, the more striking became the seeming endless variety of manifestations and forms of this elusive force. Electrotherapeutics were as yet in their infancy, but the field of application widened rapidly, and at the present time many chronic and subacute diseases were treated by this remedy. In looking up the literature on the subject of neurasthenia, it was found that many authors mentioned as a complication a derangement of the great sympathetic nervous system, which presided as regulator over the vital functions and nutrition. Intestinal antointoxication was, for instance, a functional derangement of the great sympathetic. Neurasthenia furnished all the symptoms pointing to derangement of this system, of course differing somewhat in each individual. To establish a nervous equilibrium, *i.e.*, to promote a restoration to health, the Pharmacopœia gave us little help, because the vital processes were so low that assimilation of a medicine was just as much hindered as the assimilation of food. However, with a stimulation of the sympathetic nervous system by electricity (which was perhaps the nearest to nervous motion we had), the processes of nutrition would become more active, and then we might be able to observe that medicines would produce results. The treatment of neurasthenia patients with high tension and high frequency currents was founded on a reasonable basis, which the results seemed to confirm. By the application of static electricity, all vital functions could be stimulated. We could send a high frequency current directly through the trunk, and so through the solar plexus, innervating the stomach and liver, spleen, intestines, and the ganglia, innervating the kidneys and pelvic organs, and thereby bring about not only the assimilation of food, but also absorption of medicines, which would, perhaps, under other conditions, pass out of the body like the unassimilated food. It seemed rational, therefore, to employ high tension electricity together with medicines. Of the latter, the writer mentioned bromide of strontium, sometimes combined with small doses of choral, to produce nervous calm and sleep. Static electricity was nature's safest and most rational remedy for stimulating healthy metabolism.

Dr. William M. Leszynsky said that in the first place a patient with neurasthenic symptoms should be thoroughly examined as to the presence or absence of organic disease, for it was not an uncommon occurrence to have patients with chronic nephritis or tuberculosis or even with organic nervous disease treated for a long time for neurasthenia without the true diagnosis having been made. Of course, neurasthenia might be associated with other manifestations, especially with phobias and obsessions and hysteria. As to the etiology of neurasthenia, the speaker thought that a large proportion of the cases were the result of excesses—mental, physical, and dietetic. Some years ago the late Dr. Robert E. Taylor attempted to describe a special symptomatology for those cases due to withdrawal to prevent conception. At that time, Dr. Taylor was not very successful in impressing his belief upon others, but since then, Dr. Leszynsky said, he had seen at least seven or eight cases of neurasthenia in which this practice was the etiological factor in the production of many of the peculiar symptoms, and these patients recovered within three months after the cause had been removed. There was another class of profound neurasthenics in which the symptoms were apparently the result of the constant and excessive use of saline cathartics or magnesium waters, taken for long periods of time. There were others due to the excessive use of coffee, tea or alcohol. In regard to the treatment, neurasthenics could be divided into two classes, the rich and the poor. With the former, the problem was a comparatively simple one, as the patient could carry out all the requirements of treatment, but the poor neurasthenic in the large city was the one to be pitied. As a rule, we could not change his occupation nor give him the necessary rest. As to the value of electricity in neurasthenia, the speaker thought it could not take the place of hydrotherapy, and he did not believe that any form of electricity, alone, would cure these patients. The static current he had found of value, particularly as a psychotherapeutic agent. He did not favor the complete rest cure, as it gave these patients too much time to themselves, and they usually did badly. The chief indications were a suitable occupation, medication as required, and the ability of the patient to carry out the physician's directions.

Dr. William Broaddus Pritchard said the papers and discussion of the evening pointedly illustrated the most interesting phase of this whole question, which was that it was apparently impossible to get two men to agree on this subject in any respect. The types and symptoms of neurasthenia varied widely according to the viewpoint. As a matter of fact, every subject of neurasthenia had his own particular variety of neurasthenia. The causes that produced it were also many and variable, and always multiple. To his mind, Dr. Pritchard said, it was a paradox to conceive of a child with neurasthenia. He did not believe in hereditary neurasthenia; it was an acquired condition in all cases. The only thing the patient inherited was the high order of cortex; the peculiarly susceptible quality of gray matter. The disease never develops in a fool, although it may make one. Contrary to Dr. Fisher's statement, he regarded it as essentially and peculiarly an American type of disease; not that people elsewhere were immune to it, but it was the atmosphere of superstrenuous endeavor characteristically American that was the chief factor in the production of this condition. In order to clear the complexity that surrounded this general subject, we should keep a picture of true neurasthenia before us, and around this genus arrange the subsidiary types, which would include endless protean groups of symptomatic varieties as species of the genus. The treatment of neurasthenia was more important negatively than positively. The "dont's" were more important than the things that

should be done. Most of the valuable therapeutic points had already been covered by the previous speakers. The relation between the doctor and the patient and the personality of the physician were important factors. Electricity, massage, hydrotherapy, passive exercises, all had their special field of usefulness, but he agreed with Dr. Leszynsky as to the wisdom of avoiding the absolute rest cure, which was apt to bring about a condition of morbid introspection and conduced to harmful idleness. These patients needed occupation, but along different lines than that along which their nervous breakdown occurred, and preferably in some direction which would arouse a primeval instinct or stimulate an answer to some "call of the wild."

Dr. Joseph Fraenkel said that in discussing neurasthenia each speaker, apparently, had a different picture in mind. Personally, he believed that there was such a disease as neurasthenia, but that in its true form it was rare indeed and represented a degenerative condition. Outside of this we had a great variety of so-called cases of neurasthenia, due to more or less known causes, which were benefited by any and all of the remedies that had been mentioned to-night: high-frequency current, hydrotherapy, rest, arsenic, occupation, and so on. Each case had to be closely investigated on its own merits, and we had, therefore, in these cases of so-called neurasthenia, a condition which often required the keenest diagnostic skill to interpret and treat successfully. In speaking of the Emanuel Church movement and similar workers in psychotherapy, Dr. Fraenkel said he believed their apparent success was due to their singleness of purpose. On general principles, psychotherapy was limited to a comparatively small group of functional cases, in which the symptoms were primarily psychical.

Dr. Theodore K. Tuthill said that the greatest treatment of neurasthenia he knew of was to send the patient off to the woods under the care of a guide. He should go so far from a railroad that he could not hear the whistle and then get lost and have to find his way back to camp. There was nothing so beneficial to a neurasthenic as camp life in the virgin forest. He had nothing to say against the other remedies that had been mentioned by the various speakers, but he thought the one he had recommended was the best of all.

Dr. Forbes R. McCreery said that no mention had been made of intestinal toxemia in neurasthenia. In his own cases he had found large amounts of indican and phenol in the urine. He asked whether the intestinal symptoms in these cases were a cause or an effect of the neurasthenia.

Dr. Edward Wallace Lee emphasized the importance of a more thorough, painstaking examination of the patient. In too many instances, he thought, a diagnosis of neurasthenia was made upon insufficient grounds. Also the more our knowledge was advanced in pathology, the less would we be inclined toward diagnosing functional disorders. Many of the so-called functional disturbances were due to an unrecognized pathological condition. If we studied our cases more scientifically and gave them more attention, we would get better results; this was more important, he said, than the personality of the physician, upon which so much stress had been laid by some of the speakers.

Dr. Edward D. Fisher, in closing, said in reply to Dr. McCreery that he thought the intestinal disturbances were secondary. He did not think neurasthenia could be caused by intestinal trouble. As a rule, the symptoms were functional in character and not indicative of organic disease. In reply to Dr. Lee, the speaker said that by the personality of the physician, or the personal equation, we simply meant the ability of the physician to gain the confidence of the patient, which was an important factor, and which gave the patient the idea that he was being treated by a man who understood his business.

Dr. Rockwell, in closing, said he was glad to hear Dr. Fraenkel say that neurasthenia was relatively a very rare disease. It was seldom seen in hospital or dispensary patients, and even among the well-to-do and more intelligent classes where it was mostly found, much that was popularly classed as neurasthenia was, as already intimated, simply pseudoneurasthenia.

The discussion was then closed by Drs. Tousey and Branth.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 16, 1908.

Dr. C. Ogilvy and Dr. Godfrey R. Pisek in the Chair.

This was a joint meeting with the Section on Orthopedic Surgery. The evening was devoted to a consideration of the paralyses in early life.

The Causative Factors of the Paralyses of Early Life.—Dr. Royal Storrs Haynes said that the paralyses of early life had as their primary causative factors lesions of the motor tract. These lesions might occur at any point from the cortex to the muscles and might be due to (1) congenital defects or malformations; (2) lack of development of cortical cells; (3) injury to the tract from trauma, from pressure of hemorrhage, or fluid or inflammatory exudate, from the displacement of bone or from the growth of neoplasms; (4) inflammation of the nervous system in brain or spinal cord or peripheral nerves; (5) poisoning by bacterial toxins or chemical poisons; (6) degeneration of the nerve or muscle cells. From the orthopedic standpoint it seemed to him fitting to consider those affections which occurred most frequently and which resulted in the greatest number of cases of paralysis. Beginning therefore with the periphery, he considered primary muscular dystrophy, obstetrical paralysis, diphtheritic paralysis (multiple neuritis), Pott's paralysis (compression myelitis), infantile spinal paralysis (poliomyelitis), and infantile cerebral paralysis. The other forms of peripheral paralysis he dismissed with a mere mention. Primary muscular dystrophy was an instance of primary degeneration of the motor tract, the muscles only being affected. This occurred before the tenth year, occurred most often in boys, had an hereditary tendency and ran in families. The paralysis might be of the face and shoulder girdle (Landouzy-Déjerine type), of the back and arms (Erb's juvenile type), or of the muscles of the back and lower extremities (muscular pseudo-hypertrophy). The seat of injury in obstetrical paralysis was commonly the junction of the fifth and sixth cervical nerves. In from five to six per cent. of all cases of Pott's disease paralysis occurred. At the Hospital for the Ruptured and Crippled in a series of 2,028 cases of nervous trouble, 75 per cent. were cases of poliomyelitis, 20 per cent. were due to cerebral disease, and the remaining 5 per cent. covered all other types of cases. Children in the first three years of life presented 77 per cent. of the cases. Infantile cerebral paralysis was second only to infantile spinal paralysis in the frequency of its course at this hospital. Paralysis of this type might be congenital or acquired, the former being the more frequent. The congenital cases might be due to causes within the uterus or to injury during labor. Syphilis was a doubtful cause. In conclusion, he repeated that paralysis in early life might be due to lesions in any part of the motor tract; that they might be caused by any one of several factors; that a number of clinical affections which caused paralysis existed; but that poliomyelitis and cerebral lesions caused an overwhelmingly large majority of the cases.

The Differential Diagnosis of the Paralyses Occurring in Early Life.—Dr. E. G. Zabriskie, in this paper said the chief factors in the correct diagnosis of paralysis in early life lay in the proper elicitation of the facts attending the onset, the character of the paralysis, and, in some instances the most important, the progress the disease had already made. The first important step in

the differentiation of the various paralyses was the determination of the seat of the causative factor. The differentiation of central from peripheral lesions was often extremely difficult. The condition known as spasticity, which was in reality a symptom complex, was almost invariably dependent on a degeneration or lack of development of the pyramidal tracts. Clonus was frequently lacking. Concerning the Babinski phenomenon Sachs and other writers considered the dorsal extension of the great toe as normal in children under two or four years. Other manifestations of central involvement were ataxia, either of station or muscular movements, the incoordination of the arms and the peculiar gait seen in cerebellar disease, intention tremor so closely related to ataxias, and the various kinds of clonic and tonic spasms or convulsions. Nearly all the other symptoms of nervous disease, or to speak more particularly, the symptoms of paralysis, might be met with in peripheral as well as central lesions, and it was rather by a careful consideration of the sum total of the symptoms that they could arrive at a diagnosis. The reflexes alone furnished them with little information; the same applied to the electrical reactions. The condition of sensation was of great help in distinguishing between central and peripheral manifestations. Thus, anesthesia, whether partial or complete, must necessarily follow the cutaneous distribution of the affected nerve in peripheral conditions. In those of central origin its distribution would be segmental hyperesthesias. Hyperesthesia was widely distributed in peripheral lesions; while in central, with the exception of poliomyelitis and meningitis, it was confined to a zone denoting the upper segmental limits of the disease process. The distinction between spinal and cerebral lesions depended solely on the application of whatever knowledge of the anatomy and physiology of the central nervous system they possessed. Not infrequently the entire diagnosis would rest upon the time the paralysis was first noticed, whether at birth or shortly after, whether it followed immediately or shortly after febrile states, convulsions, or coma, or whether its development was so gradual that it passed unnoticed until quite pronounced. Perhaps one of the most puzzling diagnostic distinctions one had to make was when one was obliged to distinguish between a mild cerebrospinal meningitis, acute anterior poliomyelitis, and multiple neuritis. Each of these conditions had its own distinctive features in well pronounced cases. But in some cases a diagnosis must be deferred until progress had been made. The diagnosis of infantile cerebral palsies was usually to be made by their spastic character, diminished intelligence, and history of onset. They could only be confounded with birth palsies when the spasticity was so slight as to be overlooked, and at a very early age. The determination of the group of atrophies was an extremely difficult one. Progressive muscular atrophy and chronic poliomyelitis were practically indistinguishable in most cases.

The Electrical Treatment of the Paralyses in Early Life.—Dr. T. H. Romeiser said that in the treatment of paralysis the utility and choice of electrotherapeutic measures was still a question giving rise to much discussion pro and con. There was also some diversity of opinion in regard to the form of electricity to be preferred, especially relative to the three modalities in use, static, faradic, and galvanic, and their various modifications. In the spastic paralyses not much was to be expected from electricity alone. In acute anterior poliomyelitis very gratifying results had been obtained. The object of electrical treatment, if the nerve cells were destroyed, was essentially to stimulate those muscles which were cut off from the neural physiological influence in order to maintain their metabolism and nutrition. Faradic and galvanic currents were used in most of his cases. He felt that galvanism was preferable to faradism. Electrical stimulation of the paralyzed muscles should not be begun before the inflammation in the cord had subsided. A characteristic of the muscles paralyzed in acute poliomyelitis was that contraction to the anode was greater than to the cathode. After the first year but little improvement had been observed; the best results had been obtained during the first four or six months. In none of the cases of acute poliomyelitis was electricity alone used. Of equal, if not of greater importance, were massage and properly graded exercises. The fact that without any special therapy there was a natural tendency to a progressive recovery, especially during the first few months, made it difficult to say how much of a remedial rôle electricity played. He was impressed, however, with the belief that the child gained strength more rapidly during the electrical treatment. In none of the cases were the orthopedic indications neglected.

The Mechanical Treatment of the Paralyses in Early Life.—Dr. Wisner R. Townsend said that it certainly seemed to those connected with the clinic that the children had improved more, gained more power, and were in every way in a better condition when mechanical care was given than those where no mechanical care was given. Apparatus had been ordered during eight months preceding April 1 on the Monday, Wednesday and Friday clinic of the Out-Patient Department of the Hospital for Ruptured and Crippled for sixty-six patients, all children, for the prevention of the following deformities: Drop foot, 6 cases; genu recurvatum, 25; talipes varus, 3; talipes equinus varus, 3; talipes valgus, 9; talipes calcaneus, 7; talipes calcaneovalgus, 2; talipes equinus, 14; lateral curvature, 2; drop wrist, etc., 1; weakness abdominal muscles, 3; right valgus and left calcaneus, 1; right drop foot and left valgus, 1; multiple deformities, 3. There were 38 males and 28 females; total 66. Under two years were 25 patients; between two and four years, 24; over four years, 8, a total of 57, nine not giving statement. The time between the attack and the deformity was as follows: Two days, one case genu recurvatum; 1 week, one case genu recurvatum; 2 days, one case calcaneovalgus. The average time after the attack when apparatus was applied was three months. The temporary apparatus when possible was applied earlier. Although all recognized that deformities frequently followed poliomyelitis, yet it was a fact that but very few realized how rapidly they came on and how frequently they occurred. Many different forms of mechanical appliances were used. Splints of plaster-of-Paris were inexpensive and easily applied. In dispensary work the objection was that they were so easily soiled. If the bandage was heavy it was clumsy; if too light it cracked and might not hold the limb perfectly. Braces of steel were simple and could be made of any weight to fit the varying age of the patient and, if made without joints, could be produced at a very reasonable cost. For many cases joints were not needed. In fact, they should not be used in the early treatment, and in some by the time the splint was discarded one with motion was not needed. Dr. Townsend showed a simple splint which was in general use at the hospital and had given very general satisfaction.

The Surgical Treatment of the Paralyses of Early Life.—Dr. R. H. Sayre said that the number of cases of paralysis which occurred in infancy and childhood which were amenable to surgical treatment was very much smaller than that which was best treated by mechanical support, but a certain number of cases derived wonderful help from surgical intervention. Surgery might be required either for the muscles, tendons, fascia, bones, or nerves. In many cases of paralysis certain groups of affected muscles became shortened, especially the flexor muscles when they were unopposed by the constant stretching action of the extensors. This shortening might at times be overcome by manipulation and mechanical stretching, and at other times would require surgical intervention. But could they decide what means to employ? If when the tissue was stretched to its utmost extent, and point pressure applied to it, a reflex spasm was produced, this tissue had been elongated as far as it was possible to elongate it by

stretching, and if it was desired to make it permanently longer this must be done by a surgical operation. This was a valuable guide in determining when to stretch and when to cut. In the majority of cases where they were called upon to elongate contracted muscles it was possible to do this by subcutaneous tenotomy. If the tendon was cut subcutaneously the deformity should be immediately corrected, and if a proper dressing was applied there need be no fear of non-union of the tendon. He had seen as much as three inches of the tendo Achilles reproduced after subcutaneous tenotomy. In some instances, as in contractions of the long flexors of the fingers, open operation on the forearm was advisable. The question of transplantation of the force of the unparalyzed muscle to the paralyzed one, first suggested by Nicoladoni, in order to be practicable must have a strong muscle whose force could be diverted and made to do the work of its paralyzed neighbor. It was occasionally possible by electricity and massage and gymnastics to develop a feeble muscle into a vigorous one, and subsequently operate. Certain details of technique must be observed in order to get the best results in tendon transplantation. If sepsis took place, or if they had pressure necrosis from sutures which were too tight, the result would be a failure. Unless the foot was kept in plaster-of-Paris in a position to relieve the newly attached tendon from strain, the result was apt to be a failure. It might be wise at times to drill a hole through bone and pass the tendon through it to make sure of firm union. The results of nerve transplantation and nerve splicing after traumatic paralysis had given such remarkable satisfaction that investigators had hoped for brilliant results in cases of infantile paralysis. Dr. Sayre had seen only a few cases in which he thought the operation indicated, and the results in all he had done so far had been failures. He felt personally that the operation should be tried in suitable cases, but he did not feel that it had yet been shown that a nerve that had been paralyzed for a long time could be regenerated by splicing it to a live one. Brachial palsy of the Erb type was due to overstretching of the nerve roots which resulted in rupture of the sheath, fibers, and vessels of the nerves. The only way to re-establish nerve conduction was to excise the cicatricial area and do an end-to-end suture of the nerves. In anterior poliomyelitis, however, the condition was different, and the results which were obtained by the experimental transplantation of healthy nerves in animals and of nerve suture after injury in man, should not be relied upon as giving reasonable hope that an equally favorable result would follow a similar operation on a diseased nerve. When a growing bone was compelled to bear weight while imperfectly supported, as was the case in infantile paralysis affecting the lower extremity, it very frequently became deformed; and in such cases, in addition to operations on the soft parts, bone operations were sometimes necessary.

Dr. H. L. Taylor confined his remarks to poliomyelitis. The treatment of the attack, so far as he knew, consisted in leaving the child alone. The child should be allowed to rest in bed. Massage and electricity were contraindicated during the first month, and sometimes for a longer period. In order to prevent deformity, keep up the nutrition. Deformity could be prevented in practically all the cases, at least in nine-tenths of them, by the application of a suitable apparatus which prevented the malposition of the feet. After the acute stage had passed over, the nutrition was best kept up by the use of the vibrator. The vibrator when properly used was superior to the use of electricity or massage.

Dr. Henry Koplik said he was interested in what had been said regarding the difficulty in making a differential diagnosis between the forms of meningitis and polioencephalitis. It was a well-known fact that if one observed the cases for some time, say twenty-four hours, the diagnosis would clear up. The diagnosis was not as difficult as at first appeared. He could not quite understand why when three lumbar punctures were made and the fluid examined a diagnosis could not be made, although such things sometimes happened. There was nothing more difficult to decide in cases of poliomyelitis than when to place the patient in the hands of the orthopedic surgeon. Deformities took place, but the children were too ill for operative work.

Dr. Sara Welt-Kakels discussed the papers from the standpoint of differential diagnosis. Among other cases she recalled one seen in private practice, a boy of three years. It was during the epidemic of poliomyelitis, and it was found that the child could not move the arm. It was learned that the nurse was walking with the child, leading him by the arm. The child stumbled, but was upheld by the nurse. Then it was found the child could not move the arm. Placing the member in a sling for four or five days resulted in a cure.

Dr. L. C. Ager believed that if the physician saw a case of poliomyelitis early, in 95 per cent. of the cases he could prevent deformity. A typical case was readily diagnosed; the diagnosis was practically only a matter of time.

Dr. L. E. La Fetra believed that a good deal could be done by treatment in the acute stage. Dr. Taylor advised leaving the child alone, and Dr. La Fetra agreed with this plan so far as electricity, massage, and manipulation were concerned. But much could be done by the use of icebags to the spine or counter-irritation with mustard and hot bottles. This would relieve the pain around the spinal nerve roots. This pain was a marked feature during the last epidemic. He believed that they could prevent the deformities if they began treatment at once; in most cases it was best to place the feet at right angles from the very beginning of the attack.

Dr. Walter L. Carr believed that much could be done for the relief of pain in the early stages of the disease. He did not hesitate to begin early the orthopedic treatment by placing the limb in proper position and keeping it there.

Dr. William M. Leszynsky, Dr. Henry W. Frauenthal, and Dr. Ontf also discussed the papers.

Pathological Society of Philadelphia.

At a stated meeting held November 12, Dr. A. G. Ellis exhibited a specimen of "Partial Cardiac Aneurysm, with Occlusion of the Coronary Artery Supplying the Area Involved." The condition was due to arteriosclerosis. The heart itself was enlarged and dilated. Dr. C. E. Farr exhibited "Specimens from a Case of Addison's Disease," in which classic symptoms were present and the disease was diagnosed during life. On post-mortem examination tuberculosis was found present in a number of organs, including the adrenals and the kidneys, the liver, the lungs, and a testicle. Dr. Farr exhibited also "Specimens from a Case of Stricture of the Urethra, with Pyelonephritis and Urethrovesical Fistula." Dr. John Speese exhibited a specimen of "Sarcoma of the Breast." From his investigation, this form of tumor appears to be much less common than statements in the textbooks would lead one to believe, namely, perhaps 1 per cent., instead of 7 or 8 per cent. of all tumors of the breast. Dr. A. O. J. Kelly exhibited a specimen of "Carcinoma of the Pancreas, with Metastasis," from a man 21 years old. The growth in the pancreas was exceedingly small, and might readily have been overlooked, while the liver was enormously enlarged and the seat of a large number of metastatic growths. Dr. Kelly exhibited also a specimen of "Gastric Ulcer Showing an Eroded Vessel." The organ came from a patient about 40 years old, who had been long under observation, and who had finally bled to death. On post-mortem examination the ulcer was found to be the seat of beginning carcinomatous degeneration. Dr. H. T. Karsner exhibited a specimen of "Partial Cardiac Aneurysm, with a Solitary Kidney Presenting an Anemic Infarct." It had not been possible to find the vessel to occlusion, of which it

was supposed the degeneration and bulging of the wall of the heart were due. Likewise, the most careful search failed to disclose the presence of a second kidney or ureter, or even a dimpling in the wall of the bladder suggestive of any attempt at communication with such a kidney. Dr. A. G. Ellis presented a communication, entitled "The Pathogenesis of Spontaneous Cerebral Hemorrhage." He had studied the blood-vessels in more than a score of brains from cases in which death had resulted from cerebral hemorrhage, and in almost all he had found a varying, but in no instance an extraordinary, number of the vascular enlargements usually designated miliary aneurysms. These, however, he found on careful histological study to be merely false aneurysms, resulting from laceration or rupture of the intima, sometimes also of the media, and finally at times also of the adventitia of vessels, the seat of arteriosclerosis or atherosclerosis, with the escape of blood between the coats of the vessels. The change began in the internal elastic membrane of the intima and extended thence to the other parts of the vessel. Rupture might take place from these formations or from some other part of the diseased vessel. Dr. D. J. McCarthy presented a communication entitled "The Types of Cerebral Hemorrhage," with illustrative specimens. Dr. W. M. L. Coplin presented a specimen of "Tuberculosis of a Lacteal." In the intestine could be seen a small ulcer, passing off from which was a lacteal vessel whose lumen was obstructed by a number of tubercles giving rise to a moniliform appearance. In this instance the chyle-vessel pursued a longitudinal direction, and not the transverse course thought to be distinctive of lacteals. The receptaculum chyli was not involved.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Delaware Board of Medical Examiners.

Tuesday, June 16, 17, and 18, 1908.

ANATOMY.

1. Give shape and number of segments forming os hyoides.
2. Give form, location, and attachments of ethmoid bone.
3. Give shape, size, origin, and insertion of latissimus dorsi muscle.
4. Give shape, size, origin, and insertion of trapezius muscle.
5. Describe vermiform appendix—location, attachment, structure, shape, and size.
6. Explain origin, course, and distribution of brachial artery.
7. The stomach is supplied by what arteries?
8. Explain course and distribution of cephalic vein.
9. Give formation and distribution of deep cervical plexus of nerves.
10. Explain anatomical formation of mammary gland.

PHYSIOLOGY.

1. What special centers have we in the spinal cord?
2. Name the special centers existing in the medulla oblongata and give their respective functions.
3. What is the function of the Eustachian tube?
4. What is the difference between aphasia and aphonia?
5. At what time of life does menstruation begin and end in the temperate zone?
6. In what way can you prove, physiologically, that the anterior columns of the cord are motor and the posterior sensory?
7. What are the chief functions of the skin?
8. What is the origin of urea, and the average quantity excreted in 24 hours?
9. What is the object of boiling starchy foods?
10. What are the functions of the liver?

CHEMISTRY.

1. Define specific gravity. What relation does the amount of solid matter in urine bear to the specific gravity of urine?
2. How are the compounds containing two, three or four elements distinguished by name? Illustrate.
3. What is (*a*) an acid, (*b*) an alkaloid? Illustrate.
4. How may the presence in urine of each of the following be detected: (*a*) albumin (*b*) sugar?
5. How may the presence of mercury be detected in a solution?
6. Define combustion. State the result of combustion.
7. During respiration what chemical changes take place in (*a*) air, (*b*) blood?
8. Give the symbol, valence and a principal compound of each of 10 elements.
9. Define and illustrate (*a*) mixture, (*b*) compound, (*c*) radical, (*d*) salt.
10. Mention the chemical reason for the use of lithia and its salts in cases of uric acid diathesis.

MATERIA MEDICA.

1. Give the common name, preparations, and doses of colchicum.
2. What are the physiological actions of gelsemium?
3. Name the preparations and doses of benzoin.
4. State some general rules to be observed in prescription writing.
5. Write a prescription for acute cystitis with alkaline urine; two for acute dysentery.
6. What is salol? What are its physiological actions? Why should care be exercised in its administration?
7. What are anthelmintics? Name three drugs of this class, stating the dose of each.
8. Give the common name, the active principles, the preparations and doses of nux vomica.
9. How does strophanthus differ in its physiological action from digitalis?
10. Make a list of the lithium salts with dose of each.

THERAPEUTICS.

1. Name three digestive ferments and state the indications for the use of each.
2. What are the therapeutic uses of sodium phosphate?
3. State what you know about the uses of potassium iodide.
4. Veratrum viride. What are its medical uses?
5. What is aqua hydrogen dioxide? What are its therapeutic uses?
6. Name the preparations and doses of codeine. For what is it used?
7. What is the chemical antidote for arsenic? Iodine? Corrosive sublimate? Chlorine water? Nux vomica and its alkaloids?
8. What are the therapeutic uses of bismuth?
9. What are the therapeutic uses of hydrargyri chloridum mite?
10. Write a short essay on "hydrotherapy."

PATHOLOGY.

1. Give the causes and process of cerebral softening.
2. How does calcareous degeneration of the arteries influence the circulation, and to what diseases does it predispose?
3. Describe the protective agencies by which the body guards itself against the entrance and harmful effects of pathogenic bacteria.
4. What are some of the phenomena attending pus-formation?
5. What structural changes take place in chronic gout?
6. Differentiate a tuberculous joint from one enlarged by chronic rheumatism.
7. Name some of the principal bacteria of the staphylococci and the streptococci groups.
8. Describe the rash and give the morbid anatomy of scarlatina.
9. What changes take place in hypertrophy of the heart?
10. What are the pathological conditions in gonorrheal ophthalmia?

PRACTICE OF MEDICINE.

1. Differentiate primary lobar pneumonia from acute pneumonic phthisis.
2. Give the treatment of erysipelas: (*a*) dietetic, (*b*) constitutional, (*c*) local, (*d*) prophylactic.
3. Give treatment and symptoms of acute articular rheumatism.
4. Give period of incubation, character of eruption, and complications of each of the following diseases: (*a*) measles, (*b*) variola, (*c*) scarlet fever.
5. Define hydrophobia: give clinical history and treatment.
6. Give symptoms and treatment of acute congestion of the lungs.
7. Give the etiology and symptoms of acute cardiac dilatation.
8. Etiology and symptoms of arteriosclerosis.

9. Make a differential diagnosis of follicular tonsillitis and diphtheria.
10. Name four diseases for which you consider there is a specific treatment. Write prescriptions for each.

OBSTETRICS.

1. Define obstetrics. Give a rule for determining the date of labor.
2. What is the placenta? Describe its formation and development.
3. Name, under separate headings, the positive and doubtful signs of pregnancy.
4. Into how many stages is labor divided? Define each stage.
5. Define puerperal eclampsia. Give the causes and treatment of same.
6. Name three important abnormal presentations and your management of each.
7. What are the symptoms, varieties, and dangers of placenta prævia?
8. Give the causes, symptoms, and treatment of simple chronic endometritis.
9. Name two conditions requiring the use of an anesthetic during labor. State the kind of anesthetic preferred and give the method of administering it.
10. Describe in full the application of forceps.

SURGERY.

1. Give minute directions for antiseptic surgical dressings applied to surface wounds.
2. What tendons are severed and what mechanical device is necessary for correcting congenital talipes varus?
3. Give diagnostic symptoms, reasons for, and methods of ligating aneurysmal arteries.
4. Differentiate chronic cystitis and chronic prostatitis.
5. Differentiate phimosis and paraphimosis.
6. Explain the formation of an orifice, sinus, and fistulous openings—with method of drainage and treatment.
7. In what particular do the diagnostic symptoms of appendicitis differ from those of acute peritonitis?
8. Differentiate traumatic and hospital gangrene.
9. Explain necessary structural changes in reuniting fractured bones.
10. Classify the method of reducing dislocations by manipulation.

HYGIENE.

1. What precautions should be taken in school rooms to protect the sight of scholars?
2. What are the chief sources of contamination to drinking water?
3. What physical conditions would render the taking of a Turkish bath unsafe?
4. What care should be employed in exhumations?
5. Name causes for greater prevalence of diphtheria and smallpox in cold than in warm weather.
6. State the advantage of cremation over earth burial.
7. What is milk sterilization? How is it performed?
8. How do forests benefit public health?
9. Mention some of the diseases to which artisans are especially liable.
10. Is green wall paper objectionable? If so why?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

DELAWARE BOARD OF MEDICAL EXAMINERS.

June 16, 17 and 18, 1908.

PHYSIOLOGY.

1. *The special centers in the spinal* cord are: the cilio-spinal, secretory, vasomotor, genital, vesical, and rectal centers.

2. *The special centers in the medulla oblongata* are: (1) center for mastication, (2) for secretion of saliva, (3) for sucking, (4) for deglutition, (5) for vomiting, (6) for voice, (7) center for expression, (8) cardiac centers, (9) respiratory centers, (10) vasomotor centers.

3. *The function of the Eustachian tube* is to keep the atmospheric pressure within the tympanic cavity the same as that on the outside.

4. *Aphasia* is a condition in which the patient is unable either to receive ideas or to communicate them by the ordinary means of speech or writing.

Aphonia is simply loss of voice, due to some interference with the function of the vocal cords.

5. In the temperate zone, menstruation begins at about fourteen or fifteen years of age, and ends at about forty-five or fifty.

6. Transverse section of the *anterior root* of a spinal nerve causes loss of motion and degeneration of the peripheral portion of the anterior root fibers; and stimulation of the anterior root is followed by tetanic contraction of the muscles supplied by the nerves concerned.

Transverse section of the *posterior root* of a spinal nerve causes loss of sensation and degeneration; and stimulation of the dorsal root is followed by sensations of pain, or pressure, or temperature.

7. *The functians of the skin* are: Protection, sense of touch, excretion, regulation of body temperature, absorption, and respiration.

8. *Urea* is chiefly made in the liver; it is the end product of the metabolism of the proteids. The average quantity of urea excreted in twenty-four hours is about five hundred grains.

9. *The object of boiling starchy foods* is: To burst the cellulose envelope and thus allow the digestive juices to come into contact with the granules.

10. *The functions of the liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

CHEMISTRY.

1. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of a similar volume of some other substance taken as a standard, under like conditions of temperature and pressure.

In normal urine, the last two figures of the specific gravity, multiplied by 2.33, will give approximately the number of grams of solids to the liter of urine.

3. An *acid* is a compound of an electro-negative element or residue with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element, without the formation of a base.

Examples: Sulphuric acid: H_2SO_4 Nitric acid: HNO_3.

An *alkaloid* is a basic nitrogenous substance, alkaline in reaction, and capable of uniting with an acid to form a salt in the same way that ammonium does. *Examples*: Morphine and strychnine.

4. To examine for *albumin*: "The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered.

"The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of nitric acid."

To examine for sugar: First remove any albumin that may be present, then "render the liquid strongly alkaline by addition of sodium carbonate. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color."

5. *The presence of mercury in a solution may be detected* by the Reinsch test, as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put in into a clean dry, glass tube, open at both ends, and apply heat at the part where the copper is. If mercury is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of metallic globules of mercury.

6. *Combustion* is rapid oxidation, with the giving off of light and heat. The *products of combustion* are light and heat.

7. (*a*) The chemical changes produced in the *air* by respiration are:

	Inspired Air.	Expired Air.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide...	0.04 per cent.	4.4 per cent.
Other gases.....	Rare.	Often present.
Watery vapor ...	Variable.	Saturated.

(*b*) In the *blood* the chemical changes are: (1) The giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration and (3) the blood loses a small amount of watery vapor.

8.

Ten Elements.	Symbol.	Valence.	A Principal Compound.
1. Hydrogen.	H.	1.	Hydrogenmonoxide(or water), H_2O
2. Oxygen.	O.	2.	Hydrogen dioxide, H_2O_2
3. Carbon.	C.	4.	Carbon dioxide, CO_2
4. Nitrogen.	N.	3 or 5.	Ammonia, NH_3
5. Chlorine.	Cl.	1.	Sodium chloride NaCl
6. Sulphur.	S.	2.	Sulphuretted hydrogen, H_2S
7. Potassium.	K.	1.	Potassium iodide, KI
8. Sodium	Na.	1.	Sodium carbonate, Na_2CO_3
9. Silver.	Ag.	1.	Silver nitrate, $AgNO_3$
10. Boron.	B.	3.	Borax, $Na_2B_4O_7$

9. (*a*) A *mixture* is the product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds. There is no chemical union, and the amounts of the component parts are not definite. *Examples*: Air, milk and water.

(*b*) A *compound* is a substance made up of two or more elements, chemically united with each other in definite proportions. *Examples*: Ammonia, NH_3; borax, $Na_2B_4O_7$.

(*c*) A *radical* is a group of atoms which can enter or leave a chemical reaction like a single atom. *Examples*: Ammonium, NH_4; ethyl, C_2H_5.

(*d*) *Salts* are substances formed by the substitution of an electropositive element for part or all of the replaceable hydrogen of an acid. *Examples*: Sodium nitrate, $NaNO_3$; monopotassic sulphate, $KHSO_4$.

10. Lithia and the salts of lithium are used in cases of uric acid diathesis, because: (1) They diminish the acidity of the urine; (2) they have a diuretic action; (3) they hasten the excretion of the urates; (4) and so prevent the accumulation of gravel and the formation of calculi; (5) the lithium salt of uric acid is the most soluble of all the urates.

MATERIA MEDICA.

1. Colchicum. *Common Name*: Meadow Saffron.

Preparations and Doses: Colchici cormus, gr. iv; extractum colchici cormi, gr. j; colchici semen, gr. iij; fluidextractum colchici seminis, ♏j ss; tinctura colchici seminis, ♏xxx; vinum colchici seminis, ♏xxx; colchicine, gr. 1/128.

2. *The physiological actions of gelsemium:* "When given internally gelsemium acts as a powerful depressant to the respiratory, circulatory, and nervous systems. It acts as a depressant to the heart muscle and vagus nerves, and under its influence there is a diminution in the pulse force and blood pressure. It primarily depresses the sensory side of the spinal cord; but later, if given in large amount, depresses the motor side. The drug has no effect upon the spinal nerves, but the motor cranial nerves are paralyzed by large doses. In moderate amounts it causes the respiration to become slow and feeble, and in lethal quantities paralyzes the respiratory centers.—*U. S. Dispensatory.*

3. *Preparations and Doses of Benzoin:* Adeps benzoinatus; tinctura benzoini, ♏xv; tinctura benzoini composita, ♏xxx; acidum benzoicum, gr. vijss; ammonii benzoas, gr. xv; sodii benzoas, gr. xv; lithii benzoas, gr. xv.

6. *Salol* is phenyl salicylate; and is composed of 60 parts of salicylic acid, and 40 of carbolic acid. Its *physiological action* is: antiseptic, antipyretic, and germicidal. Care should be exercised in its administration, because in the small intestine it is decomposed into its constituent parts, and symptoms of carbolic acid poisoning may develop.

7. *Anthelmintics* are agents which kill or expel worms. *Examples:* Oleoresina aspidii, gr. xxx; Pelletièrine tannate, gr. x; santonin, gr. j.

8. Nux Vomica. *Common name:* Dog button, or poison nut; *Active principles:* Strychnine and brucine.

Preparations and Doses: Extractum nucis vomicæ, gr. ¼; fluidextractum nucis vomicæ, ♏j; tinctura nucis vomicæ, ♏x; strychnine, gr. 1/64; strychninæ sulphas, gr. 1/64; strychninæ nitras, gr. 1/64.

9. *As compared with digitalis, strophanthus* acts quicker, is less enduring in its effects, is less certain, is not cumulative, has less marked vasoconstrictor effects, has greater diuretic power, and is said to be safer for aged patients.

10. *Lithium Salts, with Doses:* Lithium benzoate, gr. xv; lithium bromide, gr. xv; lithium carbonate, gr. vijss; lithium citrate, gr. vijss; effervescent lithium citrate, 5ij; lithium salicylate, gr. xv.

THERAPEUTICS.

1. There are only two *official* digestive ferments, viz., pepsin and pancreatin. Trypsin is also a digestive ferment.

Pepsin is indicated as an aid to gastric digestion in gastralgia, gastric cancer and ulcer, atonic dyspepsia, and the vomiting of pregnancy.

Pancreatin is indicated as an aid to digestion, and for the predigestion of food, in convalescence, in wasting diseases, and in intestinal dyspepsia.

6. *Preparations and doses of codeine:* Codeine, gr. ½; codeine phosphate, gr. ½; codeine sulphate, gr. ½.

Codeine is used to allay cough, and also in diabetes; sometimes it is employed as an anodyne in cases of some duration, such as cancer.

7. Chemical Antidotes. *For Arsenic:* Freshly prepared ferric hydroxide. For *iodine,* starch, or sodium carbonate or bicarbonate. For *corrosive sublimate,* white of egg or milk in moderate amount. For *chlorine water,* ammonia, cautiously. For *nux vomica and its alkaloids,* potassium permanganate, or tannic acid.

PRACTICE OF MEDICINE.

1. The symptoms and physical signs of *lobar pneumonia* and *acute pneumonic phthisis* may be the same for the first eight or ten days; at this period the fever in *pneumonia* drops by crisis; whereas in *phthisis* the fever continues for some time longer and the patient gets worse; the sputum contains tubercle bacilli and elastic fibers, and instead of retaining the rusty color it becomes purulent and greenish.

In *pneumonia,* the breathing is very rapid, the pulse-respiration rate is disturbed, the fever is usually high, and runs a regular course, crepitant râles are heard at first, then signs of consolidation follow, and crepitant râles again succeed.

In *phthisis,* the breathing is hurried and there is dyspnea, the fever is often high, but does not run a regular course, at first the signs are those of bronchitis, followed by consolidation, a softening, or excavation in different parts of the lungs; sometimes there is nothing to be heard but scattered râles.

9. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Löffler bacilli are never found.

In *diphtheria* the onset is more gradual; the temperature rises to about 101 ° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon reforms, and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Löffler bacilli may be found.

OBSTETRICS.

1. *Obstetrics* is that branch of medicine which treats of the science and art of caring for woman and the product of conception during pregnancy, labor, and the puerperium.

A rule for determining the date of labor: Count back three calendar months from the first day of the last menstrual period, and add seven days.

3. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation, and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

4. Labor is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with a complete dilatation of the os uteri, and ends with the birth of the child. The *third stage* immediately follows, the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

5. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death.

The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels and kidneys.

The line of *treatment* as laid down by Edgar is as fol-

lows: For *preventive treatment:* (1) the amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

The *curative treatment includes:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

SURGERY.

2. In *congenital talipes varus,* the following tendons should be severed: Tibialis anticus, tibialis posticus, and plantar fascia. The mechanical device necessary is the club-foot wrench.

7. In *appendicitis:* The right thigh is flexed, pain and tenderness are confined to the right iliac fossa, there may or may not be vomiting, fullness of the abdomen is above Poupart's ligament.

In *acute peritonitis:* Both thighs are flexed, pain and tenderness are more general and are increased by movement, vomiting is frequent, the abdomen in general is distended and is tense and tympanitic.

HYGIENE.

1. *Precautions which should be taken in school rooms to protect the sight of scholars,* should include the following: (1) The light should be ample, and should come from the left side or from behind the scholar, never from the front. (2) The windows should extend nearly to the ceiling, and should have proper shades. (3) Blackboards should be clean and black, neither glazed nor shiny, and must not be on the same side as the windows. (4) Schoolbooks should be of good paper with good clear type, and the lines amply leaded. (5) Pupils should assume correct attitudes in writing or reading. (6) Desks and seats should be of a proper size, style and arrangement. (7) Proper medical examination should be made of the eyes when necessary, and defects corrected as soon as possible.

2. *The chief sources of contamination of drinking water,* are: Sewage, including not only solid and liquid excreta, but also house water and waste water; manufacturing refuse, such as from dye works, bleaching works, tanneries, and numerous other industrial places; from improper storage or service of water.

3. *A turkish bath should not be taken* by patients suffering from organic heart disease, dilated heart, congestion of the lung, chronic bronchitis, with emphysema, pneumonia, or great obesity.

4. *In exhumations, care should be taken:* (1) To obtain the necessary permission from the proper parties; (2) to be sure to open the right grave; (3) to have the corpse properly identified; (4) if the coffin is at all broken, to take some of the earth from each side, above and below; (5) during the inspection to keep to windward of the body; (6) to work as rapidly as is consistent with thoroughness.

5. Ventilation is less satisfactory and the changes in temperature are greater and more frequent in the cold weather; hence vitality is lowered and there is a greater liability to take diseases.

6. *The advantages of cremation over earth burial* are: (1) Economy; cremation is very much cheaper, and there is no need for the community to purchase large tracts of valuable land for the accommodation of the dead. (2) Health; it is said that earth-burial causes the air to become poisoned, the burial grounds to become offensive, the soil to become laden with disease germs of every description, water to become poisoned, and diseases to be directly originated or propagated. (3) Body-snatching and desecration of tombs will be impossible.

7. "Sterilization of milk requires continuous heating under pressure for about two hours at 248° F., at which temperature not alone the bacteria and their spores are destroyed, but the normal appearance and taste of the milk as well. Part of the sugar is converted into caramel, part of the casein is precipitated, and the milk will no longer form a cohesive coagulum with rennet." (Harrington's *Practical Hygiene.*)

8. "In cold climates trees and shrubs obstruct the passage of the sun's rays to the soil, which is therefore liable to be cold and moist; but in hot climates the evaporation of water from the leaves tends to dry the soil, while the temperature of the air is lowered, and the ground is sheltered from the direct rays of the sun and kept cool. Thus, the heat of summer is lowered and the cold of winter lessened by the presence of trees, and having a lower temperature than the neighboring earth's surface, high forests increase the rainfall. * * * Probably in all climates a due admixture of herbage, shrubs, and trees, without dense undergrowth, but admitting the passage of free currents of air in every direction, is the most conducive to health. Large tracts of country destitute of trees and vegetation are in hot climates unbearably warm and dry, and in cold climates are exposed to every chilling wind and to every extreme of temperature, according to the season of the year. In such districts, too, rainfall is often absent or very slight in amount, the attractive influence exerted by trees and vegetation generally upon water-charged clouds being wanting." (Parkes' *Practical Hygiene.*)

9. *Some diseases to which artisans are especially liable:* Phthisis, fibroid phthisis, anthrax, glanders, tetanus, varicose veins, septic infection, lead poisoning, mercurial poisoning, arsenical poisoning, phosphorus poisoning, emphysema.

10. Yes, green wall paper is objectionable; because it may contain arsenic, which is liable to become detached from the paper, and may be present in the air of the room, and then be inhaled.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Jan. 4
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Jan. 12
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Jan 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	March 9
Delaware	J. H. Wilson, Dover	Dover	Dec. 8
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Jan. 12
Florida*	J. D. Fernandez, Jacksonville	Tallahassee	May 19
Georgia	E. R. Anthony, Griffin	Atlanta	May —
Idaho	W. F. Howard, Pocatello	Boise	April 6
Illinois	J. A. Egan, Springfield	Chicago	Jan. —
Indiana	W. T. Gott, Indianapolis	Indianapolis	May 25
Iowa	Louis A. Thomas, Des Moines	Des Moines	Dec. 8
Kansas	D. P. Cook, Clay Center	Kansas City	Feb. 9
Kentucky*	J. N. McCormick, Bowling Green	Louisville	April 27
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	May 20
Maine	Wm. J. Maybury, Saco	Portland	March 9
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 8
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 9
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 8
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Jan. 5
Mississippi	S. H. McLean, Jackson	Jackson	May 11
Missouri	J. A. B. Adcook, Warrensburg	Kansas City	Nov. 23
Montana*	Wm. C. Riddell, Helena	Helena	April 6
Nebraska	E. J. C. Sward, Oakland	Lincoln	Feb. 2
Nevada	S. L. Lee, Carson City	Carson City	May 3
N. Hampshire*	Henry C. Morrison, State Library, Concord	Concord	Dec. 30
New Jersey	J. W. Bennett, Long Branch	Trenton	June 15
New Mexico	J. A. Massie, Santa Fe	Santa Fe	Jan. 11
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Feb. 2
N. Carolina*	B. K. Hays, Oxford	Asheville	June 9
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	Jan. 5
Ohio	Geo. H. Matson, Columbus	Columbus	Dec. 8
Oklahoma*	F. P. Davis, Enid	Chicasha	Jan. 12
Oregon	B. E. Miller, Portland	Portland	Jan. 5
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia, Pittsburg	June —
Rhode Island	G. T. Swarts, Providence	Providence	Jan. 7
S. Carolina	H. H. Wyman, Aiken	Columbia	June 8
S. Dakota	H. E. McNutt, Aberdeen	Sioux Falls	Jan. 13

Virginia	R. S. Martin, Stuart	Lynchburg	Dec. 16
Washington*	K. Turner, Seattle	Spokane	Jan. 5
W. Virginia	H. A. Barbee, Point Pleasant	Huntington	April 13
Wisconsin	J. V. Stevens, Jefferson	Milwaukee	Jan. 12
Wyoming	S. B. Miller, Laramie	Cheyenne	Feb. 10

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Louisiana.—The Louisiana State Board of Medical Examiners has adopted the following resolutions: "On and after October 1, 1908, the Louisiana State Board of Medical Examiners will grant a license, without examination, to applicants who will comply with the following conditions: (1) They must appear in person before the board. (2) They must present a diploma from a college rated as Class A by the board. (3) They must present a certificate of examination by and from a State Board of medical examiners recognized by the Louisiana State Board of Medical Examiners. (4) They must furnish satisfactory proof of their identity. (5) They must give satisfactory evidence of good moral character. (6) They must pay a fee of $25.

Therapeutic Hints.

Capillary Bronchitis.—

℞. Sodii nitritis.....gr. vi
Fluidext. belladonnæ.....gtt. ii
Spts. ammon. aromat.....℥ii
Mist. glycyrrhizæ co.....℥iii
Aquæ anisi.....℥iii

M. Sig.: Teaspoonful every two hours for a child one or two years old.

R. T. Scott, M.D., Houston, Tex.

Bronchitis.—

℞. Creosot. carb.....℥ss.
Mucilag. acaciæ.....℥iss.
Aq. menth. pip.....q. s. ad. ℥vi.

M. S.: A tablespoonful every six hours.

Gonorrhea.—W. F. Glenn recommends the following:

℞. Zinci iodidi.....gr. xv.
Zinci chloridi.....gr. i.
Aq. dest.....℥vi.

M. S.: Use three times a day as an injection.

—*Journal American Medical Association.*

Migraine.—The following has been recommended for the relief of migraine:

℞. Ammonii chloridi.....gr. xx.
Tinct. gelsemii.....♏x.
Syrupi aurant.....℥i.
Aq. cinnamomi.....q. s. ad. ℥i.

M. S.: One tablespoonful at a dose. Repeat in three hours if necessary.

—*Clinical Review.*

Asthma.—Sawyer uses the following:

℞. Potassii nitratis.....℥ss.
Pulv. anisi fruct.....℥ss.
Pulv. stramonii fol.....℥j.

M. ft. pulv.

A thimbleful of this powder placed upon an earthenware plate is pinched by the fingers into a pyramidal shape, and lighted at the top of the little conical heap. It burns with a smoldering and gently deflagrating flame, and is held near and beneath the patient's face, who breathes in the smoke as it issues from the burning heap of powder. The ingredients of the powder should be dry, well mixed, and finely powdered.

A writer in the *Therapeutic Gazette* recommends the following combinations:

℞. Potassii nitratis.....℥ss.
Pulveris stramonii fol.....℥j.
Pulveris anisi fruct.....℥ij.
Pulveris lobeliæ inflat.....℥j.
Pulveris fol. theæ sinensis nig...℥j.
Ol. eucalypti.....♏xv.

M. ft. pulv.

Or, when and where the pungent fumes of sulphur in combustion may be indicated:

℞. Potassii nitratis.....℥ss.
Sulphuris sublim.....℥ss.
Pulveris anisi fruct.....℥iijss.
Pulveris stramonii fol.....℥j.

M. ft. pulv.

Far away from a pharmacy one might wish to extemporize a reliable fuming inhalation. A mixture of one part by weight of saltpeter and two parts of black tea, powdered, makes a good asthma powder for burning for emergency use, and both these ingredients are usually to be found as household possessions.

Manganese.—In malarial or catarrhal jaundice manganese is often very useful. It may be administered after the following formula:

℞. Mangani sulph. exsic.....gr. xl.
Cinchonidinæ salicylat.....℥ii.

M. ft. pil. No. xx.

Sig.: Two pills three times a day.

Or, the following formula may be employed:

℞. Mangani sulph. exsic.....gr. xl.
Fel. bovis. purif.....℥i.
Resinæ podophylli.....gr. v.

M. ft. pil. No. xx.

Sig.: One pill three times a day.

—*Clinical Review.*

Paroxysmal Sneezing.—In hay fever and paroxysmal sneezing J. B. Ball employs:

℞. Quininæ sulphatis.....gr. iss.
Arsen. iodidi.....gr. 1-24.
Extr. belladonnæ.....gr. 1-12.

One of these pills to be taken three times a day.

Pruritus Vulvæ.—After ablution with soap and warm water, the following is to be applied:

℞. Morph. sulph.....gr. vi.
Acid boric.....℥iss.
Aq. camph.....℥vi.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 28, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	405	184
Diphtheria	358	47
Measles	255	5
Scarlet Fever	191	10
Smallpox	—	—
Varicella	151	—
Typhoid Fever	47	13
Whooping Cough	24	2
Cerebrospinal Meningitis	5	7
Malarial Fever	—	—
Totals...	1436	268

Chordee.—Opium may be needed, and is conveniently prescribed in suppository form:

℞. Pulv. opii.....gr. vi.
Camphoræ.....gr. xviii.
Ol. theobrom.....q. s.

Ft. suppos. No. vi.

S.: One at bedtime. —*The Hospital.*

Vomiting of Pregnancy.—

℞. Cerii oxalatis
Pulv. ipecac.....āā gr. i.
Creosoti.....♏ii.

Ft. pil.

S.: One pill every hour until nausea is controlled. —Goodell.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the week ending November 27, 1908:

THE PHYSIOLOGICAL SIGNIFICANCE OF THAT FIRST LESSON.*

BY STEPHEN SMITH, M.D., LL.D.,

NEW YORK.

VICE-PRESIDENT OF THE NEW YORK STATE BOARD OF CHARITIES.

ON a bright summer day in the early sixties I took advantage of a leisure hour or two in Syracuse to visit that anomaly among the charitable institutions of the State of New York—viz., a school for the instruction of idiots. The very purposes of the institution—*the education of idiots*—seemed then to be an unanswerable argument against its existence. Its founder, Dr. Hervey B. Wilbur, had encountered great opposition on this very ground that no one believed it possible to teach idiots sufficiently to make the creation of an institution for that purpose justifiable by the Legislature. The institution finally took the more appropriate title, "The Custodial Asylum for Feeble-Minded."

While crossing the lawn in my approach to the asylum, I casually noticed a group of young men engaged in "making hay." Some were mowing, others were spreading the cut grass, but all were actively and intelligently at work. On entering the administrative building I found Dr. Wilbur actively employed with his daily duties. I introduced myself as the editor of the *American Medical Times*, and explained that I was desirous of obtaining, by personal observation, information as to the success of the institution in teaching idiots. On this announcement the doctor's interest in my visit was aroused, and he became very communicative in regard to his work. We examined every part of the asylum and saw all of the inmates in their several departments and classes. It would be impossible to conceive of an apparently more hopeless and repulsive task than teaching many of those mere vegetating objects. Incidentally I suggested the impossibility of educating these children to become active and intelligent workers like the young men making hay on the lawn.

"Why, my dear sir," he replied, "those young men are all idiots, but the attendant, whom I presume you did not recognize from the others; some of them were as hopeless as the worst you have seen in the asylum."

I could not conceal my skepticism, and remarked that I regarded it as impossible to make a first impression on many of the inmates.

"That has been the mistake of the world in its treatment of idiots," he replied, "but in these later years we have learned how to teach the first lesson, and on that first lesson the whole system of educating the idiot depends. Come into the class room and I will give you a demonstration of the first lesson and its effects and results."

*Read before the American Association for the Study of the Feeble-Minded at its Thirty-second Annual Session, held at Rome, N. Y., June 24, 1908.

We went accordingly into the room of the lowest class of inmates, some of whom had been admitted so recently that the doctor knew nothing of their physical or mental condition. He requested me to choose one of the latter class who was unknown to him for a first lesson. I selected a boy who sat on the floor, drooling from his open mouth, and swaying his body, but who seemed insensible to anything about him, and, as the attendant assured me, had the food placed in his mouth at his meals.

The doctor took a dumb-bell and, placing it on the floor by the side of the boy, fixed his hand on the shaft with the fingers closed around it. Then taking another dumb-bell, and standing in front of the boy, the doctor raised his instrument high in the air and deliberately struck the dumb-bell on which the boy's hand was placed. The boy was startled by the concussion, but made no other sign of recognition of the blow. The doctor repeated the act twice more with the same result.

"This is the first lesson," the doctor remarked, "and he is a very promising student, with great possibilities. Now let me show you a boy of the same grade who has been under instruction for several months with two such lessons daily."

The second boy was the type of the first, and on the trial he removed his hand from the dumb-bell when it was struck, and raised his eyes from the floor, as if to see from whence the blow came. A third boy had been under treatment for a still longer period; he watched the doctor's movements, and when he saw the blow descending, raised his hand and laughed. A fourth boy was tested, who was now in one of the graded classes. When the doctor took the dumb-bell, and handed the boy another, the boy rushed at the doctor and for several minutes there was a clash of weapons, the boy showing dexterity and immense enjoyment of the contest.

In the discussion of his method of teaching the feeble-minded, Dr. Wilbur laid great stress upon the significance of "That first lesson." His explanation was to the effect that the idiot had a dormant nervous system, and the first step in the process of educating him must necessarily be to arouse the brain to activity; that the best method of making a first impression was through the sense of feeling; and that the shock communicated by a metallic substance through the sensitive surface of the hand was the most effective method. His argument was that if one special sense of the nervous system can be aroused to activity, other special senses will be excited, secondarily, and, finally, the whole brain will become receptive of external impressions and the higher mental functions will be gradually developed.

In the light of our present knowledge of the minute anatomy of the nervous system, and the physiological functions of its constituent parts, Dr. Wilbur's method of teaching the idiot was founded on strictly scientific principles. Undoubtedly he did not understand the full significance of his own rea-

soning for our knowledge of the structure or minute anatomy of the nervous system at that period was little more than its gross appearances. We had learned that its elements consisted of gray and white matter; that the gray matter was composed of cells and the white matter of fibers. The physiology of that period taught us little more than that the cells generated the nervous force, or energy, and that the fibers, or nerves, conveyed impressions, or impulses, to and from the cells. It quite naturally occurred to a thoughtful mind, like Wilbur's, that the brain of the idiot was in an inert, or dormant state, owing to the absence of a stimulus sufficiently powerful to arouse it to activity; if that stimulus could be properly applied through one of the special senses—seeing, hearing, feeling, smelling, tasting—the idiot could be taught like any other child. He chose the sense of feeling with the remarkable results that followed. Had he known the full significance of that first lesson in the light of modern scientific discoveries of the intimate structure and functions of the cells of the brain, its immense number of so-called centers, and their relations, his work would have been invested with a new interest, and there would have been far greater precision in its execution.

And what does modern physiology teach as to the structure and functions of the nervous system? In other words, *"What was the physiological significance of that first lesson?"* Let us first briefly notice the minute anatomy of the nervous system as at present taught. Though the most complicated mechanism known to science, excepting its connective-tissue which forms its skeleton, or frame-work, the entire nervous system consists of but a single body or tissue, viz., a cell with its branches, now called the "neuron." What has heretofore been known as nerves, commissures, and branches, are but prolongations of the central cells by means of which they communicate with the external world, and with each other. The cell, therefore, is the subject of the most profound interest to every student of the diseases of the nervous system. Its vast importance may be learned from the following statements of eminent physiologists: "The cell is a unified organism, a self-contained living being." "The sole active principle in every vital function." "The medium of sensation, will, and even thought, the highest of the psychic functions." "Our own body is a very elaborate social system of countless microscopic organisms; a colony or commonwealth made up of innumerable independent units."

Confining our discussion to the brain-cells, or "neurons," we learn that they are implanted in fetal life and at birth are in a rudimentary state. In numbers they are estimated by the thousands of millions. The essential feature in the structure of the cell proper is the nucleus, and its contents, which has the function of creating the force or power, known as "nervous energy," and "nervous fluid," the exact nature of which is unknown. The nerve cell, and its branches are often, and very properly, likened to the electric battery, the cell being the battery which generates the electricity, and the nerves the wires which convey it to its destination.

The anatomist teaches that these cells are grouped into centers according to their particular functions. We have long been familiar with the so-called special senses, which are nerve-centers with special functions, viz., seeing, hearing, smelling, tasting, feeling. These centers are designed to bring the individual into conscious relations with five distinct features of the external world in which he lives, moves, and has his being.

Comparatively few of these centers have as yet been accurately determined, but enough is known to prove that every function, every act, and possibly every thought has its origin in a special center in the cerebrospinal axis. For the coordination of the operations of these innumerable centers the interior of the brain is a mass of connective nerve fibers, through which the intimate relations of the nerve centers are maintained, thus securing the most perfect harmony in the functions of all of the organs of the body. These fibers are "commissural," connecting the two hemispheres; "projection," which project "upon the cortex of the brain the results of sensory stimuli upon the body;" and "association," which "connect different convolutions in the same hemisphere." It is stated that "Were it not for the existence of these fibers, perception, memory, and thought would be impossible. Our perception of a pear is incomplete until "we have fused into one mental whole the sensations from tasting, smelling, seeing, touching and hearing the fruit fall from the tree."

Another important anatomical feature of the nerve-centers is their arrangement. First, there are the centers of the special senses through which the individual communicates with the external world. This group is sometimes called the "lower brain." The functions of these centers are to receive the impressions and transmit them to another higher series of centers, called the mid-brain. The function of these centers is to take cognizance of the special character of each impression, and transmit it to the proper center in a still higher grade. This is called the "*higher-brain*," which it is both in location, being in the frontal part of the cerebrum, and in function, being devoted to ideation, or thinking.

Without going farther into what would become tedious anatomical details, let us consider what the physiologist teaches in regard to the nerve-cells, or neurons, and the nerve-centers. First, we learn that the cells are implanted at birth in a rudimentary form and undergo an evolution from the cell of the lowest of animal life to the complex cell of the human brain. Though at birth the cell has been perfected so far as regards its structural adaptation to its special future function, yet it will remain in an inert state and undergo no further change or development until excited to activity by its special stimulant. For example, if a person is born blind the cells of the center of sight will remain in a rudimentary state and undergo no further development until excited by their proper and only stimulus—light. The same is true of a large number of nerve-centers which are in immediate functional relations with the center of sight. If now an operation is performed upon the eye and light reaches the cells of the center of vision an immediate change takes place; the cells begin to enlarge; the blood-supply is increased to meet their more active nutrition, and all of the related nerve-centers undergo similar changes as to activity and development.

The physiological facts in regard to the cells of the center of seeing are the same in the centers of all the special senses — hearing, feeling, tasting, smelling—through which the brain as a whole is stimulated to functional activity. It follows that in proportion to the integrity of the special senses is a human brain perfect, or, on the other hand, defective. It is also asserted as a physiological fact that if the apparatus by which each of the nerve-centers of the five special senses receives impressions from the external world, were destroyed at birth, the

thousands of millions of nerve-cells of the brain would remain inert and undeveloped during the lifetime of the individual. This fact leads the physiologist to believe that in the human brain there are large numbers of nerve-cells that remain undeveloped because never excited to functional activity, and, also, that at any period of life, cells hitherto inert, may receive their proper stimulus and take on functional activity.

If to the born-blind there is no world of light, and to the born-deaf there is no world of sound, may it not be a fact that other worlds exist around us, than those revealed by the five special senses, which we do not recognize because the special nerve-centers for that purpose have not as yet been stimulated to activity? St. Paul hints at this opinion when he declares that certain religious truths can be discerned only by those in whom the spiritual sense has been awakened. May not the strange mental phenomena of dreams, telepathy, hypnotism, and kindred experiences of individuals be traced to the stimulation of nerve-centers aroused to activity only under special conditions? Certainly the very suggestion of this possibility opens a wide field for speculation.

A second important feature of nerve-cells, or neurons, is that they differ in individuals as to their susceptibility to impressions, owing to a difference in their intimate texture. This difference is due to heredity, and admits of the same explanation as other examples of the transmission of physical features from parents to child and differentiates persons, families, and even nations.

A third physiological feature of the nerve-cell is that while it will develop and increase in size when functionally active, it will diminish in size, or atrophy, when at rest. For example, if the eyes were bandaged and no light were allowed to reach the ophthalmic center for any given period, the cells of that center would gradually shrink, or atrophy, and provided the light were withheld for a sufficient length of time they would return to their rudimentary condition. It follows that it is in the power of the individual, or of a person having control of him, to increase or diminish the activity, and the integrity, of nerve-cells at will.

A fourth physiological fact is, that, while the nerve-cells derive their intimate structure on which their natural susceptibility depends, from heredity, or parentage, this susceptibility may be considerably increased and diminished by nutrition. In other words, we may withhold from the nerve-cells the elements of nutrition on which their normal integrity depends, and thus diminish their power and susceptibility, or we may supply them with nutritive materials equal to the natural demands of the cells and greatly increase their force and susceptibility.

Summarizing these anatomical and physiological facts we may formulate the following conclusions:

1. The neuron—the nerve-cell and its branches of communication—is the unit of the nervous system; there are thousands of millions of them and their specialized functions are the control of every organ, and act, of the body—"sensation, will, and even thought."

2. The intimate texture of the cell, on which its susceptibility and capacity to perform its functions depends, is inherited, but may be modified at will by proper exercise, nutrition, and conditions of environment.

3. The germ-cell is implanted at birth, and its subsequent development depends upon its stimulation to functional activity by its appropriate stimulus; that is, if it is not stimulated it will remain inert and undeveloped, thus making it possible, by applying the appropriate stimulus, to bring into healthy activity cells long dormant.

4. When an active cell ceases to be stimulated it begins to diminish in size—atrophy—and will become inert as regards its function, and will remain inactive until excited to activity by its special stimulant, showing that any class of cells may be reduced to an inert state and again restored to activity by withholding or supplying their appropriate stimulus.

5. Every cell has inherent in its constitution the power of selecting from the blood substances for its nutrition and stimulation, and for which it has a "selective affinity." This feature in the constitution of the cell enables us, by means of the appropriate remedies, to increase, diminish, or pervert its action.

6. In the structural arrangement of the neurons they are grouped into "centers" according to their special functions; in these centers the cells communicate with each other by means of innumerable branches—dendrites—while the centers communicate with each other through nerve-fibers known as commissures. In the grouping of these centers there is a perfectly logical and orderly series of sequences by which impressions are made, received, and responded to on the part of the centers, so as to secure the most perfect harmony in all of the acts, functions, and even thoughts, of the individual.

7. The fundamental grouping of the nerve centers was designed to bring the individual into proper relation with the external world—the source of all power—and hence we have first, the centers of the five special senses, seeing, hearing, smelling, tasting, and feeling; from these the impressions are conveyed to other centers closely allied in function, until they finally reach their destination in the cerebral centers, the seat of the "highest psychic functions."

8. Every nerve-cell has its own special function, and these functions are as numerous as the acts, and even the thoughts, of the individual, but each depends ultimately for its activity and development upon the stimulation which it receives from one of the five special senses, through the medium of association fibers.

From the preceding summary of anatomical and physiological facts we may conclude that every vital function, as well as every mental operation, thought, word, and act, has its origin and expression in one or many of these entities or units of the nervous system. Their combined physiological functions, in health, constitute the normal individuality of the person, mentally and physically.

If now we consider the extreme susceptibility of these bodies to an innumerable variety of impressions to which they are exposed, external and internal, to the body, we can form some conception of how unstable their functions may be. Their own structure is constantly undergoing change in the act of nutrition. Their integrity thus depends upon the absorption and removal of dead tissue and its replacement with suitable nourishment. If the dead matter is not promptly removed, or if the food of the individual is not suitable, the neuron is no longer in health and must perform its function less perfectly. They are also extremely susceptible to, and receptive of, impressions derived from the external world. Thus they are affected by the food we eat and the fluid we drink; by diseases of every kind which afflict the body; by everything recognized by the senses.

It follows that any change in the constitution or

structure of the cell or neuron must be attended by a derangement of its function which would find expression in the mental acts of the individual. If a group of cells should from any cause cease to act the mental attributes which they manifest when acting normally must cease. Equally, if the same cells are overstimulated their functional activity is correspondingly increased. Or, again, if the structural properties of the cells are changed, as by alcoholic intoxication, or by any other toxic agent which finds access to the brain and for which any cells have an affinity, the mental functional expression would be changed to the extent, and in the particular feature, that the affected bodies contribute to the mentality and personality of the individual. Thus, if certain intoxicants are administered the change effected in the constitution of the bodies devoted to the function of seeing are such that external objects assume new forms, technically causing an illusion of sight. The experimental physiologist can, at will, with certain toxins, change the action of groups of cells so that the individual will exhibit certain mental traits entirely foreign to his usual habit of thought and expression. In various forms of sickness the temper and conduct of the patient undergo marked changes, often becoming delirious, due to the changed conditions of nutrition caused by toxins in the blood or by the various forms of disease. Autointoxication, on which modern therapeutists place so much stress, finds its most frequent expression in the vagaries of character which the toxins generated in that great culture bed, the colon, produce on the nerve-cells. The old-time remedy for persons of gross habits of overfeeding—blue pill at night and a seidlitz powder in the morning—has changed a sour to a sweet temper. An English clergyman who had many wealthy parishioners was accustomed, when summoned to minister to the spiritual wants of a certain class, to send the applicant several pills with the request that they be taken at bed-time and the promise that he would call on the following day. The famous philosopher, Dr. Samuel Johnson, declared in his vehement manner that every sick man is a rascal. In health the individual exhibits ever-varying "moods of mind," owing to the constant changes in cell-structures or neurons, due to nutrition and the infinite number and kind of impressions acting upon them from within and from without the body. We are not the same in every respect this year that we were last year, this month that we were last month, this evening that we were this morning. The wise Diotima said to Socrates (The Symposium of Plato): "In the same individual there is succession and not absolute unity; a man is called the same; but yet in the short interval which elapses between youth and age . . . he is undergoing a perpetual process of loss and reparation. . . . And this is true not only of the body but also of the soul, whose habits, tempers, opinions, desires, pleasures, pains, fears, never remain the same in any one of us, but are always coming and going." In the ultimate elements of the brain, then, science is seeking the true explanation of the mental phenomena which characterize the various phases of insanity. A learned authority has thus tersely stated the conclusions of science: "As his neurons are, so the man is."

The preceding discussion which very imperfectly illustrates modern views of the anatomy and physiology of the central nervous system, furnishes the facts necessary to understand the physiological significance of that first lesson, which I witnessed, as taught by Dr. Wilbur.

The subject of the first lesson was a fairly well-developed child, both as to its body and brain, whose nerve-centers of the special senses had never responded to their natural stimuli, and hence the cells of these centers were in a rudimentary and undeveloped state. The result was that all the thousand million cells of the brain which depended upon the activity of these special centers for stimulation to action, remained inert and undeveloped. And yet to the mind of Dr. Wilbur there existed in this child an apparatus, organized for a special purpose which for some reason could not take the initiative in getting itself started. It was like a clock wound and prepared to register time correctly, but no one moved the pendulum; like an electric battery fully charged, but no one pressed the button that made the circuit. How was the first impulse to be given to this dormant mechanism—the brain? Evidently it must be through the medium of one of the special senses, for in that way must an initial impression be made on the nerve-cells. Wilbur chose the sense of feeling because through that medium the most direct and profound impression could be made. But actually and practically he used also the senses of seeing and hearing. In striking with the dumb-bell he stood in front of the patient so that the child saw him raise his arm to strike, as was apparent in the second and third child. The clash of the dumb-bells was conveyed through the apparatus of the ear to the auditory center. Thus in the first lesson three dormant centers were aroused to activity by the normal stimulus of three special senses. The physiological effect of the stimulation of the cells of these centers to functional activity was an increased flow of blood for their nutrition, and a consequent enlargement or normal development of the individual cells.

But the effect of this first lesson was not limited to the centers immediately stimulated to activity by the clash of the dumb-bells. If we could trace the far-reaching connections of the neurons of the special center of feeling with the neurons of other centers, deep in the brain substance and leading up to the great centers of thought, we should have seen hundreds of thousands of inert and undeveloped cells awakened from their dormant state and beginning to assume their proper functions. If to the results which followed the direct stimulation of the center of feeling, we had added the equal, if not greater, influence which the centers of seeing and hearing had upon the brain nerve-centers, we could probably only imperfectly appreciate the tremendous significance of that first lesson. It was the initial step in a course of instruction that had unlimited possibilities in its power to build a brain, and thus rescue a child from a mere vegetable life—an intolerable burden upon its family and a curse to itself.

The lesson which the preceding illustrations of the anatomy and physiology of the nervous system teaches has a wide application to our treatment of the dependent classes. We learn that the mental attributes of every person depend ultimately upon the physical state of the nerve-cell over which we have almost absolute control, both in its individual and collective capacity. If its texture is feeble from heredity or disease we may make it strong by nutrition, exercise, pure air, and medication; if it is undeveloped we can develop it by applying its appropriate stimulus and suitable nourishment; if it is unduly developed and hence over-active we can reduce it to a rudimentary and inactive state by removing every form of stimulant and reducing its nutrition; where neither the regulation of the stimulant or nutrition accomplishes our purpose, we can rely upon specific remedies.

The logical and inevitable conclusion to be drawn

from this discussion is, that, if we thoroughly understood the exact function, and the functional relations, of all the cells of the nervous system, we could, beginning with the child, develop whatever kind, or attribute of character, we choose. In the adult we could modify existing attributes by stimulation of one class of nerve-cells, and the repression of another, to any extent that we desired. There is no doubt that the marked changes which we often witness in the mental attributes of the sane and insane, temporary and permanent, are due to conditions affecting the functional activity of nerve centers. Nothing can be more thoroughly practical than the application of the proper remedies by which the equilibrium of these centers is secured. Socrates was asked how a vicious boy could be reformed, and he replied: "Remove every possible incitement to *vice*, and substitute every possible incitement to *virtue*."

The Athenian philosopher formulated his maxim on a sound, physiological basis. We are daily applying this advice in mental disturbances by placing patients under conditions which tend both to the forgetting of disturbing objects, and becoming interested in new and diverting surroundings, thus repressing the activity of the excited centers on which the disability depends, by removing the source of stimulation and substituting the activity of other centers. But, unfortunately, it is done without other motive than experience, and hence the results are comparatively slight. We can only feebly conjecture what vast numbers of feeble-minded would be taught self-care, what enormous percentage of insane would be cured, and what universal reformation of criminals would result, if every one of these classes now in public care were subjected, individually, for five years to the skilled, patient, and persistent treatment of experts in the physiological and psychological sciences.

The defect in the system of educating the idiot adopted by Dr. Wilbur was not in the means employed, nor in the method of employing them, but in the failure to recognize the true physiological significance of that first lesson to which he attached so much importance. While he individualized each inmate in his treatment he failed to individualize the integral parts of the brain, through ignorance of its intimate structure, and therefore, treated it as a whole—as a unit—which does not tend to the attainment of the highest possible results.

This limited view of a complex and complicated mechanism may not have greatly embarrassed a master-mind like Wilbur's in his methods and efforts to teach the feeble-minded, but it is painfully evident to an intelligent visitor to institutions for the care, treatment, or education of those suffering from idiocy, insanity, epilepsy, or other affections of the nervous system, that there is too often wanting, on the part of physicians and caretakers alike, that genuine enthusiasm in their work which insures the highest degree of success. The vast variety of symptoms which these diseases present for study attract but little attention because the brain is a sealed book. All of the inmates are placed on a dead level, and the treatment, instead of being individual, is *en masse*.

This superficial and mere surface knowledge of the inmates of institutions on the part of the officers not only results in ignorance of the possibilities of improvement of large numbers of patients, but begets incredulity as to the capacity of an entire class to be improved by any method of treatment. It is equally true that the medical officers, attendants, and managers of our charitable and correctional institutions have little, and too often, no faith in the capacity of the vast majority of the mentally defective class to be taught, the mentally diseased class to be cured, or the criminal class to be reformed. And this want of faith is due to ignorance of the capacities of the human brain to be infinitely modified by expert care. The result is that no state institution, devoted to the care and treatment of these classes, is so organized and conducted as to be thoroughly curative in its methods. They are in fact custodial. In their annual reports they never call special attention to the increasingly large percentage successfully taught, cured, reformed, and discharged. They do not appear before the Legislature asking appropriations for better facilities for teaching the idiot, curing the insane, and reforming the criminal, using as an argument the 75 per cent. taught, cured, and reformed the past year, and promising with improved facilities to raise the percentage to 95 per cent. On the contrary the constant demand upon the State is for more buildings to accommodate the ever-increasing number to be added to the fixed population of these institutions.

I am aware that opinions so favorable to the far more successful treatment of the mentally affected classes will be received with doubt and incredulity by those who have had long experience in these institutions. Those connected with asylums for the idiots and feeble-minded will point to the great array of statistics of these institutions showing a fixed population with few discharged except by death; the managers of the State Hospitals for the Insane will refer to the statistics of Earle, collected a half century ago, which prove that scarcely any insane permanently recover, confirming the old maxim, "once insane, always insane;" the managers of the prisons will refer to innumerable incorrigibles who have resisted all of their methods of discipline—even starvation, whipping, and the dungeon.

But that first lesson of Wilbur, rightly interpreted, is a promise and a prophesy of a coming era of far more successful treatment of those laboring under the disability of dormant or perverted brain cells. When we recall the enthusiasm with which he patiently labored, day after day, month after month, year after year, to arouse to activity the inanimate brain of a helpless, hopeless idiot, and was rewarded by the addition to his corps of helpers of a useful man, we must recognize a beacon light showing us a new and better way.

There is on the grounds of this institution a concrete example of the scientific application of Wilbur's method. Among the laborers is a young man who was transferred from another State institution as unteachable. That verdict meant to this boy, equipped with brain and muscle for activity if he could be set in motion, a mere vegetative life. Moved by an impulse to determine experimentally what possibilities there might be in an effort to teach this idiot self-care, the superintendent undertook, personally, the task of education. Well versed in the anatomy and physiology of the brain, he began to stimulate to functional activity one nerve-center after another, with the final result that he built a brain, and converted a helpless burden upon the State for, perhaps, half a century, into a self-supporting citizen. Indeed, the animal trainer, who, stimulating patiently and persistently its feeble responsive brain-cells, creates the "learned pig," the "educated seal," and numerous other prodigies of learning among animals, ought to teach us that we have nearly unlimited power, if rightly directed, of educating the human brain, however defective.

The practical question arises, "How can such a scheme of education be realized?" An incident in

my official inquiries is to the point. I visited a family of fifteen children under the care of a foster-father and foster-mother, the former being a highly educated practising physician, and the latter a very intelligent and cultivated woman, but both were lovers of children, and actuated by the most profound religious motives. Having no children of their own, they began many years ago to gather a family, selecting by preference destitute orphans, without regard to color, race, or nationality. At my visit there were in the family circle, Americans, Irish, Welsh, Mexicans, Porto Ricans, and Negroes; their ages ranging from 8 to 22 years. They represented the poorest class of people of their respective nationalities, and several were from the city slums. These children were under a rigid system of personal training by their foster parents, as to their diet, exercise, bathing, conduct, and studies. The brain capacity of each was precisely gauged and every possible means employed to repress vicious tendencies by removing excitants thereto, and substituting the rewards of virtuous conduct. Here was a large, united, and devoted family circle, the individual elements of which were as diverse as human society could make them, in which scientific individual training was surely overcoming the disabilities of heredity, stimulating to active development dormant nervous systems, establishing that equilibrium of cerebral functions which insures against insanity, and repressing the tendencies to vice by the allurements of virtue.

My first suggestion is that in organizing the service of an institution for the care and treatment of the dependent classes every possible effort should be made to individualize each inmate from the moment of admission, and to maintain that individuality throughout its residence. My view is that from the first day to the last each inmate should be the subject of special study and record; the first examination should be exhaustive of every organ and function of the body. No rational effort can be made to improve the physical or mental condition of a person until we understand the exact present condition of the organism on which their integrity depends. Such an examination would determine the faults of nutrition from the ingestion of food to its assimilation: the precise waste of the body by tests of the excretions of eliminating organs; the condition of heart, lungs, kidneys, liver; the dynamic power of the muscles; the activity and sensibility of each of the special sense-organs; and such other tests as will give the attendant a scientific basis on which to begin to reconstruct the physical and mental constitution of the inmate.

To maintain the individuality of this patient in an institution the colony plan, with its family organization, is absolutely essential. The vast advantages of the cottage system on ample farming lands, with its diversified forms of simple, out-door industry, its opportunities for unlimited classification and individualizing inmates, and its possibilities for economy of administration, commends the colony plan to the judgment of the highest authorities.

Again, I would suggest the systematic education of attendants along the lines indicated in this paper, in addition to the ordinary instruction of the Training Schools for nurses. The structure and functions of the nervous system, and especially of the brain, as outlined here, can be intelligently appreciated by every person of ordinary education. In my experience with the trained nurses of general hospitals anatomical and physiological explanations which illustrate the nature of the duties they are to perform are received with the keenest interest, and immediately applied in practice. With such knowledge on the part of the attendant every case that comes under care becomes invested with a new and living interest which makes that care a pleasure rather than a task to be perfunctorily discharged.

Finally, it is necessary, in organizing a scheme of more direct personal treatment of inmates by skilled attendants, that there be one or more supervising officers of the highest possible qualifications, who devote their entire time and energies to the personal supervision of the instruction of every class, and, who, through the subordinate teachers, maintain constant familiarity with the progress of every inmate.

It is true that this scheme fully developed would require a very large number of thoroughly qualified and highly educated officers and attendants, with greatly increased salaries. But in the end it would be economy to make the defectives self-supporting, to cure the insane and to reform the criminals, for to the extent that these objects can be accomplished the State will cease to build more buildings, and gradually reduce the ever-increasing population of dependents, and thereby the burden of their support.

Our conclusion of this discussion is that, in these latter days, there is a far more hopeful outlook for the feeble-minded, the insane, and the criminal. Instead of reasoning backward from effect to cause, and thus reaching a vague and indefinite conclusion, skilled and expert anatomists and physiologists, inspired by the scientific spirit of the age, are gradually penetrating and unveiling the mysteries of the brain, the center and source of all mental activities. These constructive students are thus laying the foundations of a true science of psychology in the immutable facts revealed by anatomy and physiology.

300 Central Park, West.

A STATISTICAL STUDY OF RENAL COLIC AND HEPATIC COLIC.*

By BRANDRETH SYMONDS, A.M., M.D.,

NEW YORK.

CHIEF MEDICAL DIRECTOR, MUTUAL LIFE INSURANCE COMPANY OF NEW YORK.

RENAL COLIC.

The material for this study was obtained from all the lives insured in the Mutual Life Insurance Company in the thirty-seven years from 1870 to 1907, who showed a history of renal colic, renal or vesical calculus, or gravel. The calculations for the expected mortality were made in accordance with the method adopted by the Actuarial Society in their Specialized Mortality Investigation, except that each life was counted but once, and full allowance was made for the re-entry of a life subsequent to the initial entry.

The first list contained 1742 entrants. This list was then carefully revised by me and 290 doubtful cases were eliminated, leaving 1452 who gave a distinct history of renal colic or calculus. No case was admitted to this list unless there was reasonable evidence to this effect, such evidence as a Medical Director would regard as conclusive. This list showed 108 actual deaths and 109 expected, a mortality of 99 per cent. The material, however, was not homogeneous in respect to physique and residence. I, therefore, eliminated all overweights and those residing in foreign countries and the southern

*Read at the nineteenth annual meeting of the Association of Life Insurance Medical Directors, October 21, 1908.

states, and also those who had had more than one attack of renal colic. This left a group of 895 lives, practically homogeneous and without impairments other than the record of a single attack of renal calculus.

The following table gives the number of entrants at each age, the actual and expected deaths, and the percentage mortality, all arranged in quinquenniums.

TABLE I.

Age at Issue	Number of Entrants	Deaths		%
		Actual	Expected	
Under 15				
15–19	1		.020	
20–24	12	2	.448	446
25–29	81	2	3 808	53
30–34	139	4	7 365	54
35–39	180	9	10.616	85
40–44	171	9	14.318	63
45–49	131	12	11.284	106
50–54	88	8	11.172	72
55–59	57	13	9 837	132
60–64	24	4	4.716	85
65–69	10	5	2.191	228
70–74	1	1	.162	618
Total...	895	69	75.937	91

This table shows that the young and middle-aged are not seriously affected by this impairment. Below 45, the actual deaths were 26 and the expected 36.5, a mortality of 71 per cent. Above 45, the actual deaths were 43 and the expected 39.5, a mortality of 109 per cent. The Specialized Mortality Investigation of the Actuarial Society, published in 1903, shows a good mortality in this class below age 28, and an increasingly bad mortality above that age.

Does the age at which the attack occurred have any bearing on the risk? It was not difficult to approximate the age in most cases, and the following table gives the cases grouped according to the age at which the attack occurred, the number of risks in each group, the actual and expected deaths, and the percentage mortality, all arranged in quinquenniums. The last two columns give the number of risks in each age-group who were examined within five years of the date at which the attack of renal colic occurred, and the proportion which these bear to the total number of risks in each age-group.

TABLE II.

Age When Attack Occurred	Number of Entrants	Deaths		%	Examined Within 5 Years of Attack	
		Actual	Expected		Number of Risks	% of Total Entrants in Each Age-Group
Under 15	11	1	.560	178		
15–19	32	2	2.200	91	5	16
20–24	123	2	6.920	29	41	33
25–29	158	7	11.513	61	43	27
30–34	190	11	12.837	86	85	45
35–39	156	9	12.303	73	77	49
40–44	98	12	10.601	113	47	48
45–49	71	11	8.814	125	36	51
50–54	33	6	5.749	105	18	55
55–59	13	5	2.186	229	7	54
60–64	3	1	.608	164	3	100
65–69	....	....	.....	....	..	...
70–74	1	1	.162	618	1	100
Total..	889	68	74.454	91	363	41

The mortality curve set forth in this table is quite regular and for that reason reassuring. Under age 20 the mortality is high, probably due to the small number of cases in the group. After that age, the curve is almost uniform and shows a steadily increasing mortality. The point to determine was whether this mortality was anything more than a practical duplication of that furnished by Table I. It was quite natural to assume that the young persons in this table were examined many years after the attack. In the quinquenniums below 30 this may be inferred, owing to the small percentage of risks in these quinquenniums who were examined within five years of the attack. From 30 to 60, however, this inference does not hold true. The proportion of risks in each of these quinquenniums, who were examined within five years of the attack is nearly the same, but the mortality rises from 86 per cent. to 229 per cent. If we group them into decades the mortality is as follows:

DEATHS.

Age	Actual	Expected	%
30 39	20	25	80
40 49	23	19.4	118
50 59	11	.8	137

This looked so promising that it seemed worth while to investigate the point still further. The following table shows those who were between twenty and fifty-nine when the attack occurred, the first half of the table including those who were examined within five years of the attack and the second half including those who were examined more than five years after the attack. Owing to the small number of cases in each class, they have been arranged in decades.

TABLE III.

Those Examined Within Five Years of Attack					Those Examined More Than Five Years After Attack			
Age When Attack Occurred	No. of Entrants	Deaths		%	No. of Entrants	Deaths		%
		Actual	Expected			Actual	Expected	
20–29	84	3	5.011	60	197	6	13.422	45
30–39	162	10	9.599	104	184	10	15.541	64
40–49	83	8	7.150	112	86	15	12.265	122
50–59	25	5	3 606	139	21	6	4.329	139

This table shows that when the attack occurred below age thirty the impairment was trivial, irrespective of the date of the examination. Between thirty and forty those examined within five years of the attack were not good, while those examined at a later time were excellent risks. Above age forty the mortality was bad irrespective of the date of the examination.

In order to determine if this impairment is a continuing one, the mortality was calculated by insurance years. The following table gives the number exposed, the actual and expected deaths, and the percentage mortality, all arranged in quinquenniums.

TABLE IV.

Insurance Years	Number of Exposures	Deaths		%
		Actual	Expected	
1–5	3182	23	30.4164	76
6–10	1575	23	24 1774	95
11–15	721	15	13.4890	111
16–20	222	5	4.9637	101
21–25	52	2	1.5126	122
26–30	24	1	1.1225	89

The mortality curve, as set forth in this table, is most interesting. It is not uniform, owing to the small number of cases, but it rises fairly steadily throughout the insurance life of these risks. This is shown particularly well if they are grouped into decades, as in the following table.

TABLE V.

Insurance Years	Number of Exposures	Deaths		%
		Actual	Expected	
1–10	4,757	46	54.5938	84
11–20	943	20	18.4527	108
21–30	76	3	2.6351	114

In the Specialized Mortality Investigation of the Actuarial Society of America, published in 1903, Class 53 is composed of those risks who gave a history of having had renal colic, calculus, or gravel. The material in it was not as carefully selected as the class on which this report is based, for many of the cases of so-called gravel undoubtedly referred to trivial conditions of no importance. Furthermore, it is not homogeneous, for it includes many cases which showed other impairments. On the other hand, it is much larger than my class, as it numbers 6,934 entrants, and its size tends to correct the inequalities due to the above-mentioned conditions. The following table gives the number of exposures by insurance years, the actual and expected deaths, and the mortality percentage, all arranged in quinquenniums.

TABLE VI.

Insurance Years	Number of Exposures	Deaths		%
		Actual	Expected	
1–5	22,791	206	200.0	103
6–10	9,715	148	140.8	105
11–15	3,752	71	70.7	100
16–20	1,286	47	31.5	148
21–25	438	19	14.2	134
26–30	121	4	4.5	89

This shows the increasing mortality as the years pass. The rising curve is not entirely uniform, but when the deaths are grouped into decades it becomes smoother, as in the following table.

TABLE VII.

Insurance Years	Number of Exposures	Deaths		%
		Actual	Expected	
1–10	32506	354	341.8	104
11–20	5038	118	102.2	115
21–30	559	23	18.7	123

From these results, I think we can now say that renal colic or calculus is an expression of a pathological condition, which is permanent and progressive in a sufficient proportion of cases to make the mortality of this class one which increases with lapse of years.

On studying the causes of death as grouped in Table V., we found that there were forty-six deaths in the first decade of insurance, of which ten (22%) were due to Bright's disease, or arteriosclerosis. In the second decade of insurance there were twenty deaths, of which nine (45%) were due to Bright's disease, or arteriosclerosis. This is a large increase, even allowing for the fact that the second decade represented older lives, who are naturally more liable to these diseases. Other chronic diseases did not increase in the same proportion. Heart-diseases, for example, remained at 15% in each decade. It is this increasing percentage of renal and arterial disease which makes these cases so bad. If the second decade had no greater proportion of them than the first decade its mortality would be as good as the first.

TABLE VIII.

Date of Examination Subsequent to Attack of Renal Colic	Number of Entrants	Deaths		%
		Actual	Expected	
During first year	20	2	2.4912	80
" second "	72	5	4.8698	103
" third "	98	4	7.2091	55
" fourth "	82	10	5.3878	186
" fifth "	92	8	6.4649	124
Sixth year to eighth year (incl.)	207	8	15.6856	51
Ninth year to twelfth year (incl.)	168	21	15.9518	132
Beyond twelfth year	150	10	16.6965	60

It is of interest to see whether the interval which elapsed between the attack of renal colic and the medical examination has any bearing upon the mortality. Table VIII shows this, six cases being omitted in which the interval was not definitely stated.

The mortality curve in this table is very irregular, owing, doubtless, to the small number of cases in the individual groups. The first five years together give twenty-nine actual deaths and twenty-six expected, a mortality of 111%, but the first three years give only eleven actual and 14.5 expected deaths, a mortality of only 80%, while the fourth and fifth years together give eighteen actual and 11.8 expected deaths, a mortality of 153%. Altogether a careful study of this table is not productive of any definite conclusions, but a study of the causes of death as affecting this table is quite fruitful.

Among those insured within four years of the attack, there were twenty-one deaths, but only one of these was due to Bright's disease, dead eleven years after the examination, and only one to arteriosclerosis, this death occurring seventeen years after examination. Among those insured more than four years after the attack, there were forty-seven deaths. Of these deaths seven were due to Bright's and eleven to arteriosclerosis, eight of the eighteen dying within five years of examination. These facts show that for four years after the attack we were especially careful in excluding all doubtful renal conditions, by thorough urinary examination. After that time we naturally relaxed our care a little in this respect, not realizing that in some cases the effect of this impairment is permanent, and therefore our mortality from these renal and arterial conditions promptly increased. It is very likely that a more thorough urinary and arterial examination would have kept out some of these untimely deaths. Perhaps it is fair to assume also that the high mortality among those insured within five years of the attack may be accidental and due to the limited number of entrants.

The following table shows the causes of the deaths which occurred in these 895 selected lives.

TABLE IX.

CLASS XIII—Ill Defined		1
Sudden	1	
Totals	69	69

Class I., acute general diseases, is about normal. Class II., chronic general diseases, is below normal, owing to the very small amount of tuberculosis.

This may be accounted for by the entire absence of a tuberculous family history in any of the cases. The percentage of leucemia and anemia is enormous, being twenty times what it ought to be. Perhaps this indicates some etiological connection between these diseases of the blood-glandular system and renal colic. In Class III., diseases of the nervous system, we find only deaths indicating some arteriosclerotic changes in the brain, and these are in excess of the normal. Class IV. is nearly twice as large as it ought to be, owing chiefly to the increase in the organic diseases of the heart. It is possible that this is due indirectly to the nephritis, which is the primary disease, but which is overlooked in the later years of life, when heart failure becomes pronounced. Pneumonia is normal in amount. Diseases of the digestive system are only one-half the normal. Diseases of the genitourinary system are nearly double the normal, and this is almost entirely due to the various forms of Bright's disease. The remaining classes are too small to permit analysis.

Among these 895 selected risks were twenty-two who were more than 20% below the standard weight. These gave two actual deaths and 2.2 expected, a result which was so satisfactory that they were included in the select group.

Among those risks who had only one attack of renal colic there were ninety-two who were overweight. These have not been included in the selected group which we have been analyzing. The actual deaths among them were twelve, while the expected were eight, a mortality of 150%. The cases are too few to analyze in detail, but this result shows that the combination of overweight and renal colic is very short-lived.

There were 147 cases who had had more than one attack of renal calculus. These gave six actual deaths and ten expected, a mortality of only 60%. None of these deaths was from nephritis, and only one from cerebral paralysis. The following table shows the detailed results, the cases being grouped into two classes as indicated:

TABLE X.

CASES WHO HAD MORE THAN ONE ATTACK OF RENAL COLIC.

	THOSE EXAMINED WITHIN FIVE YEARS OF ATTACK				THOSE EXAMINED MORE THAN FIVE YEARS AFTER ATTACK			
Age at Issue	No. of Entrants	DEATHS Actual	DEATHS Expected	%	No. of Entrants	DEATHS Actual	DEATHS Expected	%
20–29	4	.	189	.	8	1	219	457
30–39	21	1	834	120	26	1	753	133
40–49	11		648	...	34	.	1.755	
50–59	8		1.040	...	29	3	3.500	86
60–69			..	..	6		1.337	
Total.	44	1	2.711	37	103	5	7.564	66

The number of cases in either group is too small to make any positive deductions. It is not unfair to assume that our selection was very rigid during the first five years and that we relaxed a little afterwards. Doubtless we were always more careful in examining and selecting these cases than when only one attack had occurred, and perhaps this will account for the lower mortality.

Reviewing now the whole series of statistical tables which have been presented in this study, we can arrive at some fair conclusions in spite of the scanty amount of material which we have had to work with.

1st.—Renal colic is an impairment, the effect of which becomes more pronounced with each year of age, and of insurance. This seems to be due to the fact that in some cases it is an indication of a permanent and progressive lesion. The causes of death indicate that this lesion is in the kidneys and arteries.

2d.—It is not unfair to assume that care in testing the urine and in determining the blood-pressure would exclude many of the cases which are thus permanently affected.

3d.—The time which elapses between the attack and the examination seems to be of comparatively small consequence in determining the value of the risk.

4th.—When the attack occurs below age forty, the mortality will probably be good if our examination has been carefully made.

5th.—When the attack occurs above age forty, it is a question whether a rigid examination will secure satisfactory results, though I am of the opinion that modern methods of diagnosis will give us a reasonable mortality.

6th.—The combination of overweight and renal colic is very serious.

7th.—Any person who has had an attack of renal colic should regularly every few months have his urine examined and his blood-pressure determined. He is sitting under a sword of Damocles which only constant watchfulness may prevent from falling. The profession generally regard a renal calculus as an acute condition which may be serious while it lasts, but which is generally recovered from with no permanent damage, when the stone has been passed in the urine. They should realize that this is not so in all cases, but that some are left with a permanent lesion of an insidious character which is progressive and ultimately fatal.

HEPATIC COLIC.

The material for the following study was obtained from all the lives insured in The Mutual Life Insurance Company in the thirty-seven years, from 1870 to 1907, who showed a history of bilious colic, biliary colic, hepatic colic, biliary calculus, hepatic calculus, or gallstone. The calculations for the expected mortality were made in accordance with the method adopted by the Actuarial Society in their Specialized Mortality Investigation, except that each life was counted but once and full allowance was made for the re-entry of a life, subsequent to the initial entry.

The first list contained 924 entrants. This list was then carefully revised by me and the doubtful cases eliminated. This was a harder task than with renal colic, for the diagnostic criteria of hepatic colic are much less distinct. In the vast majority of cases, for instance, in which the term "Bilious Colic" is used, it refers to some acute painful lesion of an abdominal viscus other than the gall-bladder, such as acute enteritis or colitis, enteralgia, appendicitis, etc. When these doubtful cases were eliminated, it left 413 risks in which there was a reasonably definite history of gallstone, such a history as would be accepted by a medical director as conclusive. This list of cases gave forty-five actual deaths and 34.3 expected, a mortality of 131%. In order to make the material homogeneous, I then eliminated those who had had more than one attack, the overweights and those living in foreign countries and the southern states. This left only 223 cases who showed a single attack of hepatic colic without other impairments.

The following table is based upon these selected cases, arranged according to age at issue:

TABLE I.

Age at Issue	Number of Entrants	Deaths		%
		Actual	Expected	
15–19	1		.027	
20–24	6	1	.232	432
25–29	27	2	.980	204
30–34	27	1	1.047	95
35–39	35	6	3.730	161
40–44	39	6	2.486	241
45–49	38	4	3.068	131
50–54	23	2	2.725	74
55–59	17	3	6.465	46
60–64	5	2	.947	211
65–69	4		.297	
70–74	1		.904	
Total	223	27	22.908	118

This table shows a high mortality at practically all ages with some irregularities due to the small number of cases.

In the Specialized Mortality Investigation, Class 52—those who have had hepatic colic or gallstone—shows favorable results at all ages, except from forty-three to fifty-six. The mortality of the entire Class 52 is only 107%. This comparatively favorable mortality is undoubtedly due to the fact that many cases of so-called "Bilious Colic" were included in the list. The discards from my primary list amounted to 511, more than one-half. These discards consisted almost entirely of "Bilious Colic" in which no evidence of genuine hepatic colic or gallstone could be found. They gave a mortality of 96%, while the other 413, who were admitted as having had hepatic colic or gallstone, gave a general mortality of 131%.

The following table gives the cases grouped according to the age at which the attack occurred. It shows a high mortality at practically all ages:

TABLE II.

Age When Attack Occurred	Number of Entrants	Deaths		%
		Actual	Expected	
15–19	12		.356	
20–24	40	3	1.509	199
25–29	41	3	1.919	157
30–34	36	4	3.341	120
35–39	27	5	2.943	170
40–44	32	8	7.771	103
45–49	17	3	2.294	131
50–54	14	1	1.989	50
55–59	4		.785	
Total	223	27	22.908	118

The following table shows the cases grouped according to the time which intervened between the attack and the examination:

TABLE III.

Date of Examination Subsequent to Attack of Hepatic Colic	No. of Entrants	Deaths		%
		Actual	Expected	
First year	6	1	883	113
Second year	24	4	1.647	243
Third year	29	4	2.458	163
Fourth year	13		1.126	
Fifth year	29	4	2.285	175
Sixth to eighth year	39	6	4.214	142
Ninth to twelfth year	35	3	5.497	55
Over twelfth year	48	5	4.798	104
Total	223	27	22.908	118

We can see from this table that from those examined in the first five years after the attack there were thirteen actual deaths and 8.4 expected, a mortality of 155%. One of these deaths was due to acute hepatitis, one to peritonitis, one to gallstone, and one to some disease of stomach not specified. In other words, four out of the thirteen deaths, nearly one-third, were due to diseases in whose etiology the gallstone colic may have been an important factor. Even down to the eighth year, the mortality is high, there being nineteen actual deaths and 12.5 expected, a mortality of 152%. After the eighth year the mortality is good, there being eight actual deaths and ten expected, a mortality of 80%.

The following table shows the cases arranged by years of insurance:

TABLE IV.

Insurance Years	Number of Exposures	Deaths		%
		Actual	Expected	
1–5	775	9	7.881	114
6–10	381	9	6.684	135
11–15	158	2	3.343	60
16–20	50	1	1.322	76
21–25	23	3	1.030	291
26–30	15		1.171	
31–35	12	3	1.494	201

This is very interesting, as it shows a high mortality in the first decade and a much lower mortality in the second decade. It is also of interest to note that of the nine deaths in the first quinquennium of insurance, three were due to peritonitis, gallstones, and acute hepatitis. Class 52 in the Specialized Mortality Investigation presents a similar mortality curve as shown in the following table:

TABLE V.

Insurance Years	Number of Exposures	Deaths		%
		Actual	Expected	
1–5	17,216	165	141.6	117
6–10	8,334	114	109.4	104
11–15	4,029	66	67.3	98
16–20	1,751	35	37.2	94
21–25	825	27	22.4	121
26–30	251	9	9.3	97

In both Tables IV. and V. there is a curious rise of mortality in the third decade for which I am unable to offer any explanation, as my own material was too small to admit of any definite conclusion.

The following table shows the causes of death:

TABLE VI.

Causes of Death		*Totals*
CLASS I—General Diseases—A		2
Typhoid	1	
Influenza	1	
CLASS II—General Diseases—B		4
Pulmonary Tuberculosis	3	
Cancer—Gall-bladder	1	
CLASS III—Nervous System		5
Meningitis	1	
Cerebral Congestion and Hemorrhage	4	
CLASS IV—Circulatory System		3
Organic Disease of Heart	3	
CLASS V—Respiratory System		1
Pleurisy	1	
CLASS VI—Digestive System		6
Other Diseases of Stomach	1	
Biliary Colic	1	
Other Diseases of Liver	2	
Peritonitis	1	
Appendicitis	1	
CLASS VII—Genitourinary System		2
Nephritis	1	
Renal Calculi	1	
CLASS IX—Diseases of Skin and Cellular Tissue		1
Carbuncle-neck	1	
CLASS XII—Violent Causes		3
Casualties	2	
Suicide	1	
Total	27	27

Class VI., diseases of the digestive system, is twice the normal, showing the intimate relationship of the gall-bladder to other abdominal viscera. There is one death from appendicitis, and one from renal calculi. It is hardly possible in either case that the previous diagnosis of hepatic colic was incorrect, for in both examinations the facts set forth point quite clearly to gallstone.

Besides these cases in which there was only one attack of hepatic colic, there were seventy-four who showed a history of two or more attacks. These

gave five actual deaths and 4.8 expected, a mortality of 104%. The number is too small to warrant any deductions except that doubtless we exercised greater care in selecting these risks than those who showed only one attack.

The overweights with hepatic colic who numbered thirty and gave a mortality of 122% are too few to analyze.

Altogether one fact stands out quite clearly, and that is the rarity of this impairment in insurance risks. In thirty-seven years the Mutual Life issued insurance to 413 persons only, who gave a definite history of hepatic colic or gallstone. That averages only a little over ten a year.

As a result of the scantiness of material, our conclusions must be general and rather indefinite.

1st.—The lesion is more serious than renal colic, and the mortality is higher.

2d.—The mortality is not influenced by age.

3d.—A careful study of Tables III., IV., and V., shows that the effect of the impairment disappears in a certain numbers of years, about ten.

4th.—Prior to about ten years after the attack, the mortality is high, and it is not now apparent how any methods of diagnosis will materially modify this result.

414 West Twenty-second Street.

THE ILEOCOLIC CIRCLE.

By BYRON ROBINSON, B.S., M.D.,

CHICAGO, ILLINOIS.

PROFESSOR OF GYNECOLOGY AND DISEASES OF THE ABDOMINAL VISCERA IN THE CHICAGO COLLEGE OF MEDICINE AND SURGERY (MEDICAL DEPARTMENT, VALPARAISO UNIVERSITY). CONSULTING SURGEON TO MARY THOMPSON HOSPITAL FOR WOMEN AND CHILDREN.

During the dissection of some 65 consecutive subjects I made the observation that there is one constant mesenteric arch, or rather one constant mesenteric circle, viz., that which I shall term the "*ileocolic circle*." The "ileocolic circle" is formed by the bifurcation of the jejunal artery into the ileocolic artery and ileal artery and completed by their distal inosculation. In other words, the jejunal artery divides into the ileocolic and ileal arteries

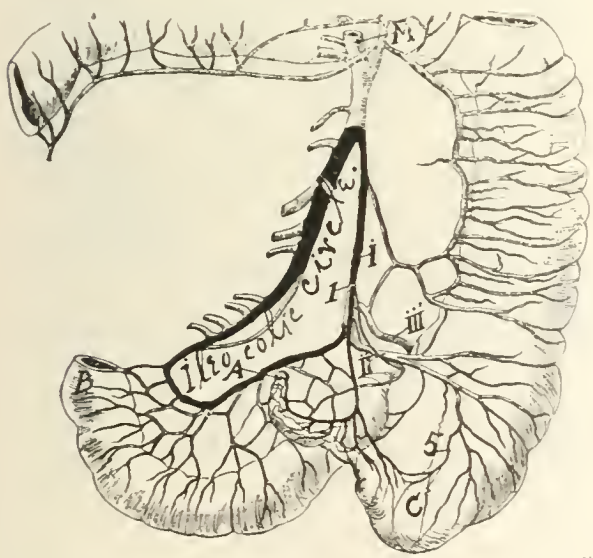

Fig. 1.—This illustration represents a dorsal view of the "ileocolic circle." The single appendicular artery (1) arises from its right circumference.

which reunite some 5 inches distalward forming a constant mesenteric vascular circle—a constant fixed primordial circular vascular landmark. The ileocolic circle is located in the ileocolic angle and is a constant structure. It may be accompanied by mesenteric apertures, from insufficient vascular nourishment, which may serve for hernial strangulation. The ileocolic circle is frequently divided into compartments by arteries of varied dimensions which are destined to nourish the mesentery within the circle or are bifurcated loops, branches of the main circle. The clinical significance of the ileo-

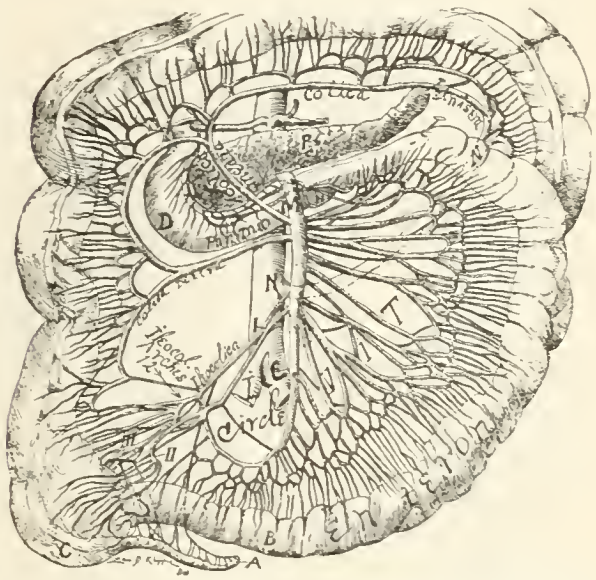

Fig. 2.—The "ileocolic circle" in this drawing is duplicated on the right side (*i.e.* the ileocolic artery). The primary appendicular artery arises from the "ileocolic circle." The secondary and tertiary appendicular arteries arise from the "ileocolic arches" or dorsal ileocecal artery.

colic circle is that its right circumference—96 per cent. (*i.e.* the ileocolic artery)—is the main source, or the origin of the arteria appendicularis which alone will immortalize it. The ileocolic circle, existing in the form of an oval, measures practically 2 x 6 inches. The dimension of the ileocolic circle depends upon the location of the bifurcation of the jejunal artery and the length of the ileal artery. The jejunal artery may bifurcate proximal, on a level or distal to the origin of the distal mesenteric artery, *i.e.* in the region of the iii. lumber vertebra.

The ileocolic circle may possess, imposed on its periphery a series of minor vascular arches. It is a primordial vascular landmark destined to nourish the ileum and cecum (with appendix as an ancient stomach). The ileocolic circle is associated and in relation with the right psoas, distal ileum, cecum, right ovary, right oviduct, ureter, common iliac, and the treacherous, dangerous appendix to which it primarily, chiefly, and directly emits the vascular supply. It is directly associated with the ileocolic arches. By placing it mesenteron on a leftward tension one may view plainly the "ileocolic circle" though not injected.

The ileal artery extends from the distal end of the jejunal artery to its distal anastomosis with its opposite fellow, the ileocolic artery. The ileal artery forms the left circumference and the ileocolic artery forms the right circumference of the ileocolic circle. The ileal artery emits branches (a dozen and a quarter) to nourish the ileum of such limited caliber (as compared with the jejunal artery—possessing a half dozen maximum branches) with consequent limited blood volume, especially at the distant ileum, that it is subject to ulceration and perforation (in typhoid fever and tuberculosis). Blood volume cures and is a prophylactic against disease. Hence the jejunum with its maximum calibered branches (rami jejunales) and consequent maximum blood volume is not only the chief digestive segment of the tractus intestinalis, but is rarely subject to disease (ulceration or perforation). The

emergence of the ileocolic artery is the point of division between the jejunal artery and ileal artery. The ileocolic artery is destined to nourish the cecum and appendix. The ileal artery is destined to nourish the ileum.

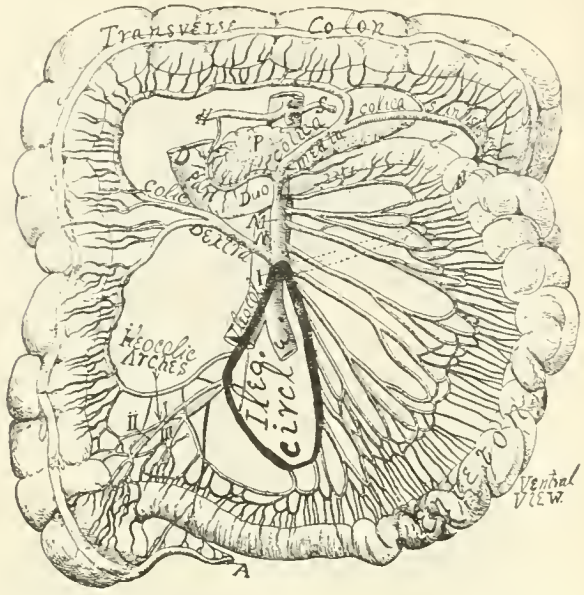

FIG. 3.—This illustration represents an "ileocolic circle" which possesses a large arch on its right circumference. The ileocolic artery arises at the junction of the jejunal and ileal arteries. The single appendicular artery arises from the ileocolic arches.

The ileocolic circle, one of the constant mesenteric arches, is located practically in the ileocolic angle. It is a circle of considerable dimension (2 x 6 inches), resembling the proximal and distal gastric circles. It is marked by a smaller dimension than the utero ovarian vascular circle; however greater than that of Willis. The "ilecolic circle" will in its due time become dignified into a recognized vascular circle like that of the philosophic Willis, which has held undisputed sway for 250 years. However, one fact will immortalize the "ileocolic circle," and that is in the majority of subjects (96 per cent.) the appendicular artery arises from its right circumference. The "ileocolic circle" is an important landmark for consideration, anatomical, physiological, pathological.

The ileocolic circle will serve as an anatomical vascular landmark. It will simplify the vascular anatomy in the ileocolic region. Its right circumference—the ileocolic artery—the origin of which will mark the division between the jejunal and ileal arteries, and hence indicate the jejunal and ileal segments of the enteron.

By the aid of the ileocolic circle the anatomist can unfold with greater practicality the vascular relations of the ileum and cecum, but especially those of the appendix.

The ileocolic circle is an important practical physiological vascular landmark. The great crux, the central rock and base of circulation is anastomosis, which is here indicated in its typical form—that of a circle; collateral anastomosis is complete, perfect. Our chief means to control the blood current for therapeutic purposes is through the "inosculating circle," *e.g.* the uteroovarian circle.

Physiologically the ileocolic circle is supplied with such numerous radiating branches of marked dimensions that if it were ligated ample collateral circulation would preserve tissue-nutrition and furnish sufficient blood volume for function of the tractus intestinalis (sensation, absorption, secretion, peristalsis).

The ileocolic circle presents practical pathological conditions. Apertures of the peritoneum within the ileocolic circle may produce (atrophic) peritoneal apertures from lack of blood supply, sufficient to allow intestinal coils to become strangulated.

Arterial sclerosis of the ileocolic circle may occur to sufficient degree to interfere with nutrition of tissue and enterocolonic function (sensation, absorption, peristalsis, secretion), particularly that of the appendix. Should an embolus appear in any segment of the ileocolic circle the collateral circulation is sufficiently abundant to preserve tissue and function and reestablish collateral circulation with focility.

The ileocolic circle is one of the most important vascular landmarks especially in relation to the dangerous and treacherous appendix—dangerous because perityphlitis kills, and treacherous because its capricious course cannot be prognosed.

I find no reference in literature to this ileocolic circle. It is a result of my personal original investigations. I launch it in the professional current to begin its endless journey. I predict that it will withstand the uncertain vicissitudes of fortune equally well with the circle of Willis and be of more practical value to mankind. Utility is the standard of value.

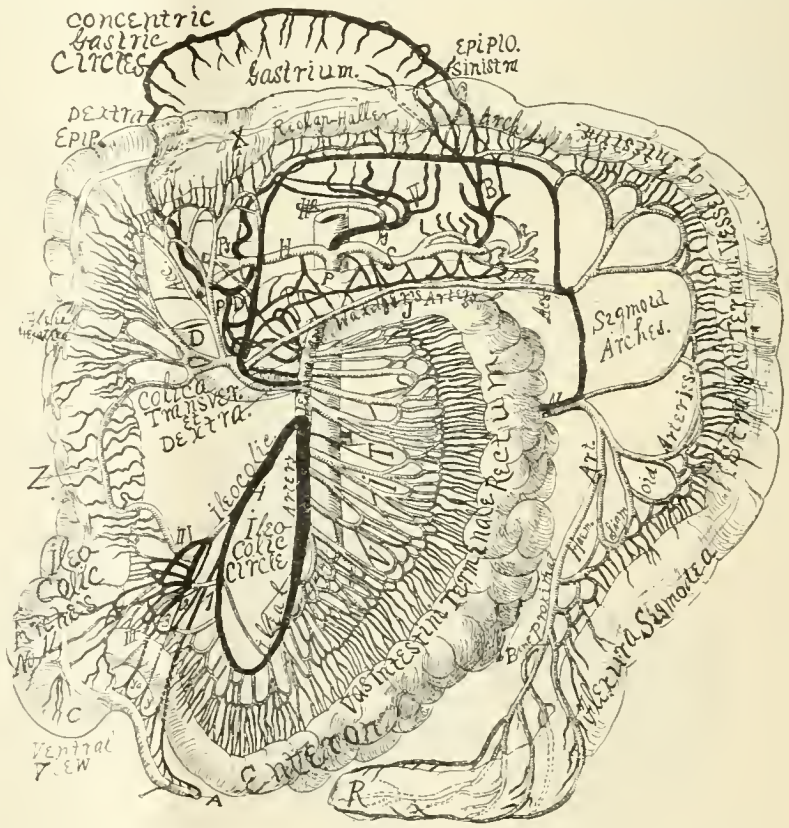

FIG. 4.—This illustration presents the "ileocolic circle," the "ileocolic arches," and the three appendicular arteries (1, primary; 2, secondary; 3, tertiary) in black. Note the richness of radiating branches from the "ileocolic circle." The ileocolic artery arises at the junction of the jejunal artery with the ileal artery, and on a level with the origin of the mesenteric artery. Observe the minor vascular arches imposed on the "ileocolic circle."

The control of blood volume to definite localities is doubtless the most important and practicable agent in therapeutics. It rests on the axiom that *blood cures disease.* This is not new, neither did Bier discover it. He introduced successful system-

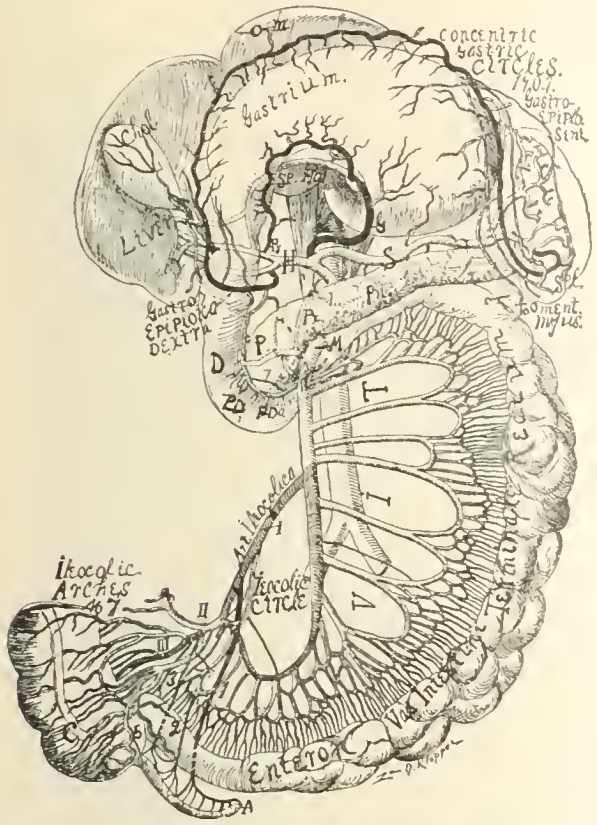

FIG. 5.—This illustration represents the "ileocolic circle" and its associated relations. Observe that the primary appendicular artery (1) arises from the right circumference (ileocolic artery) of the "ileocolic circle." The secondary appendicular artery (2) arises from the mesenteric arches; the tertiary appendicular artery arises from the dorsal ileocecal artery (or its "ileocolic arches"). The ileocolic artery originates at the junction of the ileal artery and jejunal artery.

atic practical application of congestion curing disease. For 50 years gyneologists have made practical application of congestion curing disease. For example, the uteroovarian artery, the genital vascular circle (sometimes called the circle of Byron Robinson) is the typical "*inosculation circle*" where blood current and blood volume can be maintained and controlled for therapeutic purposes. If the genital ganglia (pelvic brain hypogastric plexus, etc.) be stimulated the uteroovarian artery (genital vascular circle) along which the automatic genital ganglia are located becomes dilated and the blood volume in the artery becomes increased, the genitals become congested and many forms of genital disease are cured (especially the inflammatory kinds) —myometritis, pelvic peritoneal exudates. The stimulus to the genital ganglia and consequent marked dilatation of the uteroovarian artery may be by (1) heat (vaginal douche), (2) hygroscopy (boroglyceridetampon), (3) electricity (irritation), (4) stempessary (irritation), (5) massage (irritation), (6) gestation (irritation), (7) copulation (irritation), cathartics, and diuretics. (Stimulation to adjacent visceral tracts congests the tractus genitalis (uteroovarian artery). The uteroovarian artery, the genital vascular circle, is the one vascular circle (however, to application accessible), by controlling the blood volume of which extensive, solid, reliable advances have been established in curing genital disease. Controlling blood volume is the most rational agent of therapeutics. It may be hoped that the day is not far distant when we can control the blood current and volume in the "ileocolic circle" to cure disease—especially perityphlitis. The successful accomplishment of control of blood current and volume in the "ileocolic circle" will be equal to the established control of the blood current and volume in the uteroovarian circle. The control of blood current and volume in the ileocolic circle would aid in curing some prevalent diseases, viz., (*a*) perityphlitis, (*b*) mesoappendicular adhesions, (*c*) ileal disease (tuberculosis, typhoid ulceration).

Practically the cause of the majority of cases of perityphilitis is trauma of the psoas muscle, inducing germs or their products to migrate through the appendicular muscosa, the appendicular muscularis, and appendicular serosa causing periappendicular peritoneal adhesions, mesoperityphlitis, which compromise the appendicular blood-vessels and flex the appendix checking drainage. If the blood current and volume of the ileocolic circle could be controlled, concentrated, increased by therapeutics the mesoappendicular adhesions would absorb, whence the compromised mesoappendicular vessels would be released, and the flexed appendix would enjoy ample drainage.

The nerve ganglia associated with the periphery of the ileocolic circle are those of Auerbach, with Billroth-Meissner, and the stimulation of these automatic ganglia (with consequent congestion of the ileocolic circle) may be accomplished by numerous agents, viz.: (*a*) heat, (*b*) massage, (*c*) foods which result in extensive residue, (*d*) electricity, (*e*) exercise, (*f*) cathartics, etc.

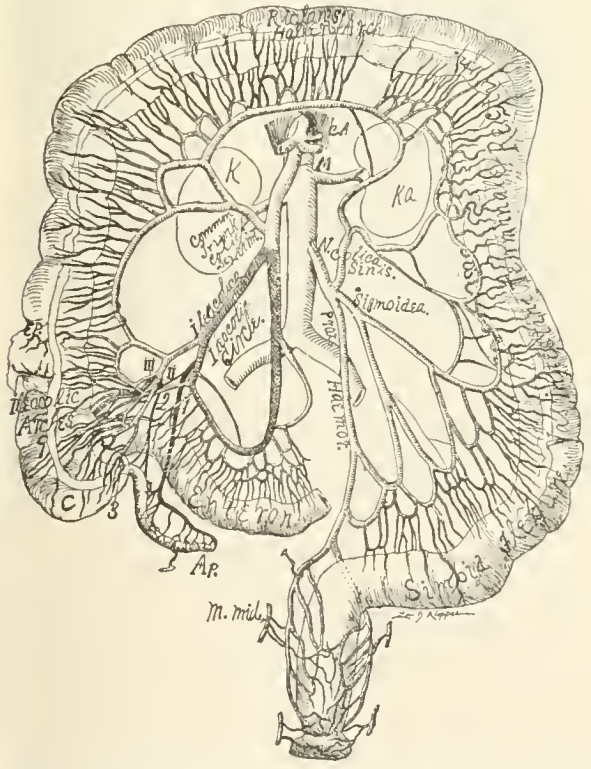

FIG. 6.—This illustration represents the "ileocolic circle" and associated relations. The "ileocolic circle" originates the primary (1) appendicular artery, while the "ileocolic arches," *i.e.* the ventral ileocecal artery (ii). The ileocolic artery arises from the junction of the jejunal artery (m) and the ileal artery.

By cathartics a partial congestion of the ileocolic circle is accomplished, however insufficiently intense to absorb completely dense compromising peritoneal adhesions, with persistent visceral drainage (*i.e.*, stimulation of the function of the tractus intestinalis—sensation, peristalsis, absorption, se-

cretion). By fluids, food, and cathartics producing two bowel evacuations daily sufficient blood may be enticed to the parts, not only for the maintenance of health but practically to absorb existing peritoneal adhesions. However it may be hopefully expected that therapeutics will discover a method of controlling the blood current and volume of the ileocolic circle and consequently of not only curing but furnishing a prophylaxis for perityphlitis and other diseases in adjacent structures. Blood cures disease. The noble Rokitansky observed that in subjects with cardiac valvular disease, tuberculosis was a rarity, the lung was congested and blood protected it from tuberculosis. In short a regurgitating aortic valve (with consequent pulmonary congestion) will cure or protect the pulmonary apices from tuberculosis.

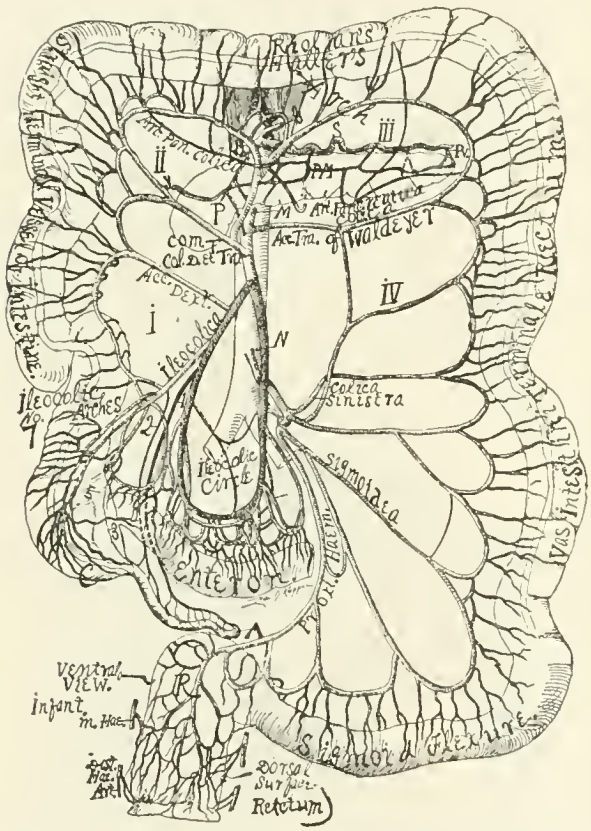

Fig. 7.—This illustration represents the "ileocolic circle," with adjacent relations. Note the primary appendicular artery (1) arises from the right border of the "ileocolic circle." The ileocolic artery originates at the junction of the jejunal artery and ileal artery. The secondary appendicular artery (2) arises from the "ileocolic arches" or "ileocolic circles." The tertiary appendicular artery (3) arises from the dorsal ileocolic artery.

Conclusions.—An inosculation circle consists of (1) a vascular arc, (2) automatic peripheral ganglia, (3) a peripheral viscus.

The *ileocolic circle* is a typical inosculation circle. The apparatus used for executing hyperemia is the inosculation circle.

The means of functionating (controlling the blood volume) the inosculation circle is by stimulating its automatic specialized peripheral ganglia, resulting in dilatation of its vessels.

The function of an inosculation circle is to congest its peripheral viscus and to transport blood from one viscus to another. The ileocolic circle is associated with important viscera, viz., distal ileum, appendix, cecum, the blood supply of which it influences. The rational therapeusis is *visceral drainage*, which induces maximum blood volume in the inosculation circle and consequent maximum visceral elimination.

THE TUBERCULOSIS PROBLEM IN THE PHILIPPINES AND THE ELIMINATION OF INTESTINAL PARASITES AS THE FIRST STEP IN ITS SOLUTION.*

By VICTOR G. HEISER, M.D.,

PASSED ASSISTANT SURGEON, PUBLIC HEALTH AND MARINE HOSPITAL SERVICE; DIRECTOR OF HEALTH AND CHIEF QUARANTINE OFFICER FOR THE PHILIPPINE ISLANDS; PROFESSOR OF HYGIENE, PHILIPPINE MEDICAL SCHOOL.

In recommending to any government a measure which has for its object the improvement of the public health, not only the medical men directly concerned, but the whole medical profession as well, share in the responsibility involved. Success following the adoption of a recommendation redounds to the credit of the whole profession; a failure is often cited as evidence of the unreliability of medical advice. It is therefore believed that those medical men who are charged with the duty of recommending legislation to legislative bodies should, whenever possible, consult with their medical brethren in order that crystalized ideas submitted should have the support of their majority.

Before a government, be it national, State, or municipal, is asked to give any very substantial support to a health measure it is desirable that it be shown with reasonable certainty that the public health will be improved, that the estimated cost be stated, that the economic value is apparent, and that it is backed up by experimental or other evidence. With the foregoing conditions in mind the following is respectfully submitted.

It has only been within the past few years that serious attention has been given to the rôle which intestinal parasites, and more particularly the ankylostoma or hookworm, play in the morbidity and mortality statistics of tropical and semitropical countries. Most striking evidence of their importance has recently become available in Manila. In the large insular prison called Bilibid over three thousand prisoners are constantly confined. From 1902 to 1905 there was an uninterrupted increase in the death rate until a mortality of over two hundred per thousand per annum was reached. Tuberculosis claimed over 50 per cent. of the victims during 1904. On December 1, 1904, all prisoners afflicted with pulmonary tuberculosis were isolated in a separate hospital located in another portion of the city. During the year 1905 the number of deaths from tuberculosis still increased, although the number of new infections was growing less. The general mortality figures of the prison were also still ascending. The sanitation of the prison was then transferred from the control of laymen to the Bureau of Health. The regularly recognized sanitary measures were at once put into effect, overcrowding was relieved, sewage disposal improved, the sick placed under treatment more promptly, and other well-known measures adopted. The death rate soon fell to about seventy-five per thousand per annum, but further reduction seemed impossible. A study of the prison's sick showed that they were dying with ailments to which they should not have succumbed. Their powers of resistance were evidently impaired. The evidence pointed to some extraordinary drain on the system. There was plenty of food, but evidently imperfect nourishment. With a view to discovering the cause, a routine practice of microscopically examining the feces of every prisoner was inaugurated. Eighty-four per cent. were found infected with intes-

*Read before the International Congress on Tuberculosis, Washington, D. C., September 29, 1908.

tinal parasites. Of these, 60 per cent. or 52 per cent. of the total number of prisoners had hookworms, 59 per cent. had whipworms, 23 per cent. amœbæ, and 21 per cent. harbored some other species of parasite.

Over half of the prisoners were hosts for at least two kinds of worms. Active therapeutic measures were inaugurated to rid the prisoners of the causes of these debilitating troubles and result was immediately satisfactory—the death rate fell to less than twenty per thousand. The following table giving the deaths from tuberculosis at Bilibid by months and years, considered in connection with the foregoing, shows that even after isolation of tuberculous patients has been carried out, still further reduction in the incidence of tuberculosis may be brought about by increasing the resistance of the individual; that is, by removing the intestinal parasites. For instance, in 1905, the year after the system of isolation was put into effect, there were still 179 deaths from tuberculosis. Much improvement, however, could perhaps not be expected until the following year, and an examination of the figures shows that the tuberculosis mortality did drop to 51. In view of the fact that the elimination of the intestinal parasites was actively begun during the second half of this year (1906) a part of the credit for this satisfactory result must be attributed to their removal, and that this assumption is correct is shown by the fact that in the year 1907, when the elimination of the intestinal parasite was the only remedy used, the deaths fell to 35, and for the present year, based upon the rate of the earlier months, the number should be 28. It is therefore apparent that in a prison which has an average population of about 3,000, and in which there were as many as 179 deaths per annum from tuberculosis, the number of cases was reduced to 28 per annum, and that this was brought about by isolating the tuberculous sick, by providing more light and air, and removing the intestinal parasites of the remainder, the latter measure having largely contributed to the result. It is perhaps also worthy of mention in passing that the statistics show that the greatest number of deaths during each year occurred between the months of June and October, which correspond to the rainy season.

DEATHS FROM TUBERCULOSIS, BILIBID PRISON.

	1904	1905	1906	1907	1908	Total
January	25	8	3	2	0	38
February	32	0	2	4	0	38
March	5	17	7	7	8	44
April	6	4	1	4	2	17
May	10	11	6	0	2	29
June	10	17	3	4	2	36
July	5	13	3	4		25
August	13	29	3	3		48
September	17	45	8	1		71
October	16	21	7	2		46
November	9	7	3	1		20
December	13	7	5	3		28
Total	161	179	51	35	14	440

Some thousands of stool examinations made in the Philippines outside of Bilibid show that about the same percentage of infections may be expected among the general population.

If then we have a prophylactic measure which will effect a marked reduction in tuberculosis mortality and at the same time diminish the incidence of a considerable number of other diseases (see sick report published in Annual Reports of the Bureau of Health during the past four years), it would appear only rational that this should receive first consideration. There is no desire whatsoever to ignore those measures which have already done so much to curtail the ravages of tuberculosis in other parts of the world; when funds are available, these should all be tried. If not, then it would undoubtedly be best to choose that which will give the greatest results. In a city like Manila, a reduction in the mortality of five per thousand would mean a saving of 1,125 lives annually; at least 150 of these would be rescued from tuberculosis. These figures are for one city. If other tropical countries with similar conditions adopted the same measures for their millions of population, the result is self-evident.

It is believed that the foregoing facts make concrete proof of what may be accomplished in a tropical country and are sufficient evidence to lay before a legislative body in order that the necessary authority and funds may be provided to put into effect the measures which are indicated.

It may be of interest to present the following table, which shows that tuberculosis steadily increased in the city of Manila until June 30, 1907, and that since that date there has been a decline:

TUBERCULOSIS IN THE CITY OF MANILA BY YEARS.

Year Ending	Total Deaths From All Causes	Deaths From Tuberculosis								
		Larynx	Lungs	Meninges	Abdomen	Spine	Other Organs	General	Total	Percentage
8-31-03	8,892	45	789	20	35	1	7	5	902	10.1
8-31-04	10,781	59	958	32	35	2	3	13	1,102	10.2
8-31-05	8,926	59	971	31	45	2	7	17	1,132	12.7
6-30-06	9,486	23	1,209	41	43	1	8	29	1,354	14.3
6-30-07	8,251	18	1,146	44	45	..	9	23	1,287	15.6
6-30-08	8,945	12	1,036	37	37	3	6	36	1,167	13.0
Total.	55,281	216	6,111	205	240	9	40	123	6,944	12 6

The increase in the disease prior to 1907 was in all probability due indirectly to the increase in rents, which resulted in the poorer classes crowding together more and more; in consequence, the light and ventilation per capita in each habitation constantly decreased.

About two years ago an active educational campaign for the prophylaxis and treatment of tuberculosis was begun. A pamphlet was prepared, the contents of which are taught in every public school throughout the Philippine Islands. Popular articles are frequently published in the daily press. Rigid inspection is made of all meat and other food products likely to contain tubercle bacilli, anti-spitting ordinances were passed and are being gradually more and more rigidly enforced, overcrowding, especially in tenement houses, has been prohibited, and light and ventilation have been provided for hundreds of houses. Whether these measures are responsible for the reduction in the number of deaths is, of course, not positively known, but it is not unreasonable to infer that much of the credit is due to the improved sanitation. The foregoing shows that at least a start has been made in combating this disease in the Philippines.

If the conclusion of this Congress should justify it, it is proposed in the coming year, in addition to the measures specifically directed against intestinal parasites, to open a free dispensary in the city of Manila for tuberculous cases and to spend about $20,000 for the treatment of the tuberculous sick by the open-air method.

Summary.—1. Before legislation on public health measures is requested, certain conditions should exist. Among these is reasonable certainty that the public health will be improved; that the cost of putting it into effect be estimated; that the economic value be made apparent; and that it is backed up by experimental or other reliable evidence.

2. The annual mortality among 3,000 prisoners was reduced from 75 to 20 by the elimination of intestinal parasites; 50 per cent. of this number formerly died of tuberculosis. This was accomplished after the measures heretofore recommended by good authorities had been faithfully but unsuccessfully offered.

3. Increasing the resistance of an individual to tuberculosis by the elimination of intestinal parasites has proven very effective in reducing the incidence of the disease.

4. As a result of a campaign of education and by providing more hygienic houses, the number of cases among the general population of Manila was apparently reduced from 15.6 to 13 per cent. of the total mortality.

Conclusion.—It is believed that the foregoing facts warrant the assertion that in tropical countries where tuberculosis and bookworm diseases are coexistent, the elimination of the hookworm will produce better results in diminishing the mortality from tuberculosis than any measure that has as yet been tried upon a large scale; at the same time the general mortality can be markedly reduced.

NEUROSES OF THE NOSE.

By CHARLES PREVOST GRAYSON, M.D.,

PHILADELPHIA, PA.

I HAVE the somewhat uncomfortable feeling that you will discover within the next few minutes that you have been made the victims of misplaced confidence on the part of your committee who did me the honor to invite me to present this paper. I shall make no attempt to be ponderously scientific, nor have I any intention of yielding to the temptation that this opportunity offers to add something new and startling to the already formidable list of reflex nerve disturbances for which the nose has been held responsible. On the contrary, I am very much of the opinion that before any further addition is made to this list the foundation upon which it rests should be critically examined to see if it be secure enough to support even the strain to which it has already been subjected. I am conscious that there is in this statement at least a suggestion of doubt on my part as to whether the nose is really accountable for all those ills of reflex nature that have been attributed to it. I know that whenever it has been charged with any offense of this kind more or less evidence has been forthcoming to substantiate the charge, but, although I do not venture to say in the majority, yet in many cases at least this evidence has been of a purely circumstantial character and has seldom been sufficient to induce me as one of the large jury of rhinologists to concur in a verdict of "guilty." In almost if not all of them the "neurotic temperament" has formed a more or less conspicuous background to the various manifestations of nerve irritation, and the vagaries of this irresponsible temperament are unfortunately apt to be as misleading as they are notorious. In the absence of this powerful contributing factor, I should regard the prompt and permanent cure of an asthma, for instance, by the removal of a septal spur as forming a *prima facie* proof of nasal guilt, but whenever its presence can be demonstrated or even fairly suspected, the possible indirect and psychic effect of the operation would lead my conscience to decline any greater responsibility than would be involved in rendering against the nose the shifty Scotch verdict of "not proven." In the face, therefore, of the adverse criticism that I may perchance draw upon my head, I say without equivocation that to my mind whenever this troublesome temperament forms one of the premises in any proposition of a pathological nature, it vitiates and lays open to suspicion and dispute any positive conclusion that may be drawn. It is because of this embarrassing uncertainty that must always confront one in that class of nasal neuroses in which the nose is presumed to be the excitant of a reflex disturbance, that I find much greater satisfaction in dealing with that other class in which the nose itself is the site of the disturbance of innervation, that class, in other words, in which symptomatically the nose is the victim rather than the aggressor. The clinical features of these affections are so distinctive, so almost unique, that it is probably extremely seldom that we encounter any difficulty in the matter of diagnosis. How fortunate it would be, both for us and our patients, if our pathway to a complete understanding of the pathogenesis were as free from obstacles! I shall not occupy your time with any consideration of the functional derangements of the olfactory nerve. Ordinarily, these are of comparatively slight clinical interest and importance. It is rather to the vasomotor neuroses as they are exemplified in the nose that I would venture to ask your attention, and I can clearly foresee the shudder with which you will suspect me of an intention to rake over the ashes of past discussions of hay fever. But this is not my principal purpose. My chief wish is to assist, simply as a mark of respect, at the obsequies of the latest "specific" for the treatment of that disease. I am not privileged to sit with the mourners, for almost from the moment of its birth I anticipated, predicted, and was prepared for its early death. And yet, I wish to lay a flower upon its grave because it was conceived in a scientific spirit, the methods by which it was made were equally scientific, and the reasoning that led to its production was, so far as it went, perfectly sound. But it went neither far enough nor deep enough. If it had, it is highly probable that no claim of specific virtue would have been made for the remedy. If the etiology of hay fever comprised no more than two factors—a predisposing idiosyncrasy and an atmospheric excitant—there would have been nothing illogical in the expectation that "pollantin" might take its place beside the antitoxin of diphtheria, but when we recognize the existence and fully appreciate the nature of the systemic condition that, it seems to me, forms a more or less prominent background in every case of this disease, we will not be surprised at the percentage of cases that have been reported as but slightly improved or absolutely unimproved. For many years I have believed that a fundamental disturbance of the nutritive processes, of normal metabolism, if you please, was responsible for the essential nervous element in the causation of hay fever. So long as we have a blood current contaminated with a number of toxic materials, the products presumably of suboxidation, so long are we almost certain to have nerve centers that are poorly nourished, oversensitive to disturbing influences, and of reduced power to neutralize the effects of such influences. It seems to be, at least in hay fever, the vasomotor centers that are earliest and most markedly affected, and when we have added to this not only the idiosyncrasy, but possibly also a long precedent intranasal lesion that has helped to make the pituitary mucous membrane particularly intolerant of any form of irritant, we have but to await the floating of some variety of pollen or other obnoxious

material within the nostrils to witness the speedy evolution of the symptom complex of this disease. If there is one fact connected with hay fever that, to my mind, throws a stronger light upon its remote causation than any other, it is that the affection is preeminently one of that class of people who lead the strenuous rather than the simple life. Why is it, may I ask, that these people have an almost exclusive monopoly of what we are pleased to term idiosyncrasies? Why is it that the laboring class is practically exempt from this species of affliction? Is it not because of the facts that its members go to bed with the chickens and rise with the lark, that they have their three frugal meals each day on the stroke of the clock, that, plain as it is, their supply of food is more often inadequate even to satisfy their appetites than to satiate them, that each day's labor involves wholesome muscle work that induces wholesome fatigue and brings dreamless sleep, and that, finally, their brains and nerves know nothing of emotional strain, of vaulting ambition, of crushing disappointment, or of sleep-destroying passions of any kind? Is it not possible, think you, that if, instead of fulfilling her natural destiny, barefooted, short-skirted, uncorsetted Maud Muller had married the Judge, if she had flung aside her rake, had abandoned the cows that she had milked, the churn that had helped to make her broad of shoulder and deep of chest, and if she had substituted for these all the nerve shattering follies and vices of the modern society woman—Heaven forbid that I should attempt to enumerate them!—might there not have come a time and a condition, I ask you, when even the dim memory of raking hay would have sufficed to throw her into a paroxysm of sneezing? It may seem useless to speculate about the nature of idiosyncrasies, but I have often thought that if we, as we all of us do, have certain conscious likes and dislikes, is it not possible that we have others, also, that are subconscious? Cannot our respective mucous membranes, for instance, owing to some individual peculiarity of structure or innervation, have certain antipathies of their own of which we may be wholly unconscious until lowered vitality, increased peripheral nerve irritability and lessened central control permit them to emerge from the obscurity of the back of the stage into the glare of the limelight at the front? I have fancied that we may either inherit or acquire in some way the seeds of these idiosyncrasies, but that they may lie fallow and inert until they are fertilized by and spring into life and offensive activity from a soil of poisoned and debilitated nerves. What a sublimely sanguine nature it must be, then, that still clings to the hope that a remedy of specific power may yet be discovered for hay fever! When a man so qualified by exceptional experience and unimpeachable judgment as Holbrook Curtis commits himself to the statement that "hay fever is a disorder amenable to no specific treatment," it seems to me that there is nothing left for the rest of us but to accept his opinion and to finally abandon that fatuous hope to which I have just alluded. And so, upon my tributary wreath I would write the inscription "*Sic semper* specifics." One more word relative to the treatment of this disease and I will take my leave of it. With no lack of respect for the profound laboratory studies that have dealt with the secretions of the hay fever sufferer, I fail to find in their results anything that is of genuinely practical value to us. It may be of some academic interest to know that the sweat contains an excess of something, that the tears that flow so abundantly during the attack contain too much or too little of something else, or that the saliva, perhaps, shows the presence of some material that is foreign to it, but of infinitely greater importance is it to remember and to remove the basic nutritive fault that is accountable for such alterations. This is a matter, I think, to which the maxim *Immanente causa non cessabit effectus* is clearly applicable. Surely the drug treatment of hay fever, from a curative point of view, is utterly irrational and fallacious. Nothing short of a drastic and radical reform of each patient's personal hygiene can effect and maintain the normality of the body tissues and secretions. I speak feelingly because as an ex-victim of the disease of some years' standing, I am confident that if I were to renounce systematic exercise and to return to indolence and the flesh-pots, the coming of August would find me once more a refugee in some mountainous region or upon the rag-weedless bosom of the Atlantic. If I were asked, therefore, in which of the two places, the laboratory or the gymnasium, a cure for this disease were the more likely to be found, you probably know what my answer would be. To put it in a nutshell, it is my belief that if a man takes care of his muscles, with all that this implies, his nerves and vasomotor centers will take care of themselves.

Another nasal neurosis very closely allied to hay fever, in fact, almost identical with it symptomatically, is that termed "rhinorrhœa spasmodica," or "paroxysmal sneezing." Pathologically, it seems to be hay fever minus the latter's idiosyncrasy to external irritants. The irritants of internal production are no doubt precisely the same in the two affections, and in both, also, the secondary nervous element is equally in evidence. This latter, however, in rhinorrhœa spasmodica is more often temporary than temperamental. In other words, the disturbance of vasomotor equilibrium is the result in most of these cases of some accidental and transient stress of an emotional nature, and it is this which may partially account for the absence of any periodicity in connection with repeated attacks of this disturbance. In illustration of this statement, I may be permitted to refer briefly to three cases that I have seen within the past two months, in none of which could any evidence be found that would justify the patient being regarded as either an hereditary or an habitual neurotic, and in none of which had there ever been a previous attack of this nature. The first was a man of middle age who was deeply involved in the stock market last fall and who throughout the winter was compelled, for want of margin, to let his holdings go one by one until, with the coming of spring, he was as much a nervous as a financial bankrupt. The second, a woman who, during several weeks of her child's critical illness, could scarcely be dragged from its bedside. And, finally, a trained nurse of rather frail physique who, for an unbroken period of six weeks, had been vigilantly watching a patient possessed of a suicidal mania. The pathogenic fact that was common to these three cases was a prolonged and flagrant violation of the laws of personal hygiene relating to food, sleep, and exercise, and the result, common also to all of them, was a most pronounced impairment of nutrition and of nervous vitality. Associated with the autotoxemia and nutritive failure were both unusual phosphatic waste and defective elimination. Although in each of them there was only such intranasal abnormality as would, under ordinary circumstances, have produced no discomfort, yet aided and abetted by the foregoing conditions it proved quite suffi-

cient to induce indignant Nature to select the nose as the medium for her protest.

In conclusion, gentlemen, I am going to recall to your attention a third neurosis of the nose that has its origin in disordered sexual functions. In the first place, we are all familiar with the fact that during the menstrual period not only is any coincident affection of the female nose apt to be aggravated, but even if it be normal it is often apt to reflect to some extent the ovarian excitement. It was perhaps his knowledge of this fact that led Fliess to seek a cure for dysmenorrhea through the cauterization of those areas in the nose that showed most plainly the secondary hyperemia and hyperesthesia. Shortly after the publication of his observation in 1897, probably many of us through the kindness of our obstetrical and gynecological friends had opportunities for testing his conclusions, but I must confess that the results of my own series of cases developed little more than the opinion on my part that while in women functional derangement of the pelvic viscera was capable of producing more or less disturbance of the neurovascular mechanism of the nasal mucosa, yet that the control of this latter would have little or no appreciable effect upon the former. Always excepting, of course, the highly neurotic woman, and upon her there is scarcely anything in the fields of medicine, surgery, Christian science, or osteopathy that may not produce the most extraordinary cures. In close connection with this, it is just barely possible that some few of you may have a dim recollection of a paper that I read at the semicentennial meeting of the American Medical Association in 1897, concerning the influence of sexual excitement upon the intranasal circulation. The two cases that I then reported have since been followed by many others, and could I conquer my aversion to hair-splitting distinctions in the subclassification of disease types, I would venture to suggest to the author of the next text-book on diseases of the nose that he devote a section to "The Rhinitis of the Newly-Married," or, perhaps, "Honeymoon Rhinitis" would be shorter and more euphuistic. I have not introduced this subject in order to discuss its treatment, because as a consistent bachelor I could scarcely do otherwise than advocate preventive rather than curative measures, but I refer to it once more simply to express the opinion that the cause of this neurosis of the nose is as frequently overlooked or viewed with the same indulgent indifferenec to-day as it was ten years ago.

251 South Sixteenth Street.

PRELIMINARY NOTE ON THE TREATMENT OF AMEBIC DYSENTERY AS CONDUCTED ON THE ISTHMUS OF PANAMA.

By W. E. DEEKS, M.A., M.D.,

CHIEF OF MEDICAL CLINIC, ANCON HOSPITAL, PANAMA.

It has not yet been determined that there is a specific organism responsible for the symptom-complex known as amebic dysentery. This is, however, either a specific ameba or some symbiotic organism or condition which initiates the pathological lesion. This may be some ulcer or injury to the mucosa, such as might be caused by the *Trichocephalus dispar* which is so common in the tropics. A variety of methods for the treatment of the condition have been tried. Irrigations of quinine, thymol, silver nitrate, boracic acid, etc., have been used. By the mouth, opiates, ipecac, intestinal antiseptics, etc. All these methods, however, have proved to be of little or no value. The present method which has given brilliant results with rarely a fatality consists in what might be called the rest supportive treatment. The patient is put to bed, absolute rest is enjoined, a purely milk diet is administered, and when great tenesmus is present warm saline irrigations are given two or three times daily. A preliminary dose of castor oil is usually advisable. The only internal medication which is given is the subnitrate of bismuth, which is administered in somewhat heroic doses, from a dram to a dram and a half every three hours. In the milder cases improvement begins in from three to five days; in the severer cases, in from ten to fourteen days. The stools then lessen in number and begin to form and in a comparatively short time, one to three weeks, twelve to twenty-four hours are passed without a movement. The diet is then gradually increased and the bismuth lessened in dosage. Usually the proteids, meat and eggs, are the last to be added to the full dietary. In from one to four weeks, depending upon the severity of the case, the patients are perfectly well. It is then well to give tonics and advise change of air for a week or ten days longer so as to increase the general resistance of the patient. If this be done there is practically little danger of recurrence; in fact, the only recurrences are associated with some conditions which again lower the general vitality and resistance of the patient. In only two cases during the past year has it been found necessary to perform cecostomy in order to carry on irrigations.

I consider it bad practice to give irritating injections, such as quinine, thymol, etc., which cannot possibly reach the amebae in the submucous ulcers, and I have even seen several instances in which the use of such injections given to patients (the accidental examination of whose stools had shown amebae, but in whom no dysentery was present) gave rise to attacks of true amebic dysentery.

Opiates are considered equally bad, as they tend to retain the irritating discharges and further the ulcerating process, although a preliminary hypodermic of morphine and atropine is sometimes of value.

Another feature which was observed in amebic dysentery, particularly the severer cases, is the condition of the skin, which loses its elasticity and can be drawn up into folds which will persist for a longer or shorter time, very slowly returning to the normal. It has a doughy feel, somewhat myxoid in character. When present it indicates a grave condition, though recoveries do take place even then. This condition of the skin has been noted particularly in grave abdominal conditions of different kinds, and if present when tubercle bacilli are found in the sputum indicates the involvement of the abdominal viscera. It also occurs in severe cases of typhoid fever and carcinoma of the abdominal viscera. The clinical significance of this skin condition has not been absolutely determined.

Charitable Bequests.—The will of the late Mrs. F. R. Halsey, which was filed recently, provides for the gift of $5,000 to the Stony Wold Sanatorium, of $50,000 to St. Thomas' Church for the exclusive use of the Halsey Day Nursery, and of $10,000 to Flower Hospital. The Pittsfield House of Mercy Hospital receives $26,000 under the will of the late Franklin W. Russell of Pittsfield, Mass., and the Pittsfield Nurses' Association, $5,000.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, December 12, 1908.

LEUCOCYTE EXTRACTS IN THERAPEUTICS.

ONE of the greatest disappointments in medicine has been the failure to find a specific remedy for each of the infectious diseases. When, in spite of much scepticism and obstinate opposition even in the face of facts, the value of antitoxin in the treatment of diphtheria was indubitably established, it was confidently believed that it would be only a matter of time, and of very short time, before an antitoxin would be found for every bacillary disease. The disappointment came when it was discovered that the mechanism of all infectious processes was by no means the same and that it was only in the case of diseases in which the morbid phenomena were produced by diffusible toxins that an efficacious antitoxin could be prepared. The other diseases, in which the poisonous products were found, or assumed, to be chiefly endotoxins, remained intractable to specific treatment. So those who still believed in therapeutics continued to treat pneumonia and typhoid fever in the old way with more or less success, and the therapeutic nihilists acted upon the "self-limited" theory with no success at all.

According to the more generally accepted theories, the natural cure of microparasitic diseases is effected in one of two ways—by the action of antibodies thrown off in excess by the cells, and therefore free in the body fluids, or by the phagocytic action of the leucocytes. The first-named method is effective in the case of diseases due to the presence of microorganisms which excrete soluble toxins, but in the second class of diseases, those in which the symptoms are assumed to be due to poisoning by endotoxins, the body fluids are less protective, and the organism is defended by the intervention of the leucocytes. The phagocytic action of the leucocytes in these cases is assumed to be effected by means of internal secretions, digestive and antitoxic, which act only upon the ingested bacteria and are not thrown out into the blood stream. Starting from this hypothesis, Dr. Philip Hanson Hiss *(Journal of Medical Research,* November, 1908) conceived the idea of extracting these protective substances from the white cells and introducing them in a free state into infected animals. If his assumption were correct these substances should then act in protecting not only the leucocytes, exhausted in their struggle against an overwhelming host of the invading microbes, but also the more specialized cells exposed to attack through the failure of the leucocytes.

The theory was tested in a number of experiments and the results were quite confirmatory of Hiss's assumption. Extracts of leucocytes from normal rabbits were injected into a number of animals suffering severely from infection by staphylococci, pneumococci, typhoid bacilli, or meningococci. Some of the animals died, but many survived infections fatal to the control animals in 36 hours, even though the injection of the leucocyte extracts was delayed as late as 24 hours after inoculation. The immediate effect was, in certain of the experiments, rather disquieting, for the animals receiving treatment often became sicker than the controls; this, however, was for a short time only, and chiefly in typhoid and meningococcic infections, and the good effects were almost immediately shown by a decided fall in temperature and a return to normal of the animal's weight. This primary increase in the symptoms of intoxication might indicate that the leucocyte extract had a bacteriolytic action, the consequent liberation of endotoxins increasing the toxemia, but the rapid fall in temperature and the quick return to normal weight led the experimenters to believe rather that the principal substance at work is one active in neutralizing bacterial poisons.

This was shown more strikingly in a further series of experiments made by Drs. Zinsser and Hiss, who injected leucocyte extracts intraperitoneally into guinea-pigs infected simultaneously with the vibrio of Asiatic cholera or with the pneumococcus. In these experiments it was curious to note that, although the animal receiving the leucocyte extract seemed well, eating and running about as usual, while the control was crouching in a corner of the cage with ruffled fur, showing extreme weakness, nevertheless there was a remarkable similarity in the exudates in both cases, and there was nothing to show that the bacteria were either immediately destroyed or even greatly hindered in their growth by the injected extracts; there was also no immediate change in the degree of phagocytosis taking place. In other words, the infection ran its course, but no untoward symptoms were produced because the toxins were seemingly neutralized as soon as elaborated.

The results of these animal experiments were so satisfactory that Drs. Hiss and Zinsser were encouraged to test the therapeutic worth of leucocyte extracts in man. The cases in which the experiments were made upon which the report is based numbered 32; of these 24 were epidemic meningitis, seven were pneumonia, and one was a chronic pneumococcus empyema. We cannot here go into the details of these experiments, all of which are reported, together with the animal experiments referred to, in the *Journal of Medical Research* for November, 1908, but will note only the results. Of the 24 patients with cerebrospinal meningitis, 14 were discharged cured without sequelæ, eight died, and two left the hospital during treatment and before the outcome could be foretold with any certainty. Of seven cases in which treatment was begun during the first week of the disease complete recovery without sequelæ occurred in all. The seven patients with pneumonia and the one with pneumococcus empyema all recovered, but so of course might any seven consecutive cases of pneumonia, and the number is too small to warrant any very positive conclusions

as to the value of leucocyte extracts in this disease. Nevertheless the uniformly favorable outcome, together with the results of the animal experiments, offers considerable encouragement for a continuance of the trials. Furthermore, even in these few cases, the uniformity with which the temperature fell and the subjective symptoms were improved after the injection of the leucocyte juice seemed to indicate cause and effect rather than coincidence. One would certainly not be accused of undue optimism in agreeing with the authors in their modest conclusion that "all these changes give the impression, at least, that we are dealing with an agent which further clinical tests will not unlikely prove of definite therapeutic value."

MEDICAL PRACTICE IN NEW YORK.

A DISCUSSION was started recently in the columns of the *New York Times*, by a writer signing himself "Emdee," on the difficulty encountered by the recent graduate in medicine in establishing himself in practice in this city. The writer lifts the veil of anonymity so far as to announce that he is a "weekly editorial writer on one of the oldest medical journals in New York," by which we suppose he means the *New York Medical Journal*, but this fact does not, as he seems to think it does, prove his assertion that "the medical journals studiously avoid nearly everything relating to the financial part of a physician's work"—a statement he could not have made had he had the privilege of reading the MEDICAL RECORD for any considerable period. The financial side of medical practice has been frequently discussed in this journal, both in signed communications and editorially.

There is nothing new in the fact that a young professional man without influence or a settled income finds it very difficult to range himself in New York, or any other large city. "Emdee" seems, however, to think that there is, and asks what the matter is with the profession of medicine, his question being prompted by the fact that "many excellent and cultured physicians are still struggling along after ten years of active attempt to practise in New York City." The matter with the profession of medicine here is simply that there are too many doctors for the amount of work to be done—the supply is greater than the demand.

Why the demand is not greater is another question. One reason is that the dispensaries and hospitals treat a great many persons who could very well afford to pay a moderate fee. Another reason is that the Board of Health does a great deal of work, such as vaccination, without charge, much of which would be done for compensation by the physicians of the city if the Board of Health did not do it. Still another reason is to be found in the "club practice" so common in certain sections of the city, in which medical treatment is secured for a ridiculously small annual fee. The last two factors are not so strong as the first, for while the Board of Health work and the "clubs" take away or keep away more or less "business" that would otherwise go to the private practitioner, they also give work at a definite salary to a number of medical men who would else go to swell the ranks of the feeless physicians.

But even with the demand much greater than it is, the supply would still be too large to meet it. The proportion of physicians to the general population is probably greater in New York City than anywhere else in the country. In the United States, for example, taking the estimated population of the Census Bureau for 1908 as a basis, there is one licensed physician to every 709 persons; in New York State there is one to 672, and in New York City one to only 653. It has been estimated that the physician in general practice must have a clientèle of 750 persons, or 150 families, to support himself and his family in comfort and in the style of cultured persons of moderate means in his own class, so if this estimate is accurate the New York doctor is short an average of 100 patients, and many of course are further behind than that. Conditions are better in Connecticut, where there is but one physician to 754 persons, but even there the *Times* correspondent would probably find it difficult to make a living unless he was more willing to get down to hard work and "scratch gravel" than he appears to be in the letter of complaint to which we have referred.

A NEW WRINKLE IN ETHER INDUCTION.

PERHAPS the greatest single factor in diminishing the danger of anesthesia of whatever character is the use of as little anesthetic as is necessary to produce unconsciousness to pain or abolish the reflexes of the patient. The administration of narcotics before anesthesia is one of the methods adopted to reach this end while all improvements in the technique of narcosis aim at a similar result. To these two methods Klapp had recently added a third, namely, the artificial diminution of the circulating blood during anesthesia by stopping the circulation in the extremities with the help of elastic bandages. Experimental work on animals has uniformly shown that such diminution of the circulating blood enables the production of anesthesia with a much smaller amount of the anesthetic, while the awakening from unconsciousness very rapidly follows the admission of the circulating blood to the vessels of the extremities. Dr. zur Verth had an opportunity to try this method in Bier's clinic in Berlin, and reports very favorably upon it in the *Münchener medizinische Wochenschrift* for November 17, 1908. He administered anesthetics in over one hundred cases after preliminary bandaging of the lower extremities; the arms were never cut off from the circulation because of the greater danger of injury to the nerves in the upper extremities. The results fully bore out the data of experimental work: Less anesthetic was used in all these cases than usually, strong individuals being easily anesthetized by means of the ether drop method; the recovery from anesthesia followed almost immediately the removal of the bandages from the legs; no injurious after-effects were noted. Besides these manifest advantages of the new method one more is mentioned by zur Verth, the possibility, namely, of performing what may be called autotransfusion in case of any accidents during anesthesia; in case of chloroform especially the blood of the extremities rich in carbonic acid gas may act as a powerful physiological stimulus to the respiratory centers that are so powerfully depressed by this narcotic. Further trial with this limitation of the circulating blood in anesthesia will be awaited with interest proportionate to the importance of any logical proposal aimed at the diminution of the risks that are ever present in the administration of anesthetics.

The Cause of Peristalsis.

The English physiologist, Starling, has increased our knowledge of the interdependence of organs by showing that not only nervous stimuli serve to connect the functions of one organ with another but that in addition certain specific chemical substances exert a similar action. These substances or "hormones" are produced by an organ in the beginning of its physiological activity and reach other organs by way of the blood, thus insuring a proper synchronism or sequence of action. Thus, secretin is such a hormone having a specific stimulating action upon the pancreas. The well-known changes that take place in the mammary glands of animals in the beginning of pregnancy are likewise occasioned by the presence of a specific hormone in the blood; in proof of this Starling has succeeded in producing similar changes in the mammary glands of virgin rabbits by injecting into their blood extracts of very young fetuses. In the *Berliner klinische Wochenschrift* for November 16, 1908, Zuelzer reports the discovery of a new hormone, a substance, namely, that excites peristalsis. This substance was obtained from the mucosa of the stomach at the height of digestive activity; when injected into the bloodstream it quickly caused a peristaltic movement of the intestines simulating in every particular the normal action, and ending with the expulsion of fecal masses from the rectum. All animals that were examined by Zuelzer showed the presence of this specific substance, an interesting detail being the existence of the hormone in only one of the four stomachs of a ruminant. It may be that the discovery of Zuelzer will prove of use in the therapy of gastrointestinal disorders; it certainly suggests that there may be a cause for chronic constipation not considered in the present theories of the etiology of this condition.

The North American's Apology to Dr. Knopf.

In the course of a discussion which took place during the meeting of the National Association for the Study and Prevention of Tuberculosis in 1907, Dr. S. A. Knopf of this city remarked that he would not hesitate to give a dying consumptive morphine to relieve his pain and distress. A reporter of *The North American* of Philadelphia distorted this remark into a plea for what the newspapers miscall euthanasia, that is hastening the patient's death, and the paper published the charge with scare heads, adding that these remarks were so hotly disputed that the meeting broke up in confusion. When the falsity of this report was brought to the attention of the editor of the offending journal he refused to retract or correct the accusation, and Dr. Knopf thereupon brought suit against the paper. After much wriggling *The North American*, rather than be mulcted in heavy damages, as it was evident it had no case, has now published a complete retraction and made apology to the injured physician. "This report," it says in its issue of November 29, "did Dr. Knopf a great injustice. The alleged confusion following the doctor's remarks had its existence only in the imagination of the reporter, and the authorized version of the speech, as the same appears in the official report of the proceedings of the Association, shows that he did not advise that morphine should be administered in quantities so large as to hasten death, but only for the purpose of relieving pain, which is the general practice of physicians." We congratulate Dr. Knopf upon his success in bringing to terms the promulgators of this false report.

What is the Matter with the Chicago Doctors?

The Weekly Bulletin of the Chicago Department of Health for November 28 says: "The medical profession is suffering from overcrowding. The condition is patent. They are writhing under it, and they grasp at remedies. It is unfortunate that this small group hit upon contagion in their blind groping and narrow view. The community demands protection. Each year sees the standard higher. Now that politicians, the clergy, and all society is enlisting to fight preventable diseases, it is unfortunate that even a small group of doctors should enlist under other banners. Of course, the medical profession in the main is for the right now, as always." This is terrible, and mysterious as well. Are the Chicago doctors spreading contagion in order to make patients? If not, what are they doing? The Three Guardsmen, Lieutenants U. S. A. Medical Corps Reserve, who conserve the morals of the A. M. A., should get busy.

News of the Week

Tuberculosis Exhibit.—The exhibit at the Museum of Natural History, New York, has proved very popular, and already many thousands have viewed it. An interesting meeting was that on the evening of December 4, when the physicians of the city were addressed by Dr. Simon Flexner, who spoke of the possibility of securing immunity against tuberculosis, and by others. The following is the official record of attendance for the first week, beginning Monday, November 30, the day the exhibit opened: Monday, 10,068; Tuesday, 14,199; Wednesday, 13,919; Thursday, 14,102; Friday, 18,141; Saturday, 29,809; Sunday, 43,713. Total, 143,951.

A Renewed Antivivisection Campaign.—The Committees on Legislation (Frank Van Fleet, Chairman) and on Experimental Medicine (Joseph D. Bryant, Chairman; John G. Curtis, Secretary), of the Medical Society of the State of New York, have issued the following notice to the practitioners of medicine of the State of New York: "The Society for the Prevention and Abuse in Animal Experimentation last year caused to be introduced into the Legislature of this State a bill seriously restricting experiments on living animals. The above named society now enters the field again and proposes another bill of the same general character as that of last year. The Medical Society of the State, through its committees on legislation and experimental medicine, successfully opposed the passage of last year's measure. Acting under the resolution referring to animal experimentation, which was passed at the last annual meeting of the State Society, its committees on legislation and experimental medicine will oppose the passage of the proposed bill. We therefore urge all members of the medical profession to disapprove the measure and on its introduction into the Legislature, to work in all legitimate ways for its defeat. Specific objections to it will be presented later."

Faculty Changes at Columbia.—Two retirements from the Faculty of the College of Physicians and Surgeons, Columbia University, New York, have just been announced. The Professor of Physiology, Dr. John G. Curtis, and the Professor of Pathology, Dr. T. Mitchell Prudden, have resigned to take effect on July 1, 1909. Prof. Curtis is the senior member of the Faculty, his connection with the college dating back to 1870. Dr. Prudden was appointed the first professor of pathology in

1897, his connection with the college having begun in 1878.

Birth Rate in New York.—The recent alarming statements in regard to the birth rate in the United States have called forth a counter statement to the effect that the birth rate in New York is remarkably high, far exceeding the death rate. It is thought that the foreign-born population with its large families is to be credited with this keeping up of the rate.

Reception to Delegates.—The delegates to the annual convention of Sanitary Officers of New York State, held at Albany last week, were received by Governor Hughes in the Executive Chamber on December 2, being introduced by Commissioner Porter. Governor Hughes, in addressing the delegates, said that questions of public health were destined to receive a great deal more attention in the next few years than they had in the past, since the great importance of preventing the spread of infection and disease was becoming more widely realized.

Typhoid Fever in Pennsylvania.—A serious epidemic of typhoid fever has been reported from Reading, Pa., where over four hundred persons are said to be ill of the disease. The State Board of Health has been called upon to aid in overcoming the epidemic, which is thought to be due entirely to the unfiltered and unwholesome water furnished to the city from Maiden Creek.

War on Diphtheria.—After a separation of a quarter of a century, the Health and Police departments of the city of Chicago have been reunited in an offensive and defensive alliance for a perpetual war on disease in general and ten years' war on diphtheria in particular. The new scheme of operation provides for the keeping of culture tubes and antitoxin at the police stations. A physician reporting a case of diphtheria will receive a culture tube through a policeman. After the culture is taken the police will forward it to the laboratory for examination, and will notify the physician of the result and of the amount of antitoxin which the examination has determined to be necessary.

Cancer Research.—An investigation into the cause of cancer and its possible prevention and cure has been begun in the College of Physicians and Surgeons, New York, under the direction of a committee consisting of Dr. Samuel W. Lambert, Dean, Dr. William J. Gies, Professor of Biological Chemistry, Dr. Philip Hanson Hiss, Jr., Professor of Bacteriology, Dr. Francis Carter Wood, Professor of Clinical Pathology, Dr. Gary N. Calkins, Professor of Protozoology, and Dr. Eugene H. Pool, Instructor in the Department of Surgery.

Death of a Centenarian.—Catherine Van Allen, the oldest resident of Oneida County, New York, died recently at the age of 102 years. Her father was a full-blooded Mohawk Indian, and her mother a mixture of Indian and negro. One of her uncles was said to have lived to be 115 years old.

Open Air Schools.—London is experimenting with open air schools, the session being from June 1 to October 31. Last summer the appropriation provided for only one, but its success was so great that next year three schools will be in session. Seventy-five children will be accommodated in each. Shelter is provided for unpleasant weather as well as for a part of each day, but the greater part of the time is to be spent in the open. The physical improvement among the children attending the school last summer was said to be very marked. The pupils are from the poorer classes and most of them are quite small; they have their meals at the school and spend the entire day there.

Blaze in Hospital.—A small fire in the basement of the building occupied by the New York Medical College and Hospital for Women was prevented from becoming serious by the good work of the superintendent, physicians, and nurses, and the thirty-five patients in the hospital were not alarmed.

Fees at Bellevue.—The rule of Bellevue Hospital to charge $1.50 a day to any patient who has more than $50 in his possession when he is admitted, has again been called in question, and a bill is to be introduced in the next Legislature providing that residents of the city admitted to Bellevue and the Allied Hospital shall be treated free of charge, and that no money in the possession of these patients shall be taken from them and charged to treatment. The rule was adopted two years ago to prevent persons able to pay from getting free treatment. The city charter already provides for the reception into the hospital of persons not residents of the city and the payment by them of such sums as may be fixed upon by the Board of Trustees.

Hebrew Infant Asylum.—Plans have been filed with the building department for the new home of the Hebrew Orphan Asylum, which is to be erected on a plot at Aqueduct Avenue and Kingsbridge Road, New York. The building will be four stories high, of ornamental brick and stone, with a frontage of 169 feet and a depth of 102 feet, and will cost $320,000.

The Chicago Presbyterian Hospital Annex was formally opened last week. The buildings dedicated were the private pavilion and a large powerhouse. The latter will greatly increase the efficiency of the whole hospital, and the private rooms in the new annex are expected to furnish enough revenue to enable the hospital to nearly double its free list. The private pavilion is six stories high, of the most modern brick, steel, and reinforced concrete sanitary construction, and with the latest conveniences. One of its features is the sun parlor on the roof, half of which is enclosed in glass and half open, so that patients may enjoy the sun in any kind of weather.

New York Red Cross.—The New York State Branch of the American National Red Cross at its annual meeting on November 24, elected the following officers for the ensuing year: *President*, William Cary Sanger; *Vice-President*, Elihu Root; *Secretary*, Mrs. William Kinnicutt Draper; *Treasurer*, Jacob H. Schiff; *Executive Committee*, the Governor of the State, C. H. Dodge, G. C. Boldt, Samuel Woolverton, W. C. Reick, R. W. De Forest, Gherardi Davis, Mrs. T. R. French, Mrs. John Birdsall, and Mrs. F. H. Potter. The Branch adopted the Red Cross Christmas stamp as a means of raising funds for its peace work among patients with tuberculosis, and recommended its general use.

New Medical Association.—Plans are under way for the organization of a Northwest Association to meet in Seattle in July of next year, and to comprise approximately 1,500 physicians who are members of the State Associations of Washington, Oregon, Idaho, and British Columbia. The Alaska-Yukon-Pacific Exposition, to be held in Seattle next summer, will draw large numbers of people to that city, and add greatly to the interest of the meetings of the Association.

Dr. Charles J. Finlay, since 1902 chief of the Department of Sanitation in Havana, Cuba, has

requested to be retired from active service on account of his advanced age, and has been appointed by Governor Magoon, honorary chief of the department in recognition of his services. Through the French Minister he has also been decorated with the Order of the Legion of Honor in recognition of his discovery of the rôle of the stegomyia mosquito in the propagation of yellow fever.

Last Medicine Man.—Hut-cho Nu-pah, last of the medicine men of the Five Tribes, died recently in Oklahoma at the age of 95 years. The influence of this old Indian, who was supposed to possess supernatural healing powers, was so great that even when he was condemned to death on the capture of his faction during the rebellion among the Creeks in 880, no one could be found to be his executioner. With his adherents dead and himself in prison, he was able to compel the election of a friend as chief, and received a pardon. There are no more medicine men in the Five Tribes.

The Annual Plea for the Army Canteen.—Brig.-Gen. George B. Davis, Judge Advocate General of the Army, in his annual report indirectly recommends the reestablishment of the canteen. He says: "The operation of the act of February 2, 1901, prohibiting the sale of beer in any post exchange, has undoubtedly caused the location near military reservations of resorts for the sale of intoxicating liquors, and which pander to the appetites and passions of those enlisted men who, largely by reason of the prohibition in question, frequent the same. These resorts are beyond the control of the military authorities and their presence near the military posts is highly detrimental to military discipline. From an examination of the evidence in general courts-martial trials made by this office," he continues, "it is evident that a large percentage of the offenses, although not charged as drunkenness, is either directly or indirectly traceable to the use of intoxicating liquors."

The American National Red Cross.—At the annual meeting of the Red Cross Society in Washington on December 8, Mr. Taft was unanimously reelected president. Mrs. Russell Sage and Dr. Louis Klopsch were elected honorary members. Officers for the ensuing year were elected as follows: *President,* William H. Taft; *Vice-President,* R. W. De Forest of New York; *Treasurer,* Beekman Winthrop, Assistant Secretary of the Treasury; *Counselor,* Henry M. Hoyt, United States Solicitor General; *Secretary,* Charles L. Magee.

The Brookfield (Mass.) Medical Club, at its regular meeting at West Brookfield on November 18, elected the following officers for the ensuing year: *President,* Dr. A. F. Peck; *Vice-President,* Dr. Lawrence T. Newhall, Brookfield; *Secretary and Treasurer,* Dr. W. J. Heffner, Gilbertville; *Executive Committee,* Dr. M. W. Pearson, Ware; Dr. Charles A. Blake, West Brookfield, Dr. A. H. Prouty, North Brookfield.

The Whitman County (Wash.) Medical Society, at its annual meeting on November 16, elected the following officers: *President,* Dr. W. B. Palamountain; *Vice-President,* Dr. A. J. Nelson; *Secretary and Treasurer,* Dr. Else.

The Stratford County (N. H.) Medical Society, at its one hundredth annual meeting, held at Dover on October 29, elected the following officers: *President,* Dr. Lewis W. Flanders, Dover; *Vice-President,* Dr. T. J. Dougherty, Somersworth; *Secretary,* Dr. H. O. Chesley, Dover; *Treasurer,* Dr. A. N. Smith, Dover.

The Pasadena Branch of the Los Angeles (Cal.) Medical Society held its annual meeting on November 16, at which the following officers were elected: *President,* Dr. A. T. Newcomb; *Secretary,* Dr. J. E. Janes.

The Fifth District Medical Society of Ohio at its fifth annual meeting on November 16, in Cincinnati, elected the following officers for the ensuing year: *President,* Dr. Hugh Death, Franklin, O.; *Vice-President,* Dr. J. C. Larkin, Hillsboro, O., and *Secretary,* Dr. John Miller, Cincinnati.

The Late Dr. Henry Denton Nicoll.—The Medical Board of the Woman's Hospital, at a recent meeting, adopted the following minute and resolution: "In the recent death of Dr. Nicoll on October 26 at New Windsor, New York, in the sixty-fifth year of his life, there has been removed from the medical profession of New York City one of its leading practitioners. His active work in the Woman's Hospital, with which he was connected for thirty years as visiting surgeon and as consulting surgeon, also his valuable services in the organization and administration of the New York Infant Asylum, will make his loss keenly felt by both of these institutions. During the last few years of his life Dr. Nicoll had to an extent retired from active practice, though still giving unstintingly to the above institutions his mature counsel and warm interest. During these later years he enthusiastically joined with others in the vicinity of his country home at New Windsor, New York, in surrounding the young men and young women of that locality with elevating and refining influences. In such a capacity he was the President of the Law and Order League of New Windsor Township, and in the village of Moodna, near his country home, he built a chapel, the center of the practical uplifting and of the moral work of the community.

"Resolved, That in the death of Dr. Nicoll the Woman's Hospital has lost one who uniformly placed its interests above that of self, considering at all times its welfare.

"That in the loss of his prudent, conservative counsel the Medical Board feel deeply his death and recognize that in his faithful administration of the office of President it has lost a devoted friend, a wise adviser and one whose influence has been and will be felt throughout the Hospital.

"That as a small token of our love and admiration for our colleague, we present this to the Governing Board of the Hospital and direct that a copy be sent to the Medical Journals of New York City for publication, and also to the family of Dr. Nicoll.

"(Signed) Clement Cleveland, B. McE. Emmet, P. F. Chambers, J. Riddle Goffe, LeRoy Broun, Austin Flint, Jr."

Obituary Notes.— Dr. William Whitfield Miller, Assistant Surgeon, U. S. Public Health and Marine-Hospital Service, died of typhoid fever in Providence Hospital, Washington, November 24, 1908, after an illness of eight weeks. He was born at Water Valley, Miss., June 26, 1880. He studied medicine in the Medical Department of the University of Virginia, and received his degree in 1901. After graduation he took a special course in pathology at Harvard University. Later he went to New York and was assistant in bacteriology in Columbia University, and assistant pathologist in Roosevelt Hospital. Subsequently he served for two years on the resident staff of that hospital. In 1905 he went to Memphis to engage in private practice, and was demonstrator of pathology at the College of

Physicians and Surgeons in that city. Dr. Miller was commissioned an Assistant Surgeon in the U. S. Public Health and Marine-Hospital Service September 4, 1906. In August, 1907, he was assigned to the Hygienic Laboratory of the Public Health and Marine-Hospital Service, Washington, D. C. In connection with the investigation of the origin and prevalence of typhoid fever in the District of Columbia he made many of the bacteriological examinations of water and milk, and during the last summer made over a thousand bacteriological examinations in the search for bacillus carriers. He discovered a pathogenic hemogregarine in the blood of white rats, and described its life cycle and the mechanism of infection by the digestive tract. A preliminary note of this discovery was published in the weekly Public Health Reports, July 24, 1908. The completed work forms Hygienic Laboratory Bulletin No. 46. Dr. Miller was married in 1906, and leaves a widow and infant daughter. Personally he was modest, had an exceptionally winning and lovable disposition, and commanded the respect and affectionate regard of those with whom he was intimately associated.

Dr. John T. Wheeler, Director of the Division of Communicable Diseases of the New York State Department of Health, died at his home in Chatham, N. Y., on December 3, aged 58 years. Dr. Wheeler was graduated from Bellevue Medical College in 1876. He was vice-president of the State Medical Society, and a member of the local Board of Education, on which he had served for twenty-seven years.

Dr. Louis P. Knapp of Hackensack, N. J., died at his home on December 3, after a short illness. Dr. Knapp was born in 1868, and was graduated from the College of Physicians and Surgeons, New York, in 1891, after which he studied in Berlin and Heidelberg.

Dr. Ella A. Jennings of Brooklyn, New York, well known as an editor, author, and lecturer, died on November 30, at the King's County Hospital. Dr. Jennings, who was by birth a Canadian, received her medical education in New York, graduating in 1878. Shortly after she founded the Provident Dispensaries which during the time they were in existence treated more than half a million patients. For a number of years she also edited the magazine, *Humanity and Life,* and lectured on health subjects.

Dr. Frank L. Adams of Oakland, California, died suddenly on November 20, of angina pectoris, aged 50 years. Dr. Adams was graduated from Cooper Medical College, San Francisco, in 1883, and after one year in a hospital, began the practice of medicine in Oakland. He was one of the founders, president, and professor of clinical surgery of the Oakland College of Medicine and Surgery, a member of the American Medical Association and of the Medical Society of the State of California, and president of the Oakland Board of Health.

Dr. John Homer of Newburyport, Massachusetts, died at his home on November 24, aged 72 years. Dr. Homer was graduated from Harvard Medical College in 1865, and was a member of the Massachusetts State Medical Association and of the State Pharmaceutical Association.

Dr. Walter A. Bacon of Central Falls, R. I., died in Pawtucket on November 22, after a long illness, in his thirty-sixth year.

Dr. John C. Hupp of Wheeling, West Virginia, died at his home on November 18, aged 88 years. Dr. Hupp was graduated from Jefferson Medical College, Philadelphia, in 1847. He was a member of the American Medical Association, and of the State Society, city physician, and secretary of the Wheeling Board of Health in 1864; president of the Ohio County Board of Supervisors from 1863 to 1866; a member of the district Board of Education from 1873 to 1879, and consulting physician to the city hospital.

Dr. George R. Graham of Baltimore, Maryland, died on November 19 of pneumonia, aged 64 years. Dr. Graham was graduated from the University of Maryland in 1883, and was a member of the Medical and Chirurgical Faculty of Maryland, a veteran of the Civil War, and a member of the Board of United States Pension Examiners of Baltimore since 1889.

Correspondence.

THE FOURTH IMPORTANT SYMPTOM IN EXOPHTHALMIC GOITER.

To the Editor of the Medical Record:

Sir:—In addition to the three chief symptoms that are regarded as pathognomonic of exophthalmic goiter, there is a fourth whose presence is no less constant than the three now generally recognized and which are as follows: (a) the swelling at the root of the neck; (b) the protrusion of the eyeballs; (c) the cardiac irritability, often very marked.

This fourth manifestation was first observed and described by Dr. Louise Fisk-Bryson of New York as far back as 1888, and the only reference to it in the literature that has come to my notice is found in Dana's work on "Nervous Diseases."

This symptom is inability on the part of the patient to expand the chest under forced inspiration more than three-quarters of an inch to an inch. Since my attention was first called to the matter, about eighteen years ago, I have had occasion to put it to the test in more than thirty well-marked cases—many of these being at the Craig Colony for Epileptics—and it has been a distinct feature in every case without exception. The most recent case was that of an Italian woman of about 40 years, who was referred to me by Dr. Julius Friedenwald of this city. Careful measurement next the skin showed three-quarters of an inch expansion only. Among the thirty odd cases the greatest expansion was 1¼ inches.

Baltimore, Md.

Professor of Nervous Diseases,
College of Physicians and Surgeons.

OUR LONDON LETTER.

(From Our Special Correspondent.)

NAVAL REPORT—MITCHELL BANKS LECTURE—EXTENSIVE OPERATIONS FOR CANCER—CULTURES OF LACTIC ACID BACILLI—TRELOAR CRIPPLES' HOME—ALBUMIN AND RENAL DISEASES—SLEEPING SICKNESS.

London, November 20, 1908.

The "Blue Book," dealing with the health of the navy for 1907, was issued last week, and shows further improvement on that of the previous year. The average loss of service has fallen to 10.46 days per man. The total cases of disease and injury are 85.23 per 1,000 less than the average for five years. There was a marked decrease of malarial cases, partly due to the use of mosquito curtains and the prophylactic use of quinine in malarial districts. An investigation of ear cases was made in the home division to see if a connection with gun fire could be traced. Though the result was negative as far as disability goes, it is remarked that it has been previously shown that a certain degree of deafness or a decrease in the acuteness of hearing, especially in a crowd, is noticeable among men who have been exposed to the shock of gun fire, and this greater in proportion to the duration of the fire. Officers and men should, therefore, the report says, as far as practicable, take advantage of one of the methods of ear protection now in use. On this I may remark that the facts may be added to those which are employed to urge the abatement of noises in our large towns.

The Mitchell Banks memorial lecture was delivered on the 3d inst. by Mr. Henry Morris, president of the Royal College of Surgeons, on the council of which the subject of the memorial lecture served for eight

years. The name of Mitchell Banks is known wherever modern surgeons are found. Those who knew him well speak of his attractive personality, his impressive earnestness as a teacher and remarkable attainments. Your readers will remember his address at Montreal in 1897, when his views on cancer had been accepted by those who long opposed them, and accepted cordially when offered as original by German surgeons, though they had been held for a generation by his own countrymen. On the radical cure of hernia and on urethral fever also Banks did splendid work, to which Mr. Morris did justice in his lecture, but I will confine my remarks to what he effected in regard to the operative treatment of cancer of the breast, as it illustrates the way in which a prophet gets no honor in his own country, as well as the greatness of his surgical acumen, operative skill and perseverance in a proceeding of the value of which he was firmly convinced. Banks made no undue claim to originality. From the first he referred to Charles Moore's historic paper on "Inadequate Operations in Cancer," published in 1867, as one that "made me think." And he thought to good purpose. He adopted the routine removal of the whole of the paths and lymphatic contents of the axilla, and the skin covering the mammary gland, as well as very wide resection of the fascia connected with the muscles upon which the gland rests. He arrived, continued Mr. Morris, at his own conclusions through witnessing many imperfect operations and by observing the frequency of early recurrences and the situations and tissues in which they appeared. He brought no fresh microscopical information to bear, but his conviction as to the proper operative procedure was entirely an induction from clinical experience, and this quite apart from the advances in aseptic and antiseptic surgery, which have given others the courage to follow him. His first paper was in 1877. Gross of Philadelphia supported the more extensive removal in his work on "Tumors of the Breast" (1880). In 1882 Banks communicated a paper to the British Medical Association, with notes of forty-six cases. In 1887 he brought the subject before the Harveian Society of London and reported eighty-two operations. Prominent surgeons present questioned the practice and others held by the old views, notwithstanding the authority of Banks and Gross. The constitutional theory of cancer to which the elders clung receded before the microbic theory and in 1889-1892 additions to our knowledge of the minute anatomy of the lymphatics of the breast and pectoral fascia were published, showing that the entire mammary gland was not removed in the usual operations. In 1900 Banks delivered the Lettsonian lectures and gave analyses of his 213 operations. In them, too, "with the courtesy which softens controversy, but with the candor and straightforwardness which command respect," he commented on the work of others and quietly remarked that, in justice to himself and the memory of his friend Gross, he thought it rather hard that a group of surgeons should date this treatment to the labors of Haidenhain and themselves. Mr. Morris hereupon quoted the appreciation of Jacobson, who said that if honor is to be given where due a fair share must fall to Banks. Mr. Morris touched briefly his own practice, which has followed that of Moore and De Morgan, but adding, "for many years I have been in the habit of removing the fascia over the serratus magnus and often a layer, and, on occasions, in places, the whole thickness of the muscle." He had also, he said, as a teacher at the hospital and examiner at the Royal Colleges and the University, pointed out to students and candidates that a good half of the gland is in contact with the serratus magnus, and only the rest with the pectoralis major, for he had found a general impression that the mamma rested entirely on the pectoralis. He thought too much importance is attached to clearing the axilla from above downwards, the essential precaution being to avoid cutting across lymphatics or leaving behind any glands or fatty tissue. "Nor do I believe," continued the lecturer, "in the danger of making a direct cut into, or even of removing a slice from, a cancer tumor, for the purpose of diagnosis, before the operation is commenced, provided the wound is stuffed with a little aseptic gauze and covered with collodion previous to proceeding with the excision, and the knife used for the incision is laid aside. The danger lies in inadvertently dividing affected infiltrated tissues, which was so frequently done in the days of inadequate operative measures."

On Friday last a case of pernicious anemia was shown in the Clinical Section of the Royal Society of Medicine, which led to some remarks on the use of cultures of lactic acid bacilli, of which various preparations are being tried for rather different conditions. The case itself is interesting from several points of view. It is that of a man of 34, admitted to hospital October 10, 1907, with tenderness over colon and extreme anemia. There were enormous numbers of *Streptococcus fæcalis* and Gaertner's bacilli in the feces. Liver and spleen not enlarged. The patient had suffered from diarrhea for several years, but kept at work until palpitation and dyspnea came on. Blood count 1,468,000 per c.mm. red corpuscles, leucocytes 3,500. He was treated four months with arsenic, intestinal antiseptics, vaccines of streptococci, etc., after which, January 23, 1908, the blood count was 1,568,000 to 3,000 per c.mm. He was put on a culture of lactic acid bacilli from January 19 to March 2. On March 19 the red corpuscles were 1,725,000, the white 1,750. The lactic bacilli were omitted a month, when the reds fell to 1,392,000. The lactic bacilli were again given and on April 23 the reds were 1,000,000. From then the remedy was continued to the end of September, when the count gave 4,800,000, white 6,400.

Dr. Herschell pointed out the importance of the activity of the ferment being ascertained. Many of the preparations are inert, some perhaps injurious. Most of them are made by drying a milk culture of the bacillus and in the lengthy process the chances of contaminations are innumerable. They do not readily dissolve and so some makers have added effervescing powders. Moreover, instead of containing the true Bulgarian bacillus, which can most readily be acclimatized in the intestine, some tablets are made up with rennet for curdling the milk, and one of the weaker lactic bacilli which are at once destroyed in the stomach. A tablet should dissolve in three or four minutes in water, be neutral, odorless, and when incubated on Cohendy's milk serum should give a culture of Bulgarian bacillus, with perhaps one other organism added to improve the flavor of the milk curdled by it.

Dr. Gordon Dill, who showed the case, agreed with Dr. Herschell and said he was now examining the various products on the market, and many of them he had already found to be inert.

Sir William Treloar, when Lord Mayor in 1907, devoted much labor to the establishment of an institution for poor cripples, in whose welfare he had long been interested. He is now appealing for subscriptions to send a Christmas dinner to many, a custom he has observed for several years. This is as a little treat for them in their own homes, but the institution he has set on foot is a kind of home and college in the country, where cases which cannot be dealt with in children's or orthopedic hospitals can be received and if possible benefited. In October Sir William received a party of medical men at his institution at Alton. Dr. Biscol gave an address on cripples, in which he pointed out how much we owe to Percival Pott, whose acumen was so remarkable, and, as he lived 129 years ago, had no help from the scientific instruments of research now at our disposal. The visitors were guided over the "Home and College" by Dr. Gauvain. The buildings are very simple, in fact, they were constructed originally for a military hospital, but have been reroofed and altered and largely equipped, so that in a few months they may be brought up to date. The notable features in going over the grounds are the large amount of cubical space in the pavilions, the verandas with covering, the system of heating, effected by a couple of engines of 80 horsepower, the pleasant views and appearance of forethought for the comfort of patients.

Professor Foxwell of Birmingham says it is fallacious to regard albumin in the urine as always indicating serious disease. The amount of urea excreted is of greater import, as the normal relation between the intake or output of nitrogen is essential. The subjects of surgical operations which may properly be delayed should be under observation for at least a fortnight, the urine being daily examined and the percentage of urea estimated. This he regards as the only way of assuring onself that a patient is fit to undergo an important operation without the risk of fatal postoperative renal trouble. Pathological reports on the kidney are apt to be misleading if sections are only taken from the parts which appear to be diseased and no attention given to the rest of the organ, which may look healthy.

The text was published on Wednesday of an agreement and protocol between this country and Germany as to sleeping sickness. It provides that each Government shall take such steps as are practicable to prevent natives of their respective domains who may be suffering from sleeping sickness from passing into each other's territories. The agreement also deals with notification and is to remain in force for three years.

Progress of Medical Science.

Boston Medicol and Surgical Journal, November 26, 1908.

The Relation Between Human and Animal Tuberculosis, with Special Reference to the Question of the Transformation of Human and Other Types of the Tubercle Bacillus.—Theobald Smith discusses the differences between the human and bovine bacillus. He notes that bovine infections are essentially alimentary in origin and localization and largely restricted to childhood. Much energy has been expended on the study of transformation of type between the two organisms. Smith does not think that the time has yet come for us to state positively that one type can or cannot be transformed into the other. Evidence is conflicting. We may safely take the ground that any regular or wholesale transformation conversion of bovine into human bacilli in the human body is out of the question. We know that human tuberculosis can exist without the aid of bovine tuberculosis and an important aid in the final solution of this question will be the study of human tuberculosis in those regions in which the bovine disease does not exist, and into which dairy products are not shipped from regions in which the bovine disease does exist. The author suggests, as pertinent line of inquiry and experimentation, the following: (1) A continued study of cases of pulmonary tuberculosis with the view of ascertaining if the bovine type is exclusively responsible for any cases in which a regular discharge of tubercle bacilli takes place. (2) A further study of the transformability of tubercle bacilli by passage of tissues containing bacilli and guarded from all possible sources of error, together with a most careful examination of the nature and permanency of the changes induced. (3) A study of the varieties of tubercle bacilli among populations where dairy products coming from tuberculous cattle can be excluded as a contribntory cause.

The Comparative Value of Change of Climate and of Treatment in Sanatoria Near at Hand in Cases of Pulmonary Tuberculosis.—C. E. Edson advances the following propositions: As outdoor life is one of the essential aids to the cure of pulmonary tuberculosis. The climate surroundings of the patient have to be considered. Consciously or unconsciously we select a climate for every patient, even when we keep him at home. That climate is most favorable which most readily permits an outdoor life. A change of climate will be of advantage to a patient if we can thereby place him under meteorologic conditions which, to a greater degree than before, and more constantly, permit him to lead the necessary outdoor life with ease, safety, and economy of vital expenditure. The accompanying change of scene and surroundings may be expected to act advantageously in an indirect way. In making any proposed change of climate attention must be given to the facilities in the new region for obtaining suitable food, accommodation, care, and medical supervision. If these conditions can be as well met as at home in a better climate, the patient should be advised to make the change. If the patient's financial, social, or domestic circumstances are such that he cannot in the new climate secure proper and sufficient food, accommodation, care, and medical attention, or if his mental attitude is such as to make separation from home inadvisable, he should not be sent away.

New York Medical Journal, November 28, 1908.

A New Method for the Transfusion of Blood.—A preliminary communication on this subject is presented by R. T. Frank, who illustrates his ideas by several diagrams. In essence the plan strives to do away with the delay and annoyance in freeing the radial artery of the donor of the blood, ligation of minute side branches, stripping off of the adventitia, suturing etc., and the dissecting out of the vein of the recipient, cutting it across, etc. A portion of a vessel from some animal (dog's carotid) is prepared beforehand and used as a connecting vascular bridge. Thus far the author's experience has been entirely with animals in whom the procedure seems entirely feasible.

Adiposis Dolorosa with Involvement of the Large Nerve Trunks.—One case, that of a woman of 45 years of age is reported by P. N. Bergeron. The features of the case were the marked pain elicited by pressure over the nerve trunks, the sensitiveness of all the subcutaneous adipose tissue and the presence of so few circumscribed masses of adipose tissue. The patient's present illness was of three years' duration and began with pain in the outer surface of the right arm and shoulder. Later it spread to the forearm, hand, outer right thigh, leg, and foot, later in the left leg. In two or three months general abnormal sensations appeared and some loss of power in the arms and hands with various systemic disturbances. There were circumscribed collections of adipose tissue about the bursæ of the elbow joint and two right metacarpophalangeal joints of the right hand. The subcutaneous tissue lacked firmness and imparted to the palpating finger the impression of masses of worms. There was no apparent muscular atrophy though all the muscles seemed weak. Marked improvement followed the use of six grains of thyroid extract and twenty-five grains of aspirin daily, with light massage. The case is still under treatment.

Journal of the American Medical Association, November 28, 1908.

Causes of Eczema.—M. B. Hartzell rejects other than local causes for eczema in most cases. It seems to him that eczema may occur in any one if the local causal irritation is prolonged or sufficiently often repeated, as is shown in many cases of occupation eczema, in which the skin inflammation appears only after a shorter or longer period of immunity. It is often, moreover, in local eczemas difficult to detect the exciting cause, and he thinks, unless we can entirely exclude such, the assumption of an internal cause is not justified. While he is not prepared to accept the theory of a parasitic origin of the disease, Hartzell is willing to admit an important rôle to microorganisms, which he believes may often transform a simple local inflammation into a chronic eczema. The fact that antiseptic substances, like tar, resorcin, etc., are often of great service, supports this view. He does not deny that eczema may arise from causes within the body, but he thinks that by far the greater proportion of cases arise from external irritation. He emphasizes the fact that our knowledge of the internal causes is extremely shadowy and ill defined, seldom accurate enough to afford any rational basis for internal treatment. All physicians have seen eczema get well under local treatment, but few, he thinks, would expect very good results from internal treatment.

Abnormal Lactation.—G. Gellhorn reviews the subject of abnormal lactation, referring first to the secretion from the mammary glands sometimes observed in newborn infants, and of which a satisfactory explanation has not yet been given. The theories of Starling and of Halban that it is due to some chemical substance formed during pregnancy are noticed but not fully accepted by the author. Whatever the cause, the phenomenon soon disappears and the glandular activity only reappears at puberty. The appearance of the mammary secretion at menstruation, for which it may even be substituted, and the full establishment of the function of lactation occasionally in virgins, old women, and even in males has been observed both in man and in the lower animals. Prolonged lactation, its occurrence in association with false pregnancy and with pathological conditions, operations, and the close relations of the uterus and ovaries to the function are noticed at length, and there are a number of striking illustrative cases of the different abnormal conditions reported in the text. Gellhorn, from the experiments of Ribbert and of Basch, concludes that it may be accepted as fairly established that the specific function of the mammary gland is independent of the nervous system. The object of the paper is stated by its author to be to call attention to the fact that further accurate observations are still needed to settle some of the questions regarding the physiology and pathology of this function. Especially he mentions the connection between lactation and certain pathological states as calling for careful consideration, and hopes that a discussion on this subject will bring out facts observed in this country. Aside from its scientific interest, the etiology of the lactal secretion has a considerable practical importance, and Gellhorn specially mentions the importance of a thorough knowledge of the atypical functioning of these organs to the expert in medicolegal practice.

Mercury in Tuberculosis.—B. L. Wright remarks on the resemblance between tuberculosis and syphilis in their pathological histology, and suggests that the authentic cases of syphilis in which Lustgarten and others found his bacillus were complicated with tuberculosis and that the germs found were really tubercle bacilli. That these organisms disappeared under mercury wat at that time a strong argument that they were the bacilli of syphilis. Now that we know the real organism of syphilis, it would seem probable that the disappearance of the Lustgarten bacillus under mercury occurred because this drug had an antituberculous as well as antisyphilitic action. Wright's attention was first drawn to the action of mercury in tuberculosis while on duty in the U. S. Naval Hospital, Pensacola, in the spring of 1905. Mercury was employed in several cases with a mixed tuberculous and specific infection with remarkable results, the tubercle bacilli disappearing and the lungs showing marked improvement on physical examination. This suggested an antituberculous action of mercury which seemed to him on reflection to be reasonable, and since assignment to the hospital at New Fort Lyon, Colo., he has resumed the experiment of this medication, now giving mercury by deep muscular injections to avoid the gastrointestinal symptoms which were an annoyance when it was exhibited by the mouth. Since its use the death rate

has been reduced from 11.29 per cent. in the first quarter of 1908 to 4.76 per cent. in the second quarter, and 0.95 per cent. in the third quarter of the year ending September 30. Considering the fact that 60 per cent. of the patients were advanced cases, this result seems the more remarkable. Of the total number of patients under treatment 85.5 per cent. have been improved and there have been two cases counted as cures. Two officers, not included in the above, have recovered so far as to return to duty and are holding their improvement. Of the remaining 13.5 per cent., 2 patients have held their own, 6 have failed and one has died. The contrast between the patients who refused the mercury treatment and those who received it, all under the same conditions otherwise, was very marked, only 33 per cent. of those refusing having improved and this chiefly in the general condition rather than in the pulmonary lesions. Wright believes that mercury acts as a tonic and as a bactericide in the blood. His method is to give an injection of 1-5 grain of hydrargyrum succinimidum every other day until thirty injections have been given. Then the patient is placed for two weeks on iodide of potassium, followed by a week without medication. Then the mercury is resumed with slightly reduced doses for another thirty days, and so on. The drug should never be pushed to the point of salivation and the doses given above are not absolute, but must be determined by close observation of each individual patient.

Rupture of the Urethra.—Rexwald Brown insists on the importance of avoiding the use of the catheter or sound as a diagnostic or therapeutic measure in case of traumatic rupture of the urethra. This is not so much on account of the danger of making false passages, an accident that is serious enough to be guarded against for its own sake, but chiefly on account of the danger of infection. The passage of even a sterile catheter along the urethra carries the microorganisms that have their habitat there along to the laceration and increases their virulence. Minor grades of urethral tear, causing only slight hemorrhage and little pain or difficulty in micturition, call for only watchful expectant treatment. Nature will probably repair the injury. In severer cases, where there is great pain, very difficult or impossible urination, hypogastric distress and signs of hemorrhage, immediate simple urethrotomy on a grooved staff should be performed. The two ends of the torn urethra are approximated over a catheter with catgut sutures and the catheter fastened, to be retained a few days. The perineal wound should then be closed around a drainage tube, to remain forty-eight or sixty hours. If several hours have elapsed before the case is seen, and there is great distension and distress and the patient is in a serious condition, incise the perineum deeply at once and put in tube drainage. After several days, when the parts have almost reached normal again, the torn urethra can be repaired as above. Dixon's advise of immediate suprapubic cystotomy with retrograde catheterization seems to the author hardly advisable, save in very rare cases, simple perineal section being usually sufficient as an immediate operation, with perhaps the shelling out of clots.

Lumbar Appendicectomy.—C. G. Levison reports two cases in which the appendix occupied a retrocolic position and was operated on by the lumbar route. He says the rule to be observed in the surgery of the appendix is to make the incision correspond to its localization, and McBurney's point must sometimes be ignored to a certain extent. When the exudate is situated in the loin, the diagnosis of a retrocecal appendix should be made, excluding as far as possible paranephritic abscess and gall-bladder disease. If low down, the differentiation from pelvic disease should be made. Naturally, the classic form should be first thought of. He finds this subject almost completely overlooked in the literature. It is his conviction that in cases in which the appendix cannot be found at operation, it is situated in the retrocecal space. This has been his experience in several cases, and he believes that other surgeons must have had the same fortune.

The Lancet, November 21, 1908.

Vicious Circles Associated with Disorders of the Digestive System.—J. B. Hurry groups these circles as follows: (1) Those associated with the mouth as oral sepsis leading to dental disorders and gastrointestinal catarrh with resulting malnutrition. The resulting systemic disturbance will tend to lower local oral resistance and encourage the continuance of infection and absorption. (2) Circles associated with the stomach, as atomic dyspepsia with anemia, weakened peristalsis with hindered absorption from the stomach walls, gastric imitation or catarrh caused by irritating ingesta, etc. (3) Circles associated with the intestine visceral congestion and a failing myocardium with defective peristalsis and fermentation of the ingester with enfeebled nutrition and dyspepsia, etc., intussusception where the vigorous peristalsis of the intussuscipiens increases the length of the invaginated intussusceptum, the descent of a hernia enlarging the ring and thus encouraging redescent, etc. (4) Circles in connection with constipation, and defecation, as dilated rectum encouraging constipation, thread worms encouraging scratching and leading to the catching of the worms or their ova under the nails and conveyance to the mouth and swallowing by the host. When a circle is present a recognition of the reciprocally acting forces will solve many an enigma in obscure disease and pave the way for rational treatment.

The Influence of Heredity in Tuberculosis.—A. Latham's conclusions are as follows: (1) The hereditary transmission of the germ is so infrequent that it is a negligible factor. (2) The incidence of tuberculosis depends in the main on two factors: (a) exposure to infection which in turn is governed by the dose received and the virulence of the particular strain of bacillus, and (b) the undermining of the resistance of the individual by unsanitary conditions and disease. (3) The more adequate the preventive measures taken in any community, the less are the incidence and mortality of the disease. (4) The more adequate the medical treatment, that is, the greater the proportion of persons in whom the disease has been arrested and who have acquired thereby a partial immunity, the less are the mortality and incidence of the disease. (5) As at death, we all or nearly all show evidence of having at some time been infected with tuberculosis, and, as most of us are able to overcome the infection, it is clear that the diminished opportunity for repeated infection brought about by preventive measures and better medical treatment, cannot wholly account for the diminishing incidence and mortality of the disease. (6) There is some evidence to suggest that the diminishing incidence and mortality of the disease may be due in part to a partial immunity inherited in the course of generations from tuberculous ancestors in whom the disease has been cured. (7) The theory that there is an inherited predisposition to tuberculosis is based on insufficient evidence.

Heredity in Cancer.—The paper of E. F. Bashford is largely statistical. The author says if experiment does not as yet support the conception of an inherited predisposition, why does cancer arise in one individual and not in another who has been subjected to the same irritant in the same region of the body? Cancer is primarily circumscribed. Conditions of origin are fundamentally distinct from conditions of mere growth into a tumor. The soil provided by a rat or mouse can be modified in two directions. It can be rendered absolutely unsuitable or more than normally suitable for the growth of transplantable carcinomata and sarcomata. Another form of constitutional influence which is of moment, at any rate in the case of some transplantable tumors, is that the presence of a primary tumor can effect a secondary modification favorable to dissemination and metastasis formation. A tumor can be modified by the influence of the soil. There are, therefore, constitutional conditions which are favorable and others which are unfavorable to the growth of cancer and they can be induced experimentally at will. In conclusion the author says that with nothing but negative evidence of the part played by inherited constitutional conditions before us and with positive evidence of the importance acquired constitutional conditions can play in furthering the growth, and perhaps the development of cancer, we shall more profitably spend our time if we frankly seek to ascertain how they are acquired than if we continue to preach the doctrine that they are inherited and that it is hopeless to contend against them.

Heredity in Diseases of the Nervous System.—W. R. Gowers says that many diseases commonly called "nervous" diseases are really in the nervous system but not of it. Yet there are special growths, such as glioma and certain endotheliomata, which seem to have a predilection for true nervous tissue. But all such affections are so rare that one cannot claim that they are in any sense hereditary. Other diseases, such as sudden cerebral seizures, apoplexy, etc., depend on causes which take their heredity far away from the brain in which the seizure occurs. Heredity may play an important part in the secondary production of chemical agents from organisms acting on somatic processes. Endogenous toxins, as in diabetes, may give definite nervous disturbances. Heredity in nervous diseases seems to work along certain lines. We may have early abiotrophies, a convenient instance of typical form being pseudohypertrophic paralysis. A second class may include the hereditary maladies which begin later in life, after the period of growth is over. Seldom, but yet sometimes remarkably, can heredity be traced in paralysis agitans, tremors, Graves' disease. A third class in which heredity is operative consists of the so-called functional affections. Heredity applies

only to a portion of the cases of epilepsy. Those resulting solely from organic lesions of the brain, from disease, trauma, or difficult birth, are not concerned with heredity.

British Medical Journal, November 21, 1908.

A Specific Skin Eruption in Pneumonia.—F. M. Pope records the case of a young man of twenty years admitted to hospital with a pleurisy and pneumonia of the base of the right lung. He had a temperature of 104° F. and delirium, grew worse for three days, showed a dilated heart, and a crop of papules on the upper back. They were of a deep rose color, circular and about 3 to 4 mm. in diameter, darker than the average typhoid spot, and disappeared completely on pressure. Six days later the first spots were fading and a second crop identical with the first had appeared. The man was now very ill and had extensive consolidation of the base of the left lung. Three days later still the spots were observed to be pustular. A smear of the pus was stained, and the only organisms to be seen were pneumococci. A small abscess behind the right ear was opened on November 3. A culture was made from the pus; the growth consisted of pneumococci and staphylococci. A film taken directly from a pustule on the same day showed also pneumococci and staphylococci. According to the author the eruption seems to resemble that of smallpox to some extent, as it was first papular and then pustular; a vesicular stage was not observed. Infection with staphylococci followed, as often in variola. The abscess appeared too late to be in causal connection with the eruption. The patient made a slow but good recovery.

Pelvic Pathology and Seasickness.—G. V. Elder believes that pelvic abnormalities are at the bottom of many cases of seasickness in women. In the case of a married woman whose stomach had rejected everything for ten days there were no symptoms or signs pointing to a pathological condition, and beyond a "soreness," which could easily be attributed to constant vomiting, she complained of nothing. Nutrient enemata were resorted to in the hope of alleviating also the great thirst which existed, but even they set up a sort of reflex return. On the twelfth day, while making her drink some thin water gruel so as to have something in her stomach to be "sick" with, the author saw her actually vomit for the first time, and was immediately struck by its character—typically cerebral. Being quite certain that no cerebral mischief existed, she was asked, and consented, to have the pelvis examined bimanually, when the following conditions were found: Extreme congestion of parts, a badly torn cervix, an ovarian cyst about the size of a hen's egg on the left side, and finally a retroverted uterus. On closer inquiry the usual facts were elicited. Daily treatment, consisting of mild, warm douches and the insertion of glycerine "tampons" brought about a marked improved condition. In a week solids were kept down with only occasional attacks of vomiting, pelvic pain was relieved, and the patient got steadily better, though the weather continued moderately rough. This patient was also subject to "carsickness"—a peculiarity which, according to the author, adds considerably to the miseries of a sea voyage.

Early Diagnosis of Organic Disease of the Nervous System.—T. R. Bradshaw discusses the significance of knee-jerk, ankle clonus, and exaggerated knee-jerk, absence of the latter, ocular signs, and thoracic, abdominal, and pelvic symptoms, with a relation of several clinical histories. Entire absence of the knee-jerk is always indicative of organic disease. If the patient is able to walk about, this absence generally indicates tabes or neuritis of diabetic origin. Ankle clonus, if sustained, always means organic disease. Absence of the knee-jerk must always be looked on with grave suspicion, as it is never due to hysteria or functional disorders. Occasionally it seems to persist in tabes. Inequality of the pupils is apt to give rise to a suspicion of general paralysis, but it may be normal to the individual. Diplopia, permanent or transitory, is suggestive of organic disease, as is also nystagmus, as suggesting disseminated sclerosis. Slight oscillations of the globe must not be mistaken for true nystagmus, as they may be due to mere fatigue or be a part of a general muscular tremor. The Argyll-Robertson pupil practically means tabes or general paralysis, so that in its absence it is hardly safe to make a diagnosis of these conditions, especially the former, unless the other signs and symptoms are very well marked. Bladder troubles are very common in nervous diseases, but retention of urine may be referred to stricture or prostatic enlargement when the real trouble is loss of vesical reflex, and the opposite is also true. Unconscious nocturnal enuresis may be the only indication of nocturnal epilepsy. A persistent frequency of the pulse in the absence of fever may be present in both the early and late stages of tabes. The visceral crises of this disease often lead to diagnostic errors. They are usually of sudden onset and intensely severe, but between their occurrence gastric symptoms are generally wanting.

Berliner klinische Wochenschrift, November 16, 1908.

Case of Brain Tumor with Operation and Recovery.—Oppenheim and Krause report a remarkable case of a fibrosarcoma of the dura pressing upon the first temporal convolution. The symptoms consisted of aphasia and amnesia, choked disks, differences in tone on percussion of the skull, and a paralysis in the region of the left facial nerve. There was no hemianopsia, and no other motor or sensory abnormal phenomena. Krause operated, after Oppenheim correctly diagnosed the site of the lesion, and removed a tumor the size of a small apple, the operation being performed in two stages. Gradial recession of symptoms and return of speech followed, though a sudden paralysis of the right upper extremity appeared. This soon disappeared, its cause being, according to Krause, edema of the brain substance because of the removal of pressure exerted by the tumor. The patient recovered very well, though a secondary operation was necessary because of necrosis of a small portion of brain tissue, which accounted for a persisting sinus; the latter closed soon after. Several months later a recurrence of the original symptoms with more extensive paralytic phenomena took place, and the patient was again operated upon. Another tumor was removed from the same spot, Krause explaining it not as a recurrence, but as a growth from a minute portion probably left during the first operation. The patient recovered after this second operation and has since been able to go about her household duties with ease; the speech defects, however, were not completely removed, though the improvement was still in progress at the time of the report. Krause adds that such tumors of the dura, though histologically sarcomata, are benign clinically; he had occasion to remove several of them from the spinal cord or the brain without observing recurrences.

Münchener medizinische Wochenschrift, November 10 and 17, 1908.

The Ophthalmoreaction.—Wolff-Eisner concludes his article as follows: The reactions to subcutaneous and cutaneous application of tuberculin are specific for tuberculosis; clinically, however, they must be used with care as positive results give evidence of latent as well as of active disease. Positive ophthalmoreaction shows the existence of active tuberculosis, and its appearance in those clinically well makes them very suspicious cases. Negative ophthalmoreaction in manifestly tuberculous patients is of bad prognosis; such reactions are more and more frequent with the progress of the disease.

Prophylaxis of Tuberculosis.—Harass says that the prophylactic measures in tuberculosis may be divided into general hygienic and specific prevention. Recently, the latter methods have been enriched by the conception of local predisposition to the disease and the management of persons thus predisposed. The most important site of such predisposition is the apex of the lungs, and recent work has shown that it depends upon defective ventilation of the pulmonary tissue because of deformity or premature ossification of the first rib. Such deformity may be congenital or may develop in connection with other serious conditions as, for instance, deformities of the spine. The prophylaxis in early life should consist of proper attention to respiration and the selection of gymnastic exercises aimed at influencing the insufficient expansion of the apices. In selected cases of later life operation may be successful in removing the obstruction to proper ventilation of the apices.

Anesthesia in Ophthalmology.—Messmer says that local anesthesia is best adapted for ophthalmological work. It allows cooperation of the patient with the operator, which is very important in operations like the one for strabismus. Vomiting and nausea are obviated, and there is no danger of dislocating the lens by any sudden movements during certain operations. The operative field is fully exposed because no mask is used. Cocaine hydrochloride is the best anesthetic; fresh solutions are to be made each time and the solution may be sterilized by boiling. Such boiling once just before use does not interfere with the anesthetizing properties of the drug. The strength to be used is 5 per cent. solution. Care should be taken that only the necessary amount of cocaine is used, as

otherwise untoward consequences, such as loss of corneal epithelium, intoxication with the drug, disturbances of accommodation and even glaucoma may follow. Messmer closes his paper by giving details of anesthetizing the eye for the different operations.

Rumination in a Human Being.—Bruegel reports a case of a man twenty-six years old who was in the habit of returning half-digested food from his stomach to the mouth ever since he was seven years old, repeating this process several times after each meal. This occurred for the first time ten to thirty minutes after the meal and at that time the taste of the food little differed from its original taste; as the food became more and more sour the desire for "chewing the cud" decreased and finally the morsel was allowed to stay in the stomach. The phenomenon was somewhat under the control of the will, so that the patient was little embarrassed by his affection when in company of others. Gastric analysis showed the absence of free hydrochloric acid; the esophagus was very sensitive and cocainization was required for the introduction of the tube. An examination with the fluoroscope showed spindle-like enlargement just above the cardia, appearing after the taking of food; the musculature of the esophagus was seen to contract distinctly, thus propelling the food into the stomach. The existence of an obstruction was concluded from this observation, but no further details could be learned, as the patient left the city soon afterward. Bruegel abstracts the literature of the subject.

Deutsche medizinische Wochenschrift, November 12, 1908.

A New Reflex.—Jacobson says that the upper extremity is not as rich in reflexes because it is more highly differentiated and therefore more under the influence of the will than the lower extremity. There is, however, one reflex which may be looked upon as the analogue of the Babinski phenomenon in the lower extremity. This reflex is quite a constant symptom in cases of spastic paralysis of the upper extremity of cerebral origin. The patient is asked to extend the fingers and to place the forearm with the palm directed upwards upon the hand of the examiner. If the lower end of the radius is now struck a smart blow by means of a percussion hammer, the fingers are seen to flex, the movement being especially prominent in the end phalanges, if the affection bears the above-named character. Otherwise, the fingers remain in the extended position.

Passive Hyperemia in Gynecology.—Seeligmann has constructed an apparatus consisting of a cylindrical glass speculum and a rubber ball which enables the physician to apply Bier's methods of suction hyperemia to gynecological cases. The application of this treatment has led to quicker results than with the older methods of therapy. The author has tried it in chronic metritis and endometritis, in amenorrhea, in parametritis, and in the affections of the uterine adnexa. Sometimes he combined the suction with scarification of the cervix and removal of some blood by the suction apparatus; this procedure proved especially valuable in postclimacteric disturbances if performed at the time when menses would have appeared before the climacterium. One case of puerperal fever was very favorably affected by the application of suction, a great deal of purulent secretion being removed out of the uterus in this fashion, the temperature falling after each application.

French and Italian Journals.

A Case of Chronic Hypertrophic Pyloric Stenosis in an Infant of Three Months.—G. Nové-Jesserand and M. Péhu describe an interesting case of pyloric stenosis, due to hypertrophy of the muscular fibers in an infant of three months, a condition which is extremely rare at that age. The infant was normal at birth, but after eight days of life it began to vomit its food, and continued to do so throughout its short life. A complete gastric intolerance was established, and toward the end more food was vomited than was ingested. The stools were few, irregular, and badly digested, but not diarrheral. The case resisted all treatment, gradually lost weight, and finally reached a condition of malnutrition which compelled the consideration of an operation. Shortly before this intermittent tension of the epigastrium was noted, and peristaltic waves in the stomach walls, with a pyloric tumor. An attempt was made to do a posterior gastroenterostomy. The infant died three days after the operation. The autopsy showed a marked hypertrophy of the muscular fibers, not forming a true tumor. There was inflammation of the wall of the stomach. It was intended to do a pyloroplasty, but the enlargement was so great as to render this operation impossible. The gastroenterostomy was easier, there was less shock, and more chance of recovery.—*Lyon Médical,* October 25, 1908.

Hydatid Cysts of the Lung.—Louis Moriquio has seen a number of cases of hydatid cysts of the lung in South America, where this disease is much more frequent than in this country. They occur in children from the country who are in constant contact with the dogs of the family. The diagnosis is easy if the cysts occur at the apex of the lung. There is complete dullness at the apex, absence of fremitus and respiratory sound, and bulging of the apex. There are generally no clinical symptoms. When there is a cyst at the lower part of the lung it is generally possible to detect an area below it in which the lung signs are normal. The contour of the thorax remains normal, but the heart is pushed to the right. There may be cough, expectoration, hemoptysis, and fever. In such cases pleurisy may be suspected. When there is no fever the good general condition of the child will be against a diagnosis of pleurisy or tuberculosis. The radiograph is very important as an aid to the diagnosis, showing a larger area of shadow than the physical signs show of consolidation. An exploratory puncture may be made, and is generally made, but it causes spasmodic cough with dyspnea, fever, and attacks of asphyxia. These are never fatal as far as the author's experience goes. The treatment of the condition should be surgical, as this course gives a definite cure after months of exposure to danger of infection and lung complications.—*Archives de Médecine des Enfants,* October, 1908.

Hebotomy or Symphyseotomy?—Cyrille Jeannin believes that we should always prefer hebotomy to symphyseotomy on account of its superior advantages to the patient. These are that it substitutes for an articular an osseous wound; its technique is easier and it is done in a less dangerous locality; immediate accidents are less frequent, and remote ones still more rare; the mortality of mother and fetus is less; in cases of a repeated intervention the operation may be done on the opposite side of the pelvis, which will lessen the difficulty, since the operator need not cut through cicatricial tissue. The final result in many cases is a permanent widening of the pelvis, due to the fact that the cicatrix is always fibrous instead of osseous.—*La Presse Médicale,* September, 1908.

Recurrences of Bronchopneumonia in Children; Their Relative Benignancy Shown by Statistics.—Guido Biagini has found that in children who have undergone intubation the attacks of pneumonia when repeated have been of less severity than a first attack, and believes that this is due to a certain immunity conferred by the earlier attack. This is not an anibacterial but an antitoxic immunity. In general a first attack of bronchopneumonia renders a child more susceptible to a second attack. The toxic products of the bacillus of diphtheria cause a multiplication of the pneumococci in the blood of adult guinea-pigs. Collecting all the intubated children treated since 1892 from the hospital at Florence, the author found 52 cases, of which eight had recurrent attacks of pneumonia, and of which the author gives histories. He then collected all the cases of bronchopneumonia, numbering 576, seen during that period, of which 113 had recurrent attacks. He found that the recurrences among these children were more fatal than among the intubated children.—*Rivista di Clinica Pediatrica,* October, 1908.

Action of Roentgenized Serum in Leucocytosis and in the Treatment of Leukemia.—Andrea D'Ambrosio finds that the serum of animals that have been submitted to the *x*-rays produces a lessening of leucocytes in an animal into which it is injected, whether it was subject or not to increased leucocytosis. The mononuclears are diminished in numbers, especially the lymphocytes, and the polynuclears are increased. This power is not diminished by low temperatures, but is destroyed by a temperature of 60°. Serum of nonroentgenized animals separated from the other constituents of the blood and roentgenized in a tube acquires no such property. This power continues for several days after the serum has been drawn. Repeated injections of this serum prolong its effect. A greater leucocytic power is caused by repeated applications of the rays. Clinical observations on man show that injection of serum from a healthy man who has been submitted to the rays causes marked leucolysis. With intravenous injections this is lost after twenty-four hours, but with hypodermic injections the condition is produced more slowly, but is more efficacious, lasts longer, and is progressive. This action is accompanied by a general improvement, increased elimination of uric acid by the kidneys, and reduction in the size of the spleen. Probably this serum contains specific antibodies produced by the stimulus of the *x*-rays upon the tissues, which cause all these good effects on the leukemic condition.—*Giornale Internazionale delle Scienze Mediche,* September 30, 1908.

Book Reviews.

Essentials of Refraction. By Thomas G. Atkinson, M.D., Author of "Applied Physiology"; Associate Professor of Physiology and Neurology, American College of Medicine and Surgery, Chicago; Professor of Physiology, Chicago College of Dentistry; Editor of the *Medical Standard*, etc. Chicago: G. P. Engelhard & Company, 1907.

This work belongs to the quasiscientific class. It is an attempt on the part of the author, who is himself inadequately informed in much that is essential concerning the subject of his writings, to furnish the so-called "refractionist," who may or may not be a medical man, with enough information to enable him to correct errors of refraction and to permit him to recognize disease of the eye sufficiently early to advise the patient to seek competent aid.

The volume is one of 235 pages, is well printed, and fairly well illustrated. The illustrations are original. The chapters that have to do with the physics of light and of optics, the properties of lenses, and the mechanical adjustment of glasses present these subjects briefly, in an elementary way, and sufficiently accurately, but the chapters which have to do with the practical correction of errors of refraction, diseases of the eye, muscular imbalance, asthenopia, and the hygiene of the eye are inadequate and often erroneous.

Spectacles and Eyeglasses. Their Forms, Mounting, and Proper Adjustment. By R. J. Phillips, M.D.; Ophthalmologist, Presbyterian Orphanage; Late Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine, etc. Fourth Edition, Revised. With Fifty-six Illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

Phillips' work is an excellent one. It gives a description of lenses, their mode of manufacture, the properties of various kinds of glass, the various styles of eyeglasses and spectacles, the proper methods of adjusting glasses, values of the prismatic effect of decentering lenses, prisms and their proper application, sets forth the errors that may attend the adjustment of glasses and the methods of remedying them, the importance of a correct understanding of the proper relation of cylindrical lenses to the eye, etc. The work is written by one who fully understands the subject. A mastery of the teachings of this little book will enable the optician to supplement satisfactorily the work of the oculist, or the oculist, if necessary, to perform the duties of the optician. The book should be in the possession of every oculist and optician.

The Principles and Practice of Gynecology. For Students and Practitioners. By E. C. Dudley, A.M., M.D.; ex-President of the American Gynecological Society; Professor of Gynecology, North-Western University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago; ex-President of the Chicago Gynecological Society, etc. Fifth Edition, Revised and Enlarged. With 431 Illustrations and 20 Full-page Plates in Colors and Monochrome. Philadelphia and New York: Lea & Febiger, 1908.

This fifth edition of Dudley's Gynecology follows closely on the same lines as its predecessors. There are two new chapters; one, an introductory chapter, which is a strenuous defense of the existence and plea for the recognition of gynecology as a distinct specialty, and a refutation of the plea of those who would merge, or submerge, gynecology in general surgery. This chapter is brief but forcible, and is admirably reinforced by the rest of the volume. The other new chapter is on the incontinence of urine in women. In this edition the text has been revised throughout, recent advances in the subject have been duly noted, and many parts have been rearranged and rewritten; but at the same time the author has condensed the text so that, in spite of the inclusion of a considerable amount of new matter, the size of the volume is about what it was before. The chapters which have been subjected to special changes and additions are those dealing with the treatment of the following subjects: Salpingitis, Ovaritis, and Pelvic Peritonitis; Myoma Uteri; Carcinoma Uteri; Descent of the Uterus; Retroversion and Retroflexion. The work remains, what it has been from the very first, one of the most sane and serviceable of the textbooks on gynecology; and as such it is heartily recommended both to students and to practitioners.

Hygiene for Nurses. By Isabel McIsaac. Author of "Primary Nursing Technique," Graduate of the Illinois Training School for Nurses, etc. New York: The Macmillan Company, 1908.

This book is a compilation from the writings of numerous authors on the subject of hygiene. Direct quotations are plentiful, and some of them are of considerable length, one extending through twenty-five pages. The subjects treated of in this volume are: Food, air, climate, ventilation, heating, lighting, soil, water, sewage, garbage, causes and dissemination of disease, personal hygiene, household hygiene, school hygiene, medical inspection of schools, hygiene of occupation, employment of women and children, disinfection, and quarantine. Most of the material here presented is well chosen, and will be of service to "the young pupil nurse" or "the first-year nurse," for whom this volume is apparently written; but pages on the duties of medical inspection of schools can hardly be considered necessary for this class of reader. The print and general get-up of the volume are excellent.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea & Febiger, 1908.

The current number of "Progressive Medicine" commences with W. Ewart's paper on "Diseases of the Thorax and Its Viscera, Including the Heart, Lungs, and Blood-vessels." About one-third of this article is taken up with the important subject of tuberculosis, and is both timely and valuable. W. S. Gottheil discusses the recent advances made in dermatology and syphilis, and several illustrations enhance the value of this contribution. The subject of obstetrics is dealt with by E. P. Davis, and the volume closes with W. G. Spiller's article on "Diseases of the Nervous System." As usual, the whole number is well worth reading and keeping for future reference.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S.; Late Lecturer on Anatomy at St. George's Hospital, London. New American Edition. Enlarged and Thoroughly Revised by J. Chalmers Da Costa, M.D., Professor of Surgery and Clinical Surgery, and Edward Anthony Spitzka, M.D., Professor of Anatomy in the Jefferson Medical College of Philadelphia. Imperial octavo, 1,625 pages, with 1,149 large and elaborate engravings. Philadelphia and New York: Lea & Febiger, 1908.

When this work was first published, half a century ago, it was seen to be so superior to any other anatomical treatise extant that it was at once accepted as the standard work on the subject in the English language, and many generations of students have been guided by it in their study of this foundation branch of medical knowledge. At the present day there is no dearth of anatomical treatises—indeed, there may be said to be a plethora of such works, and the student must be hard indeed to please who cannot find among so many one that will meet his requirements. Gray no longer holds the supremacy it did, though its successive editors have done their part well in keeping it abreast of its rivals. The present edition, the seventeenth, would hardly be recognized by the student of fifty or even thirty years ago, and we doubt whether he would be altogether pleased with its changed appearance. The illustrations are more artistic, it is true, and many are printed in colors, but somehow one misses the old woodcuts and feels that it isn't the old companion of his student days. It is an excellent work, indeed, but it is no longer *facile princeps*, and its increase in size is a decided drawback to its use as a dissection manual. This is perhaps unavoidable, but the book would be more useful to the student if it were issued in two volumes. The old familiar nomenclature is followed, though the BNA terms are usually given in parentheses.

A Manual of Diseases of the Nose and Throat. By Cornelius Godfrey Coakley, A.M., M.D., Professor of Laryngology in the University and Bellevue Hospital Medical College, New York, etc. Fourth Edition, revised and enlarged; illustrated with 126 engravings and 7 colored plates. New York and Philadelphia: Lea and Febiger, 1908.

Four editions of this work in a few years attest better than can anything else its true value. The literature of this special field of medicine is becoming overburdened, but Dr. Coakley has scored a distinct success in producing a manual of value for practitioner and student alike. In the present edition the main changes have been a fuller description of the technique of the radical operations for chronic diseases of the accessory sinuses and a new arrangement of the matter covering the general topic of deformities of the nasal septum. Under this heading the submucous resection operation is fully detailed. We know of no better volume to place in the student's hands than is this, and the practitioner will read it with profit.

Society Reports.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Eighteenth Annual Meeting, Held in New York City, September 22, 23, and 24, 1908.

HERBERT F. PITCHER OF HAVERHILL, MASS., PRESIDENT, IN THE CHAIR.

The Advancement of the American Electrotherapeutic Association.—Dr. HERBERT F. PITCHER of Haverhill, Mass., delivered this, the Presidential Address. After greeting the association, he said that this was a therapeutic society, the one missing link in the practice of medicine. All the other departments were making satisfactory progress, but when a remedy was sought the profession threw up its hands in despair. They could select a dozen drugs from the United States Pharmacopœia, and practise medicine as successfully as with the thousands of official remedies placed within its sacred pages. The world's most prominent and broad-minded physicians were to-day drug nihilists. He did not wish to be understood as saying that there was no place for drug therapy; but the physician of the future would use fewer drugs and more brains, his training would be more complete, his resources greater. He cautioned against neglecting that which was the stock in trade of the old-time physician, namely, observation. The very best that was in a man must go into his work. Ability, skill, and conscientious effort must not be grudgingly expended. The ultimate aim and duty of the true physician was to prevent disease and cure sickness. Their profession was the legitimate medium through which sanitation and prevention of disease were disseminated. They were not only physicians, they were teachers and philanthropists. Theirs was the only profession who freely gave away their own livelihood. Their incomes might not increase, but their glory as humanitarians would constantly grow brighter. Medical science to be useful must be practical. In becoming electrotherapeutists, they did not necessarily neglect any remedy true and tried. Electrotherapy was a progressive science, and they were as yet beginners in this great study. They should not expect to reach perfection. With a high conception of their profession he asked that they work with a will and the single purpose of elevating the practice of medicine to the science of medicine. This association was established eighteen years ago and was the first of its kind in existence. Until within a few years the membership of this association was limited to one hundred and fifty. At the present time they numbered only about two hundred members. With the splendid opportunity of this association for scientific research and advancement in electrotherapy, he said he could not understand the reason of this stagnation, unless they lacked ambition. Within a few years they should number a thousand members. A subject of the greatest importance to them and which should come up for discussion and be voted upon at once, was changing the association to a corporate body. They did not expect to be defendants in a suit for damages, but it was a wise saying, "In time of peace prepare for war," and they should realize that in the event of adverse litigation every member of this society would be personally liable for the full determined damages. This risk would be avoided by the simple procedure of forming a corporate body. In two years they would celebrate their 20th anniversary, and he said it was not too early to begin to prepare for the event. Investigation and research should be carried on in a scientific manner by all the members. Do not work for personal aggrandizement alone, but for the advancement of science. Give the association the benefit of their studies. Let every theory, however absurd it might appear at the present time, have the opportunity of vindication. Banish all feelings of avarice, prejudice, and jealousy, and he asked that their society become a brotherhood with the motto of "One for all and all for one."

Disruptive High Frequency Discharges, by the Reaction Method, as a New and Important Therapeutic Agent.—Dr. MORRIS W. BRINKMAN of New York read this paper. Since they were perfectly familiar with the fact that any degree of energy might be the source of a sensory impression, and that according to the degree would be the acuteness of the perception, so a tissue at variance with its normal sensory capacity might be hyperesthetic or again anesthetic. He wished to impress upon all contemplating the use of this method the importance of thoroughly controlling and measuring the current employed. The duration of the treatment was brief and was determined by a primary anemia which was perfectly obvious. The cessation of the treatment was followed by a congestion, depending for its vigor upon many conditions, which must present themselves at once to every careful operator. The electrodes must be exactly adapted to the location under treatment, and were invariably provided with an insulator, whose function was to insure the delivery of the spark at the desired point, from the sharp metallic end of the electrode. The metallic electrode should be so adjusted in its glass sheath that a definite spark length would be secured. He had rarely found a current greater than 600 watts necessary. The procedure was obviously valuable for all forms of localized pigmentation, sluggish ulcers, the obliteration of fine blood-vessels when heavily applied, superficial tubercular conditions, etc. The procedure might be applied to a great number of conditions of the mucous membranes. All forms of hypertrophied mucous membranes were instantly controlled by this form of administration. The use of the static spark in the past for somewhat similar conditions was known to every practical worker, but the efficacy was so small as to make it valueless for serious work of this kind.

The Static Brush Discharge Concentrated to a Blue Pencil Point.—Dr. FREDERIC DE KRAFT of New York read this paper. The brush discharge concentrated to a blue pencil flame when obtained from a static machine having sixteen to twenty revolving plates running at a fairly high rate of speed and applied to the bare skin of the patient, had been the means of securing some results in the writer's hand in cases where other measures had failed. This brush discharge might be described as a unidirectional high potential convective discharge and when obtained from the positive side of the machine was of a violet color, very rich in ultra-violet, violet and blue violet rays. Its action was attended with the formation of a great quantity of ozone and nitrous oxide. After describing the technique he said that repeated applications along the entire spine and over the abdomen increased peristalsis of the intestines, as was shown by freer and softer stools. Placing a metal plate in the bottom of the bowl containing a solution of starch and iodide of potassium, and approaching it with the grounded positive electrode, will be turn blue if the twenty plate was running at 500 revolutions per minute. This method of applying the brush discharge had served to alleviate the pain from ulcerated teeth in many instances after a ten-minute seance. They had seen a swollen cheek restored to its natural color in a few minutes. Sprained ankles and other joints had been speedily relieved of swelling and pain. Insomnia had yielded in a very few treatments. In constipation due to deficient secretion, and in those cases where an element of spasm of the muscular layer was present, good results had been obtained. Cases of neurasthenia had been helped, as well as severe cases of inflammation of the sciatic nerve following or due to gonorrhoea.

Roentgen-Ray Diagnosis of Bone Disease.—Dr. M. K. KASSABIAN of Philadelphia gave a lantern slide exhibition of the pathological conditions as they appeared in the radiogram in cases of periostitis, osteitis, tuberculosis, acromegaly, rickets, osteomalacia, epiphysitis, and osseous tumors.

X-Ray in Dental Examinations.—Dr. SINCLAIR

Tousey of New York read this paper and made an exhibition of lantern slides illustrating a number of the conditions determined by dental radiography and by the use of his dental fluoroscope. A radiograph would show whether the permanent teeth were present in the jaw or not. Abscesses were discovered and located. The radiograph would show the direction of the root canals and enable the dentist to afford an opening for the pus through the root canal in cases where the latter were difficult to locate or trace. The cause of facial neuralgia was sometimes discovered by an *x-ray* examination of the teeth. Root fillings might be examined. The condition of the alveolar process surrounding the roots of the teeth and extending up beyond them was an important subject for study. In cases of pyorrhea or Riggs' disease this process was sometimes found to be completely absorbed and very often the tooth was seen to lie in a large pocket produced by the absorption of the bony process around it. Supernumerary teeth might be revealed. The relation of the roots of the teeth to the antrum, and the presence of pus in the antrum, were subjects for study. Pulp stones or concretions in the nerve substance were sometimes found.

The Treatment of the Enlarged Prostate by the High Frequency Current.—Dr. M. M. Johnson of Hartford, Conn., said that Dr. Hunter of Norfolk, Va., brought the Roentgen ray to the foreground as a treatment of this condition, on account of its well-established atrophying power on glandular tissue. There was no doubt that this ray was potent in absorbing glandular tissues, but the difficulty lay in concentrating the rays on the prostate. The patient was placed in the Sims position in using high frequency. It was not necessary to insulate the couch. Snow's vacuum rectal tube was lubricated and passed into the rectum and firmly placed against the prostate, and held there by the operator, who raised and lowered the handle of the tube holder, moving the electrode over the entire surface of the prostate gland. The tube holder was connected with the resonator by a single wire. The strength of the current was indicated by the spark gap. The patient was not conscious of the least discomfort. Of the twelve cases treated, six were senile hypertrophy and six were in men under forty-five years of age, and who were suffering from nervous breakdown. The humane feature of the treatment was so marked; there was no ether, no vomiting, no nervous shock, no tedious convalescence, no loss of valuable time, and no death. It was ideal.

Treatment of Varicose Veins and Varicose Ulcers by the Static Wave Current.—Dr. H. Finkelpearl of Pittsburg, Penn., briefly reviewed the etiology and morbid anatomy of these conditions as well as the treatment. He reported three cases, treated by the static wave current with good results.

The Treatment of Arteriosclerosis and Hypertension.—Dr. William Benham Snow of New York read this paper. Hypertension, or arterial tension above the recognized normal range, was noted to precede the structural changes, and a study of averages showed that with advancing years the changes became more marked and resisting to treatment. Hypertension might be either compensatory or contributing. The conditions necessary to a condition of hypertension were one or more of the following: (1)Resistance in the circulatory channels; (2) increase in the quantity of the circulating fluid; (3) increased heart force. The contributory causes of hypertension arose from toxic or pathological processes in the organism, and were generally associated with intestinal infection or the inception of irritants or chemical poisons. Excessive indulgence in stimulating foods, condiments, alcoholic beverages, together with the products of faulty metabolism, and intestinal infection, played a great rôle in the induction of hypertension. A study of many cases of arterial tension with and without organic change in the structure of the arterioles and large glands through which most or all of the blood must pass, presented a variety of clinical pictures as to prognosis and response to treatment by physical measures, which affected to reduce arterial tension, the results depending upon the extent of pathological change present in the circulatory apparatus and dietetic régime adopted, as shown by comparisons made by the sphygmomanometer. Dr. Snow believed that there was probably no field of investigation which offered more to humanity than the setting forth of the importance of the regulation of habit and diet, balancing the demands of exercise to the quality and quantity of food taken. The intelligent management of these cases would not only include the regulation of the diet, but the employment of such means as would further the reestablishment with maintenance of normal results.

Physiotherapy in the Practice of Medicine.—Dr. William D McFee of Haverhill, Mass., believed that in order to get the best results, they should have many modalties at their command, and choose from these the one particularly indicated and adapted to fight the symptoms of disease; otherwise they would have many failures. Combined methods of treating many of the diseases should be employed.

Electricity in Errors of Refraction.—Dr. Samuel J. Harris of Boston, Mass., read this paper. He said that after an exhaustive study of this subject, based on the study of over five hundred cases, he believed the amelioration of sight by massage might be divided into three groups: (1) Mechanical action as regards the zonule and the crystalline lens. (2) Tonic action upon the ciliary muscle and the accommodation. (3) Trophic action (circulatory, secretory, and excretory) upon all the intraocular tissues and liquids, ciliary glands choriocapillaries, retina, etc. His conclusions were that the persistent elongation of the zonule was so much easier to obtain the younger the subject and the less the accommodation had been exercised (amblyopic eye). That by massage hypermetropia might be considerably diminished often so much as to do without glasses. The younger the subject, the better the results. That visual acuity was sometimes so improved that an eye suffering from amblyopia exanopsia as the result of high hypermetropia might become serviceable for work. That some squinting eyes might thus recover sight enough for stabismus to be cured with the secovery of binocular vision. That different accommodative asthenopias were also susceptible to great improvement, and many cured. That some presbyopias might postpone the wearing of glasses, as in vision near by without the short sight diminishing in any way, that it was the acuteness of vision only that improved. That in progressive myopia in young subjects whose defects augmented 3 to 5 D, they could arrest the increase. That astigmatism was amenable to treatment by massage once the proper apparatus was perfected. He believed then from the study of his cases that a large number of persons, especially children now wearing glasses, could by this treatment carried out by an ophthalmic surgeon and an expert, be relieved of wearing glasses, and others could be so much benefited that glasses could be worn of from one-third to one-half the strength of those previously worn. He believed that electricity in its various forms was one of the greatest additions to the therapeutic armamentarium of the ophthalmologist, and in the future must become his greatest ally.

Catarrhal Deafness and Its Treatment.—Dr. Albert C. Geyser of New York stated that the changes or deviations which took place in catarrhal deafness were as follows: The Eustachian tube was closed, preventing the entrance of air and the hindering of drainage. The membrana tympani was forced inward by the external air pressure, and held there and prevented from vibrating. The ossicles were crowded together with more or less inflammatory changes in their articulations, and their free movement was hindered and no vibration reached the perceptive apparatus. Assuming that the nasopharynx had been properly cleansed, the hihg-frequency current from a glass vacuum electrode delivered to the entire mucous membrane of the nose was probably the best stimulating

measure. An aseptic or antiseptic spray should be used. An attempt should then be made to force air into the Eustachian tube. To break up the fibrous ankylosis that existed between the membrana tympani and the articulations of the chain of ossicles, a pump was used capable of alternating between a suction and compression stroke; this pump was attached to an Otis auroscope. The pump should be so adjusted that the suction stroke only was used.

Tuberculosis and Its Treatment.—Dr. J. D. Gibson of Denver, Colo., said he wished to affirm more than he had ever before the great usefulness of physical modalities as adjuvants in the treatment of pulmonary tuberculosis. In addition to the ordinary treatment of the disease, he had added the *x*-ray, electricity, and ozone. He used the *x*-ray to produce a hyperemia, local congestion or engorgement of the tissues treated. This congestion prepared them for the next step in the process, the inhibition and destruction of the bacilli. Electricity was used by him only for its tonic properties. The static high-tension currents, as the brush discharge and wave currents, were the ones he generally used. Ozonized nebula was a much prized agent as an aid to expectoration, giving relief to the cough.

Possibilities of Radiant Light.—Dr. T. D. Crothers of Hartford, Conn., read this paper Every year the new realm of so-called physical therapeutic measures had become more and more prominent, and in connection with drugs their efforts were most promising. The radiant light bath and concentrated radiant light had attracted his attention. These were agents of great and largely unknown power. The question of the value of light in such conditions as rheumatism, acute and chronic inflammations, neuritis, cirrhosis, and so-called malaria was one of great difficulty and depended very largely upon the accuracy of the diagnosis. In a general way, if the principal derangement was nutritional disturbance and starvation, the light had a variable effect. If the main difficulty was in the circulatory apparatus, its value was more pronounced. In toxemic conditions with congestion and defective circulation, it had a marked action, and in the psychic and functional disturbances, its effects were both startling and disappointing. His conclusions had been, that only from a general clinical study could any reliable estimation be made of the value of light in therapeutics, and this must be made by comparisons and combinations with other measures.

Observations Upon the Employment of the Caldwell Cavity Tube as a Surface Electrode.—Dr. Charles Rea Dickson of Toronto, Canada, believed that we possessed in the Caldwell tube a most useful adjuvant, and that when employed as a low-frequency high-potential vacuum electrode for treatment of lesions on the surface of the body it was a very valuable implement in their armamentarium. The effects produced by the form of procedure he described in detail, were briefly those of a combined *x*-ray, blue-violet, and ultraviolet rays, low-frequency, high-potential static charge, and spark. They thus had the mild irritant and ionizing effects of the *x*-ray and ultraviolet, the sedative action of the violet rays, the markedly tonic effect of low frequency with its relief of congestion and stasis and liberation of ozone and nitrous acid with their oxidizing, ozoning, and antiseptic properties, aided by the germicidal action of the ultraviolet, and lastly the pronounced stimulating action of the static charge and sparks on tissue metabolism.

The Physiological Action and Therapeutic Effect of Vacuum-Tube Discharges.—Dr. John H. Burch of Syracuse, N. Y., made a summary of the physiological effects of vacuum-tube discharges as follows: (1) The more refrangible light frequencies, emanating from the fluorescing tube itself; (2) the chemical effects of nascent ozone; (3) the effects of ionization; (4) heat; (5) mechanical vibratory effects; (6) germicidal effects; (7) the effects of the electrostatic charge itself. Vacuum-tube discharges seemed to be indicated in nearly all conditions depending upon local congestion and stasis. Perhaps no field offered more brilliant opportunities for the employment of vacuum-tube discharges than dermatology.

Anterior Poliomyelitis.—Dr. Henry W. Frauenthal of New York presented some brief records, with photographs, of cases that had shown some unusual manifestations resulting from the epidemic of 1907.

Report of Some Cases of Electrochemical Minor Surgery.—Dr. Edward S. Smith reported three cases, one of fecal fistula following an appendectomy, one of tumor of the cheek of unknown pathology, and another of cervical abscess, treated electrochemically with wonderful success.

The Correction of Flat-Foot.—Dr. Herbert McIntosh of Boston, Mass., read this paper which he illustrated with lantern slides. The indications for curing a flat-foot were (1) to reestablish the injured arch and (2) to restore the ligaments and muscles to their normal conditions. Each muscle that supported the arch should be stimulated. Stimulating vibration should be applied to the plantar fasciæ and the calcaneoastragaloid ligament. The remedy for pain, congestion, heat sweating, and other vasomotor phenomena was the static wave current. Complete rest was essential. The most important factor in the treatment was proper shoeing, and a shoe to be fit should have several characteristics. 1. It should afford perfect freedom of motion. 2. It should permit the toes to exert their prehensile action as nature had taught them to do. 3. It should give the great toe freedom to rise when the foot was thrown forward before the metatarsophalangeal articulations finally touched the ground. 4. It should permit the toes to spread out when they touched the ground. 5. The instep should be amply high so as to permit the foot to arch. 6. It should not bind the leg above the ankle. 7. It should have a flexible shank. 8. To preserve to the foot when covered with a shoe the power to balance and involuntary shifting of lines of weight, it was necessary to supply a modified heel. 9. Shoes should be made with low heels. 10. The floor of the shoe under the metatarsal bones and phalanges should be flat. 11. The shoe should permit a close approximation of the anterior end to the ground. 12. An inner sole should be provided running back to the shank and capable of being loosely attached in front over a fixed point and free at its posterior end.

Electricity in the Relief of Pain.—Dr. F. Howard Humfris of Honolulu, Hawaii, presented this paper. In electricity we had an agent which afforded instant relief in the majority of cases of pain and from its mode of action tended to remove the cause. Electricity was not palliative but was curative. It removed stasis aided metabolism and restored the physiological function which was painless to the pathological painful structure. The different modes of electricity from which they had to choose for the relief of pain were the direct current, the induced current, the static modalities, the sinusoidal, magnetic currents, the various high frequency currents, phototherapy, and perhaps the vibrator since it was driven by an electric motor. The secret of success lay in the choice of the appropriate modality. Unfortunately they had as yet no laws to guide them as to what modality was best suited to each condition. For most of the neuralgias a mild constant current would often succeed where most remedies failed. Static electricity filled an important place as an agent in the relief of pain. The five hundred candle power light had a truly remarkable action in the relief of pain. The use of the *x*-ray for the same purpose was well known to all. When the pain was generalized the radiant light baths, with 1,000 candlepower was very useful. The patient should not be allowed to suffer unnecessary pain when an agent existed which would relieve it, as electricity.

The General Practitioner His Own Radiographer.—Dr. E. Gard Edwards of La Junta, Colo., urged the ad-

vantages of radiography in all cases of fracture and wounds by foreign bodies remaining *in situ* as well as in many obscure diseased conditions. He cited many instances to point out the desirability of all physicians procuring proper apparatus for the work who were not in a position to have such work conveniently done for them.

The Five-Hundred-Candlepower Incandescent Lamp. Dr. S. T. Birdsall of Glens Falls, N. Y., reported a case of chronic cystitis which was relieved of all the previously distressing symptoms by two exposures of the lower abdomen to the five hundred (500) candle power lamp after failure to benefit the patient by irrigations and by use of the Morton wave current with vacuum electrode in the vagina.

So-called Chronic Rheumatism, or Septic Arthritis.—Dr. J. W. Torbett of Marlin, Texas, found many cases of chronic joint inflammation which had yielded to general treatment only after treating an existing urethral stricture. He believed that in all cases of chronic joint inflammation one should examine the various mucous membranes for points of irritation where might occur retention of secretion, putrefaction, and absorption of toxins. Such origin of joint inflammation might be in the urethra ,prostate, uterus, tubes, colon, intestines, gall-bladder nose, or tonsils.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 5, 1908.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Surgery and was devoted to a symposium on the surgery of the biliary passages.

Surgery of the Bile Passages, with Special Reference to End Results.—Dr. John C. Munro of Boston read this paper. In reporting the after results of operations upon the biliary passages he utilized all except recent cases that had come under his care during the last five years; there were somewhat over 300 operations and the end results were known in 198, including the fatal cases. Of the known results 122 patients were reported as being well and entirely free from symptoms referable to the biliary passages. He had lost track of 106, but he thought it was safe to count on a good result in a large majority of these, judging from the nature of the original lesion and the operation employed. Jaundice was present in 90 cases of recovery, absent in 57, and not recorded in 46. It varied in degree from slight to profound. In the 90 in which it was present, 63 were cases of simple gall-bladder stone, while in 43 cases of this type it was noted as absent. This proportion was quite different from that published by others. Fourteen common-duct cases had jaundice and three did not. In three cases of pancreatitis, for which the gall-bladder was drained, jaundice had been present, and in two it had been absent. In the operations for infection of the gall-bladder or the ducts without stone, he found a history of the presence of jaundice in seven, and its absence in seven. He found two cases with jaundice operated upon for symptoms produced by adhesions alone. In analyzing the 46 cases of recovery, where no note was made as to the presence or absence of jaundice, he found that 19 were primarily operated on for some gross lesion elsewhere, such as uterine fibroid, ulcer of the stomach or duodenum, umbilical hernia, etc. The biliary lesion in these cases was discovered accidentally in the routine examination. The duration of the symptoms in the recovery cases might be divided into two general classes, those of short duration (one year or under), and those of long duration (over one year). In the former were 48 cases with an average of four months; five more had symptoms of only a few days' duration. In the longer duration cases there were 111 averaging six years, besides nine in which the duration was of an indefinite number of years. Among the fatal cases the shorter group averaged six months in 12 cases; while the longer group averaged nine years in 14 cases, the longest being 16, 19, and 25 years respectively. The condition of the pancreas was noted as being pathological in 27 cases. He believed that a swollen, indurated pancreas could be differentiated with a fair degree of accuracy from the normal gland. The existence of adhesions had an important bearing on the question of the value of medical treatment in gall-stone patients, and he found that in 127 cases they were noted as being present, while in only 22 was there a note of their nonexistence. Among the postoperative calamities he always dreaded complications occurring in the lungs or bronchi. Three in over 200 cases of recovery had a typical pneumonia; one patient had an acute edema of the lungs; one had a bronchitis following a phlebitis; another was a septic case, while 10 complained of a slight cough that gave no anxiety. When the gall-bladder was functionless as a result of either stricture, impacted stone, acute or chronic infection of the visceral walls, or conditions, he removed it if the condition of the patient warranted. If the gall-bladder was functionating, or if, temporarily out of commission, there seemed a reasonable chance that it would reestablish itself with drainage, he had been content to drain. He found, therefore, in the patients reporting themselves as "well" that drainage had been employed four times as frequently as extirpation. Taking the recovery cases that he had been unable to trace, he drained a little less than three times as often as he removed the gall-bladder. Taking all the recovery cases, he had performed cholecystotomy in 125, cholecystectomy in 35, and choledochostomy in 26 cases. The patients that reported a recurrence of symptoms were divided into several distinct classes: (1) Those in whom the symptoms were probably not due to the presence of stones but to some unrecognized lesion. (2) Those in whom the symptoms were secondary to adhesions following the removal of stones, or the drainage of infected passages. (3) Those in whom stones had been left behind at a previous operation. (4) Those in whom new stones had formed. Including the cases that had come after operation by other surgeons, there were 10 in which stones had been overlooked. These patients either had a biliary fistula that refused to close, or persistent return of the symptoms for which the first operation was undertaken. In every instance but one the overlooked stone was in the gall-bladder or cystic duct. The only reason for overlooking these stones seemed to be a lack of thoroughness at the first operation. That stones might form anew in the gall-bladder was possible, but extremely rare. Cases of death from so-called toxemia, or cessation of the hepatic functions, and from capillary hemorrhage, were the most appalling that fell to the surgeon's lot. In the first class he had lost six cases. The patients did not die of shock, but they died with a high pulse and temperature, dilirium, stupor, and apparent cessation of the hepatic function. On Dr. Leary's suggestion he gave 30 c.c. of rabbit's serum subcutaneously in those cases in which hemorrhage was expected; in almost all the cases there was no tendency to hemorrhage. Dr. Leary had reported the earlier cases in a communication to the Massachusetts Medical Society in June, 1908, and gave the reasons for and methods of securing the fresh serum. Nearly a year had elapsed since the speaker had used the serum for this purpose without a sign of bleeding in jaundiced or purpuric patients, and he felt that there must be some value in the method. In conclusion Dr. Munro said that (1) an analysis of his cases demonstrated that jaundice was present in a majority of all, even the simple gall-bladder cases, at some time. A very large majority of common duct cases had jaundice. (2) The pancreas was not infrequently pathological, as determined by an examination of the opened abdomen. (3) Adhesions were present in a large majority of the cases, and might be the di-

rect cause of the symptoms, rendering all medical treatment worse than futile. (4) Pulmonary complications must be reckoned with in prognosis, but they had been less frequent than anticipated. (5) Cholecystostomy was normally a more suitable operation than cholecystectomy unless the gall-bladder was definitely functionless. (6) Recurrence of symptoms might be due to adhesions or a contracted gall-bladder as well as to overlooked stones. (7) Toxemic cases were best treated medically until the acute stage was passed. (8) Fatal capillary hemorrhage might be controlled to an extent not yet determined by the use of fresh animal serum.

Treatment of Biliary Disease as Determined at the Operation.—Dr. Howard Lilienthal read this paper. He said that embarrassment due to the surprises of abdominal section became less frequent with experience. It was always well to obtain permission for any necessary procedure rather than be too certain as to the exact nature of a contemplated operation. The stomach contents should always be examined before operation upon the bile passages. When symptoms pointed to the gall-bladder, and that viscus was found apparently normal at operation, no disease of other organs being discovered, he said it was best to do a cholecystectomy. The gall-bladder might be found completely embedded in the liver. Thick-walled gall-bladders were liable to cancerous degeneration. When there was a suppurative pericholecystitis the gall-bladder should not be removed primarily. In cases of profound sepsis, with or without jaundice, he advised a quick cholecystostomy, and a radical operation should be done later, thus dividing the work into two stages. The pancreas and the pyloric region should always be examined. In speaking of the technique, he said that one should, first, avoid as far as possible gauze packings. They damaged the peritoneum, rendering it more susceptible to infection, and they also caused adhesions. Secondly, the common duct might be reached more easily, after the gall-bladder had been removed, by drawing the stump of the cystic duct into view by means of traction sutures. Thirdly, these tractors were useful in finding the bleeding place in recurrent hemorrhage.

Cholecystectomy Versus Cholecystotomy.—Dr. John F. Erdmann read this paper. In an article published in 1906 he wrote that the indications for cholecystectomy were as follows: Perforations by trauma, ulceration other than that due to abscess or gangrene, obliteration or stricture of the cystic duct, chronic cholecystitis with thickened walls, atrophy, gangrene, acute suppuration, enlargement of dilatation (these latter being usually due to either calculous obstructions, strictures, or angulations of the gall-bladder), marked adhesions, hour-glass contractions, chronic or recurring cholecystitis, cholelithiasis, and malignancy. The contraindications were: Apparently healthy bladder in cholelithiasis and pericholecystitis, perforation into other viscera when the difficulty of closure of the connection was great, perforations in the suppurative variety when adhesions were extensive, and when life would be jeopardized by such radical interference, malignancy when extensive, and those cases in which hurried operation was indicated to save life. While adhering to those views in the main, Dr. Erdmann said that he was not so radical now and considered his cases more closely before performing cholecystectomy. The reason for this change was the distinctly surgical one of convenience: occasionally one must do a secondary operation upon the common duct, either for an overlooked stone or for a stone that had been concealed or formed in the liver and which had come down, necessitating a choledochotomy, or leaving the patient a chronic invalid in case the stone did not pass. When such secondary operation was called for, one had lost, in the absence of the bladder, the anatomical landmark to the duct. The question of cholecystectomy and cholecystotomy very naturally arose chiefly in the cases of acute cholecystitis, and in a certain percentage only of chronic gall-bladder cases, where upon opening the abdomen the gall-bladder was found atrophied or contracted, thickened, with or without calcareous degeneration, and when the cystic duct had become occluded, resulting in a hydrops of the gall-bladder. In cases of malignancy the question arose as to whether one should do cholecystectomy or close the abdomen without interference. In the acute cases, where the patient's condition demanded a rapid operation, and the bladder was gangrenous, a few minutes more of operative procedure would justify a cholecystectomy: the danger of infection, sloughing, and hemorrhage was removed with a smaller risk by operation than was taken by leaving the diseased viscus. Should the condition be grave, and only a thickened gall-bladder with infection be present, the removal of the bladder contents only was done; this latter step included necessary cystic and common duct work if called for. Where no great consideration of time and shock arose he did a cholecystectomy if the bladder wall was friable, very thick, or the bladder markedly elongated and thick, with patches of gangrene or grayish white sloughs. Evidence of calcareous degeneration in an acute cholecystitis also called for a cholecystectomy. Acute cholecystitis in cases of old contracted gall-bladders demanded cholecystectomy, as they were simply smoldering foci for repeated attacks, and a cholecystotomy in those cases was of no more than temporary benefit. Where the gall-bladder was acutely inflamed and the bladder distended, the walls not over thick or infiltrated, with no mucous membrane destruction by gangrene or ulceration, he said he was now prone to drain. Ulceration perforations of the gall-bladder should have the radical operation done instead of attempts at closure. Finesse of judgment as to the procedure in cases of malignancy could be obtained only by experience. In twenty-six cholecystectomies, out of a hundred and four operative cases of all kinds one case was recorded of death due to malignancy. There were fifty-three cholecystectomies, with three deaths. Excluding the malignancies in both operative procedures and a case of multiple abscesses, in all of which death was inevitable, he had a record of twenty-five cholecystotomies with no deaths and fifty-one cholecystectomies with one death, or less than 2 per cent. These fifty-one cases included associated appendectomies, subphrenic abscesses, two pregnancies, and one post-partum hemorrhage in the second week, making a decidedly complicated set of operations. There was one case of cholecystotomy with choledochotomy, with recovery. There were twenty cholecystectomies with choledochotomies, with five deaths. Choledochotomy was done in four cases, with no deaths. This series of cases, therefore, by excluding three malignancies and one of multiple hepatic abscess, consisted of one hundred cases operated upon, with seven deaths, none of which occurred in twenty-five cholecystotomies, and only one in fifty-one cholecystectomies. A summary of the cases of cholecystotomy and cholecystectomy with those in which additional work was done would show that out of the hundred considered, excluding the malignancies and the one of multiple abscess of the liver, cholecystotomy was done twenty-five times, cholecystotomy with choledochotomy once, making twenty-six cases without a death. Cholecystectomy was done fifty-one times with one death, and cholecystectomy with choledochotomy nineteen times with four deaths, a total of seventy case with five deaths.

Dr. Joseph A. Blake said that one found with experience that there were many difficulties to be en-

countered in operations upon the biliary passages. He was particularly interested in what was said regarding the use of rabbit's serum in arresting hemorrhage. In the badly suppurating cases, a cholecystotomy should be done rather than a cholecystectomy; in many cases the lesion was so walled off by adhesions that cholecystotomy was a very easy operation, and could be done under local anesthesia. Later the gall-bladder could be removed if it was deemed necessary. Many of these gall-bladders would recover if simply drained. For drainage purposes the rubber dam carried down acted well.

Dr. Lucius W. Hotchkiss said that the cigarette drain or the simple rubber dam drain acted effectually.

Dr. Alexander B. Johnson said that during recent years his own experience with gall-bladder disease had been quite large, and he favored the removal of the gall-bladder in nearly all the serious cases. Quite a number of cases came to him during the last few years of acute cholecystitis, some very severe cases, some gangrenous, and some with a complicating stone in the gall-bladder, which obstructed the cystic duct, and these cases had been operated on by other surgeons, who did a cholecystotomy. The subsequent removal of the gall-bladder which became necessary was exceedingly difficult. He had seen a number of fistulæ follow drainage of the gall-bladder. Among thirty cases of cholecystectomy done during the past three years, fistula followed in only one instance, the bile discharging for more than a year. This patient returned to the hospital and was again operated on.

Dr. George E. Brewer said that the statement made by Dr. Munro that sixty-three cases of simple gall-bladder stone were accompanied by jaundice was somewhat contrary to the usual experience; when the stones were limited to the gall-bladder, jaundice was exceedingly rare. All recognized the seriousness of carcinoma of the gall-bladder; even in the early stages carcinoma was a fatal disease. There was one condition which might simulate gall-bladder disease, namely, syphilis of the liver, and it was sometimes almost impossible to differentiate the two. This was a point that should always be considered.

Dr. Willy Meyer asked whether they should drain or extirpate in cases of gall-bladder stones. These stones readily reformed and, therefore, he believed that surgery should be thorough. If the gall-bladder contained mucus and not bile, it should be removed.

Dr. Ellsworth Eliot believed that where the cystic duct was so seriously damaged that subsequent deformity might incapacitate the gall-bladder, cholecystectomy was the best operation to perform. The value of any operative procedure was to be judged by the results obtained.

Dr. Munro said that when the gall-bladder was functionating it was not removed; if it was not able to resume its function, it was taken out.

Dr. Lilienthal believed that in simple gallstone disease, with no infection and no thickening of the walls, cholecystotomy should be the operation of choice except in exceptional cases. The gall-bladder should be removed in all cases where there was serious inflammation.

Stated Meeting, Held November 19, 1908.

The President, Dr. John A. Wyeth, in the Chair.

Medical Service in a Modern Army in War, as Exemplified by the Japanese Army in the Russo-Japanese War.—Major Charles Lynch, Surgeon, U. S. A., late representative of the Medical Department of the United States Army in Manchuria, gave this discourse. He expressed his gratification in finding that the members of the Academy of Medicine had sufficient interest in military matters to desire that an officer of the army should discuss the army medical service with them. He said that his service had comprised the last ten months of the war, nearly all of which was spent at the front in Manchuria with the Second Japanese Army Corps. After giving a brief general description of the war and the geography of Manchuria, whose climate was cold and dry in winter, hot in summer, and had two months of heavy rainfall with almost impassable roads, he referred to the wonderful success of the Japanese and said that this success was nowhere more notable than in their medical department. The Spanish-American and South African wars had shown America and Great Britain lamentably weak so far as their army medical departments were concerned. It was his purpose to tell the reasons which enabled the Japanese to accomplish such noteworthy results. The discussion of any army medical department naturally fell under three general headings: (1) Organization; (2) sanitation; (3) professional care of ill and injured. Administration and organization were placed first because no matter how good medical talent was in the possession of a country it would not be available to the army if it could not be properly distributed and used. First, the medical department must be sufficient in numbers to perform the work required of it. This was one point where Great Britain and America had failed. The Japanese found that they required 1 per cent. of medical officers and 9 per cent. of inferior medical personnel to the total fighting force. The Japanese claimed that all medical officers in war should have had army service in peace, and they were much dissatisfied with the civilian surgeons whom they commissioned for temporary war service, this notwithstanding each of these men were given four months medico-military training before going into the field. He did not consider it necessary that our army should have enough medical officers in the regular army to perform the work in a serious war; there were many posts in a war army that could be well filled by civilian practitioners. If one-fourth of our medical officers in war were trained surgeons of the regular establishment we would be in a fairly safe position. To maintain a less number than this invited disaster. The plan of maintaining only enough medical officers to care for the sick and wounded in time of peace was one which a nation desirous of efficient medical service in war should never tolerate. The Japanese recognized that the quality of their medical officers was quite as important as the quantity. The inducements that they offered were sufficient to secure a good class of men. Russia was far inferior to Japan in this respect. The medical officers of the Japanese army had the highest possible ideal of patriotism while the Russian doctors hardly felt themselves a part of the army. If this country wished to attract the highest class of medical men to the army medical service it was apparent that the inducements to enter the army must be increased, as the present possible rewards in civil life were much greater than they were some years ago. The Japanese medical department had complete autonomy and the Russian did not. Certain duties were required of the Japanese medical department, and it was held responsible for them without let or hindrance. In the Russian Army the responsibility was so divided between the army medical department and the Red Cross that it was a wonder that the results were as good as they were, and at times they were very bad. Our organization was much nearer the Japanese than the Russian, but Major Lynch feared that war would show that our medical department should have absolute control of its own transportation and should supply ambulances and all sanitary apparatus.

In battle, aid to the wounded was given in various stages from front to rear. First was regimental aid on the firing line and at the temporary dressing station, then the dressing station, the field hospitals, the transport department for patients, the stationary hospitals, the line of communication hospitals, the hospital ships, the receiving hospital

at home, hospital trains, rest stations, and reserve hospitals with convalescent camps. This was the Japanese organization, and it varied little from that of other nations which had given serious consideration to the organization of a medical department. While the stream of wounded constantly ran to the rear and ended at home, medical supplies took the contrary direction. He showed how all these organizations worked in connection with the battle of Mukden, which was the greatest battle of which we had record. Various scenes of the battle were illustrated by stereopticon views, as well as the manner of caring for the wounded at the front, of collecting them, and of taking them to the temporary dressing station behind the firing line. Even here they were exposed to artillery firing and it was becoming increasingly difficult to perform medical service in the field owing to the increase in the range of small arms and artillery. Little professional care was given the wounded at the dressing stations, though emergency operations were sometimes performed. On the field of battle transportation could be provided only for those absolutely requiring it. All others had to walk. In the field hospitals only emergency operations were performed because it was necessary to hurry the wounded to the rear as fast as possible to make room for others; time was not available, nor was it possible to make preparations for clean work. Each field hospital was supplied with an *x*-ray apparatus, but it was seldom used at the front. The stationary hospitals were three times as large as the field hospitals and were intended to replace the latter or to receive patients from them. The communication hospitals received the wounded from the stationary hospitals. In showing the illustrations of the field medical supply, Major Lynch called attention to the size of the boxes; there were none larger than could be easily handled by two men.

Although the work of the medical department was extremely complicated during a great battle, as could be seen from this brief description, the Japanese had practically all the wounded on their side under shelter within twelve hours. This was the maximum time. This achievement was simply marvelous considering the duration of the battle of Mukden, which lasted from March 26 to April 10. If any link in the long chain broke or even weakened disaster would have almost inevitably followed. The Japanese used no hospital trains in Manchuria, as they did not have the necessary rolling stock, and if they had possessed it they could not have permitted it to interfere with the supply of their troops; so they resorted to ordinary cars returning from the front. The Japanese were able to have trains for sick and wounded at all times with the necessary attendance. The Russians had some fine hospital trains, so that a man might be very comfortably transported, but there were so few of these trains that the Russian patients were put on trains returning from the front often without any provision being made for food or attendance. This was quite characteristic of the difference between the medical service of the two countries. Japan always provided adequate, though sometimes rough, means for the care of ill and injured, while Russia rejoiced in overabundance at one place and entire lack of everything at another. During the war Japan operated twenty hospital ships, two of which belonged to the Red Cross of Japan. In peace these ships were in commercial service, with the proviso that the company operating them would turn them over to the Red Cross, equipped for hospital use within one week after being notified to do so. It was the policy of Japan to send all injured and ill requiring it to their division districts as soon as possible. Some of the wards in the temporary hospitals were built and ready for patients within 48 hours of the receipt of notification that they would be needed. At one time Hiroshima had excellent accommodations for 22,000 patients. The Japanese provided accommodation for about 70,000 patients in their home hospitals, and for 10,000 convalescents in their convalescent camps. These camps showed a wealth of good care on the part of the Japanese so far as the soldiers were concerned, and the Russians received equally good care at the hospital for prisoners of war at Matsuyama.

In discussing sanitation, Major Lynch said that it was generally known that in all wars, except the Franco-Prussian on the German side, the deaths from disease had greatly exceeded those from wounds. In the past there might have been some justification for this, but fuller knowledge had proved of no benefit to the United States in the Spanish-American War, where, had the need arisen, we could not have put 50 per cent. of the men mobilized into the field against the enemy. The Japanese had made use of present day knowledge regarding sanitation, and in consequence protected their army better from the inroads of disease than had any other nation up to the present time. In the field the Japanese reported one death from wounds to 0.47 of one death from disease. He was of the opinion that these figures were substantially correct. Russian statistics were valueless, but from observation and conversation with Russian surgeons he was quite sure that the Russian loss from disease was at least twice as great as this. The Japanese had not more than one-third as many men constantly ineffective from sickness as their enemy. While the Japanese attained notable success in preventing diseases of known causation or methods of spread, they failed with beriberi. National sentiment had been a great factor in the matter of sanitation. A soldier who returned home suffering from a preventable disease was made to realize by his family and friends that he had been a credit neither to his country nor to them. This was a powerful factor in making soldiers observe sanitary instructions. In Japan a commander whose force suffered from disease to an unwarrantable degree was likely to be called upon for an explanation. A Japanese officer might disregard the advice of his medical officer on sanitary questions just as he might in this country, but in practice he did not do so, as he appreciated how much good hygiene meant to his command. So far as he knew all the high commanders in the Japanese service were not only willing, but anxious, to gain the benefits that would accrue to their troops from the advice of experts on the subject of sanitation. The medical department of the Japanese army pronounced upon the physical fitness of officers and soldiers entering the service, educated them in sanitary matters, supervised their sanitation during the course of their service, and determined when they were no longer fit for active duty. The physical standard maintained was a very high one. The Japanese soldier was not conscripted until he was 20 years of age, which was, in the speaker's opinion, a great benefit. In all the officers' schools almost one-half the time was devoted to physical training. During the whole course of each man's service he was kept in good physical condition by hard drills with much running exercise, and physical contests were encouraged among the men. A pamphlet entitled, "Health Memoranda for the Use of Soldiers in Time of War," prepared by the medical department was issued to the soldiers, but more dependence was placed upon the personal teaching of the surgeons. Frequent sanitary inspections were made by medical officers of all grades in the Japanese service and by these means sanitary faults could not escape detection, and could be corrected before great harm resulted. These inspections were extended to include the inhabitants of the country as well as the troops. A monthly physical examination was made of all Japanese troops which was of value as a means not only of weeding out the unfit, but also of detecting communicable disease. The clothing and equipment of the Japanese soldier were excellent, with the exception of his shoes, and in these some improvement had been made. He carried about 58 pounds, which was too much for any soldier, though the Japanese did not seem to be distressed by it.

No army in a long campaign had been so well supplied

with food as were the Japanese in the Russo-Japanese war. Even during the battle of Mukden the men were almost universally well-fed. The standard established for the soldier's daily allowance of food was 2,580 calories. Four times monthly the surgeons weighed the food as it was served to a few men at table and the number of calories was calculated; if the food was found insufficient the authorities were notified in what respect the ration should be increased. Practically all the water used by the Japanese in the field was sterilized by one method or another, and the speaker was convinced that the United States would have to adopt this principle if its army was not to suffer from water-borne diseases to an unwarranted extent. The Japanese medical department analyzed the water supplies of the troops, but this was only for the purpose of selecting the best; the water was sterilized no matter what the result of the analysis. Boiling was the method of sterilization relied upon to the exclusion of all others whenever it was applicable. Boiling stations were established on the lines of communication. At halts the large kettles used in the preparation of rice were used. During battles the men boiled water in their own water bottles. During the war a water cart was constructed which contained about 60 liters and was a boiler as well as a cart. The fire box was large, which permitted of the water being brought to the boiling point in a very short time. In the field, latrines were invariably pits and their contents were well covered with earth or ashes. The habits of the Japanese soldier were good. Drunkenness was almost unknown. Successful efforts were made to prevent the soldiers from cohabiting with Chinese women unless they were regularly licensed. Love of country and love of family were used to effect this remarkable result. The soldiers had their hot baths every day, and even at the front they rarely missed a day. Both quarantine and disinfection were carried out thoroughly in the army; quarantine stations were established through which returning soldiers had to pass. The Japanese regarded typhoid fever and dysentery as contagious diseases and isolated them as carefully as they did smallpox. This, the speaker believed, was absolutely necessary in an army where the opportunities for contact infection were so numerous. The Japanese clearly recognized the possibility of infection by flies. The only way flies could be prevented from having access to the food was by serving it immediately before it was to be eaten. After being washed the dishes were covered to protect them from flies, and mosquito netting was used to screen all hospitals for contagious diseases, even those well up toward the front. In the field creosote pills were issued to the soldiers in little tin boxes upon which was written: "To defeat the Russians take one three times daily." It was believed that the medical department had made an error in the administration of this intestinal antiseptic, nevertheless the Japanese had only about one case of typhoid fever and dysentery to the Russians six. Typhus fever, though quite common in Manchuria, was rare in the army. It was treated like other contagious diseases. Tuberculosis was not commonly seen in the army; cases were promptly discovered and sent home for discharge. Smallpox was rare. Diphtheria, scarlet fever, mumps and measles occurred only in isolated cases. Whenever we mustered in an army we had hundreds of cases of mumps and measles. Major Lynch thought the Japanese population suffered so generally from these diseases in childhood that all men entering the army were made practically immune by previous attacks. Beriberi proved a terrible scourge to the Japanese army, probably from 40 to 50 per cent. of all diseases resulted from it. In peace 14 per cent. of the army had beriberi, according to the Japanese report; in the Chinese-Japanese war this percentage rose to 18, and in the Russo-Japanese war it reached 16 per cent. His experience with the disease, which had been fairly large, led him to see no reason why beriberi should be regarded as a dietetic disease, and he felt convinced that careful isolation of cases and the proper methods of disinfection could be depended upon to prevent its spread. An increase in the proteids in the diet of the soldiers did not diminish beriberi. He ascribed the great increase of this disease during war to the overcrowding in the barracks, which gave every opportunity for infection from man to man.

It was safe to say that the lesson taught by Japan would be taken to heart, and that within a few years all great armies would require instruction in hygiene of their entire personnel. The United States now has a school for instruction in hygiene at West Point. In regard to the professional care of the sick and wounded, Major Lynch said that the Japanese could teach us nothing on the practice of medicine and surgery. Japan was a young country so far as the scientific study of medicine was concerned, and there was need of good native teachers; the foreign instructors had not kept up in the advances of their profession. The Russian medical department had many poor practitioners and some good surgeons. The Japanese, however, returned a large percentage of sick and wounded men to the ranks. Neither Russians nor Japanese benefited to the greatest possible extent from the first aid packet. It seemed to the speaker that if we desired to profit by the experience of the Japanese we should recognize that we must have a strong force of medical officers in the regular establishment and the only way to attain this result was to create public interest and sentiment. He thought further, that as physicians and citizens, the profession should endeavor to create public opinion. So far as sanitation was concerned we labored under greater difficulties than the Japanese because of the absence of good teaching of personal hygiene to the individual officers in peace. In order to reach the results that the Japanese had attained it was necessary that there should be good instruction in personal hygiene in the schools. This would greatly benefit the public in times of peace. A great deal had already been done in our army, and to-day our military forces were in a state of transition which was gradually approaching a logical organization. The bill to increase the efficiency of the medical department of the army had been passed and attention could be directed to progress in other directions. A Medical Reserve Corps had been created. The American National Red Cross was also making progress.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 26, 1908.

DR. J. RIDDLE GOFFE IN THE CHAIR.

Want to Discontinue the Medical Directory of New York, New Jersey, and Connecticut.—Dr. C. G. COAKLEY read a letter received from the Genesee County Medical Society inviting other county medical societies of this State to instruct its delegates to the coming meeting of the Medical Society of the State of New York to move for a discontinuance of the publication of the medical directory of New York, New Jersey, and Connecticut. It was claimed that four other county societies of this State wished the same action. It was moved, seconded, and carried unanimously that the Medical Society of the County of New York vote for a continuance of this directory and that the Secretary send a copy of this resolution to all the county medical societies of the State asking them to take similar action.

Nominations.—The nominations of officers, censors, and delegates to be elected at the one hundred and third annual meeting, to be held November 23, 1908, were made.

The scientific session was devoted to a symposium on opsonic therapy.

Opsonins, Opsonic Index, and Immunity.—Dr. EUGENE L. OPIE of the Rockefeller Institute for Medical Research reviewed the fundamental facts regarding the relationship of opsonins to immunity. The power of various

cells, particularly leucocytes, to take into their substance bacteria and other organisms had long been recognized as one of the most important factors in the protection of the animal body from infection. The discovery in the serum of the blood of substances capable of destroying and dissolving bacteria had furnished evidence that bacteria might be overcome without the intervention of phagocytes. A comparatively recent discovery had shown that both serum and cells had an essential part in phagocytosis. Wright showed that the number of bacteria which a phagocyte could devour in a given time might be counted under the microscope, and he showed that the leucocytes of the blood were unable to take up bacteria unless the blood serum was present; the normal blood serum contained something which made phagocytosis possible. This body acted by attaching itself to the bacteria. This body in the serum Wright called opsonin. According to Wright, the leucocytes were ready to take up as many bacteria as the serum could prepare for them. To measure the activity of phagocytosis it was necessary to measure the ability of the serum to prepare microorganisms, in other words, to measure the opsonins. These substances were not susceptible of absolute measurement, but by comparing the serum to be tested with that of one or more normal individuals, it was possible to assume how many times its opsonic strength was greater or less than normal. This relative strength had been termed the opsonic index. A low opsonic index indicated that an individual was particularly susceptible to infection by the organism with which the index had been tested. Increase of opsonins in the blood indicated in general terms that the power to resist infection was increased. The opsonic index measured with a fair degree of accuracy the power of the blood serum to promote phagocytosis; but the majority of observers in this country at least had reached the conclusion by comparative tests that the opsonic index was subject to great inaccuracy. There was evidence that immunization with the tubercle bacillus or its products was accompanied by increase of the opsonic power of the blood serum. With localized infectious lesions, such as abscesses, suppurating sinuses, and various forms of tuberculosis limited to a joint, lymphatic glands, or other well-defined locality, the opsonic index had been often found less than normal. It had been assumed that bacterial products were not absorbed in sufficient quantity to set in motion the mechanism of immunity; the injection of killed cultures of bacteria was recommended for the purpose of stimulating the formation of opsonins.

The Treatment of Erysipelas by Bacterial Vaccine.—Dr. George W. Ross of Toronto, Canada, read this paper. His belief was firm from a study of fifty cases of erysipelas, that a vaccine prepared from the *Streptococcus erysipelatis* and properly administered, exercised a specific and controlling influence upon the course of the disease, preventing its spread, lessening its severity, and hastening recovery. The reason for this belief he briefly summarized under two main heads: First, from the standpoint of immunity. The opsonic power of the blood was low during the acute process of the disease and when more or less rapid spread was manifested; again, the subsidence of such symptoms as malaise, mental unrest or apathy, pain and tenderness, and the localization of the inflammatory area were closely associated with an increased immunity as evidenced by a rise of opsonic power. He was prone to attach great importance to these considerations of immunity because he had frequently observed parallel series of events in therapeutic inoculations with bacterial vaccines in many cases of boils, septic hands, tuberculosis of the glands, bladder, etc., and in many other cases of localized bacterial infections. Second, from the standpoint of clinical observation of the course of the disease as apparently influenced by inoculation with their vaccines. Whatever surface might be involved subsequent to inoculation manifested a less severe form of inflammatory process; the mental unrest and physical discomfort were rapidly controlled; the pyrexia seemed to subside more rapidly and long-continued pyrexia had not been met with; the complications and sequelæ seemed to be much less common. He said he would, therefore, submit the evidence adduced in this communication was sufficient to justify the use of a vaccine prepared from *Streptococcus erysipelatos* in the treatment of erysipelas, particularly as there was no recognized remedy for this disease.

The Opsonic Index in Pulmonary Tuberculosis.—Drs. Gerald Bertram Webb and William Whitridge Williams of Colorado Springs, Colo., presented this communication. Their general conclusions as to the value of the opsonic index in pulmonary tuberculosis were as follows: (1) The technique was sufficiently accurate; (2) they found it of very little value in guiding their doses of tuberculin, although their aim had been to keep the index above normal; (3) they regarded fluctuations as almost positive evidence of the presence of tuberculous activity; (4) they thought it of great value in the study of autoinculations, believing it in such cases to be a guide as to the amount of exercise patients should be allowed; (5) they did not believe that the opsonic index by any means told them the whole degree of immunity of their patients to tuberculosis; (6) they believed that complete arrest of pulmonary tuberculosis could only be registered by absence of fluctuation in the opsonic index following exercise.

The Use of "Vaccines" in Gonococcus and Streptococcus Infections.—Dr. Nathaniel Bowditch Potter of New York read this paper, illustrating with lantern slides. The following figures were offered which were of interest. Of the noninoculated cases there were 58 that were surgical and medical, with six recoveries, a percentage of 11 (Libman); 47 medical cases, with eight recoveries, a percentage of 17 (Lenhertz); 28 surgical cases, with 19 recoveries, a percentage of 689 (Bertelsman). Of the inoculated cases there were 30 both medical and surgical, with 14 recoveries, a percentage of 47 (Potter).

Dr. Norman E. Ditman said that the opsonin served the purpose in directing attention to vaccine therapy. The opsonic index measured but one form of immunity, and was of value when done in hundreds and when the average of these was obtained. The value of the opsonins at the present time was largely in the field of research; while that of vaccines was in practical therapeutics.

Dr. C. G. Coakley told of his work in chronic suppurations of the nasal accessory sinuses, the vaccines being obtained from cultures isolated from each individual patient. Thirteen patients were under treatment for a period of four months, and but one was cured; the other cases made no improvement.

Dr. William H. Park said that those in the Health Department were still studying the vaccines, and as yet their opinions might change from week to week and from month to month. He did not know the relative importance of the vaccines; he did not think one could tell the relative importance in any one disease of opsonic substances and other substances. They did not seem to show any quantitative relationship. Wright had convinced many men of the value of vaccines and had caused them to study them more carefully and thoroughly. All were coming to see that they could not in individual cases rely upon the index; in individual cases it was a mistake to have indices.

Heart Disease.—In cases of heart disease we should investigate first the symptoms afforded by the attitude of the patient in bed, by the color of the lips and cheeks, by the pulse, by the jugular veins, or by dropsy, before proceeding to physical examination. For this reason books written before the discovery of auscultation (such as the treatise of Corvisart) are worth reading, if only to show how much the physicians of that day could find out apart from the help of physical signs. Symptoms, and not physical signs, guide our prognosis and treatment.—*Gee's Aphorisms.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DISEASES OF THE EYE. By M. STEPHEN MAYOU, F.R.C.S. 12mo, 388 pages; cloth; illustrated. Oxford University Press, American Branch, New York.

LEHRBUCH DER SPEZIFISCHEN DIAGNOSTIK UND THERAPIE DER TUBERKULOSE. Von Dr. BANDELIER und Dr. ROEPKE. 4to, 177 pages; paper; illustrated; bound, 7 marks; unbound, 6 marks. Curt Kabitzsch (A. Stuber's Verlag), Würzburg.

ARZTLICHE BEREDSAMKEIT. Von Dr. Med. HENRY HUGHES. 8vo, 59 pages; paper; $1.00. Curt Kabitzsch (A. Stuber's Verlag), Würzburg.

INDIANA STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION, 1907. 8vo, 315 pages; cloth; illustrated. William B. Burford.

A MANUAL OF BACTERIOLOGY. By HERBERT U. WILLIAMS, M.D. 8vo, 466 pages; cloth; illustrated; $2.00. P. Blakiston's Son & Co., Philadelphia.

STATISTIQUE DES PERSONNES ATTEINTES DE CANCER. By le Dr. JULES DOLLINGER. 4to, 167 pages; cloth; illustrated Imprimerie da la Société Anonyme, Atheneum.

PROGRESSIVE MEDICINE. Edited by HOBART AMORY HARE, M.D. 8vo, 293 pages; paper; illustrated; $6.00 per annum. Lea & Febiger, Philadelphia.

CONTRIBUTIONS TO THE PHYSIOLOGICAL THEORY OF TUBERCULOSIS. By CHARLES CREIGHTON, M.D. 4to, 242 pages; cloth; illustrated; 12/6 net. Williams & Norgate, London, England.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Edited By W. D. HAGGARD. 8vo, 570 pages; cloth; illustrated. Published by the Association.

A TEXTBOOK OF HUMAN PHYSIOLOGY. By GEO. V. N. DEARBORN, A.M. (Harv.), Ph.D., M.D. (Col.). 8vo, 550 pages; cloth; illustrated. Lea & Febiger, Philadelphia.

HYGIENE FOR NURSES. By ISABEL MCISAAC. 12mo, 208 pages; cloth; illustrated; $1.25 net. The Macmillan Company, New York.

NEUROLOGICAL AND MENTAL DIAGNOSIS. By L. PIERCE CLARK, M.D. 12mo, 188 pages; cloth; illustrated. The Macmillan Company, New York.

CHIRURGIE FÜR ZAHNÄRZTE. Von Prof. Dr. Med. LUDWIG BRANDT. 4to, 458 pages; paper; illustrated; $1.25 net. Verlag von August Hirschwald, Berlin, Germany.

HAY-FEVER, HAY-ASTHMA. By WILLIAM LLOYD. 8vo, 101 pages; cloth; illustrated. Henry J. Glaisher, London, England.

THE PRINCIPLES AND PRACTICE OF GYNECOLOGY. By E. C. DUDLEY, A.M., M.D. 8vo, 806 pages; cloth; illustrated. Lea & Febiger, Philadelphia.

TEXTBOOK OF PHYSIOLOGICAL CHEMISTRY IN THIRTY LECTURES. By EMIL ABDERHALDEN. 8vo, 722 pages; muslin. John Wiley & Sons, New York.

MANUAL OF PSYCHIATRY. By J. ROGUES DE FURSAC, M.D. 8vo, 406 pages; muslin. John Wiley & Sons, New York.

SANATORIA FOR CONSUMPTION AND CERTAIN OTHER ASPECTS OF THE TUBERCULOSIS QUESTION; Supplement in Continuation of the Report of the Medical Officer for 1905-06 to the Thirty-fifth Annual Report of the Local Government Board, 1905-06. 8vo, 670 pages; paper; illustrated; 5/. Darling & Son, London (Compliments of D. Bulstrode, London).

CHRONISCHER MAGENKATARRH. By Dr. FRIEDRICH CRAMER. 8vo, 176 pages; paper; illustrated. J. F. Lehmanns, Munchen.

THE STRUGGLE AGAINST TUBERCULOSIS IN SWEDEN. Edited by STURE CARLSSON, M.D. 4to, 201 pages; illustrated; paper. Central Press, Stockholm.

DISEASES OF THE SPINAL CORD. By R. T. WILLIAMSON, M.D. (Lond.), F.R.C.P. 8vo, 432 pages; illustrated; cloth. Oxford University Press, New York.

GLANDULAR ENLARGEMENT AND OTHER DISEASES OF THE LYMPHATIC SYSTEM. By ARTHUR EDMUNDS, M.B., M.S., B.Sc., Lon., F.R.C.S., Eng. 12mo, 230 pages; cloth; illustrated. Oxford University Press, New York,

THE LAW IN GENERAL MEDICAL PRACTICE. By STANLEY B. ATKINSON, M.A., M.B., B.Sc. 12mo, 240 pages; cloth. Oxford University Press, New York.

FOURTH ANNUAL REPORT OF THE HENRY PHIPPS INSTITUTE FOR THE STUDY, TREATMENT, AND PREVENTION OF TUBERCULOSIS. 4to; paper. Edited by JOSEPH WALSH, Henry Phipps Institute.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 5, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	574	153
Diphtheria	385	39
Measles	271	10
Scarlet Fever	221	7
Smallpox	—	—
Varicella	179	—
Typhoid Fever	77	11
Whooping Cough	37	1
Cerebrospinal Meningitis	5	1
Malarial Fever	—	—
Totals	1749	222

Medical Students in Germany.—The numbers of medical students in German universities during the summer course of 1907 were as follows: Munich, 1,248; Berlin, 876; Freiburg, 645; Leipzig, 498; Würzburg, 449; Heidelberg, 397; Kiel, 340; Marburg, 291; Bonn, 277; Breslau, 277; Jena, 275; Tübingen, 242; Strassburg, 233; Königsberg, 216; Halle, 210; Greifswald, 201; Erlangen, 199; Göttingen, 176; Giessen, 173; Rostock, 122. Total, 7,345.

Prognosis in Phthisis.—"Never give a definite opinion as to how long a patient suffering from phthisis will live; for the only certainty is that, if you do, you will be wrong." (Gee.)

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, for the week ending December 4, 1908:

SMALLPOX—UNITED STATES.

		Cases.	Deaths.
California, San Francisco	Nov.' 7–14	8	..
Kansas, Topeka	Nov.' 7–14	7	..
Ohio, Cincinnati	Nov.'13–20	2	..
Tennessee, Nashville	Nov.'14–21	1	..
Texas, Encinal	Oct. 22–Nov.'26	49	..
Washington, Spokane	Oct. 7–14	1	..
Tacoma	Oct. 24–Nov.'1	4	..

SMALLPOX—INSULAR.

Philippine Islands, Manila	Oct. 3–10	4	..
Algeria, Algiers	Oct. 1–31	..	22
Arabia, Aden	Oct. 19–Nov.'2	..	19
Brazil, Bahia	Sept. 1–30	174	6
Canada, Halifax	Nov.' 7–14	4	..
Victoria	Nov.' 7–14	1	..
Ceylon, Colombo	Oct. 3–17	56	11
Egypt, Cairo	Oct. 21–28	7	1
France, Paris	Oct. 24–Nov.'7	4	..
India, Bombay	Oct. 20–27	..	2
Calcutta	Sept. 26–Oct. 10	..	3
Italy, General	Nov. 1–8	4	..
Naples	Nov. 1–8	12	..
Russia, Odessa	Sept. 26–Oct. 3	2	..
Warsaw	Oct. 10–17	..	5
Spain, Barcelona	Oct. 31–Nov. 7	..	2
Turkey, Constantinople	Nov. 1–8	..	7

YELLOW FEVER.

Brazil, Bahia	Sept. 1–30	..	1
Para	Oct.' 17–24	3	3
Martinique, Fort de France	Oct. 24–31	1	..
Mexico, Campeche	Nov. 7–14	1	..

THE PROGNOSIS AND TREATMENT OF THE DEEP LESIONS OF THE EYE, ASSOCIATED WITH GOUT, WITH SPECIAL REFERENCE TO SECONDARY ACUTE GLAUCOMA.*

BY CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

DURING the past year the writer has seen an unusually large number of cases, illustrating grave lesions of the retina and chorioid, associated with chronic gout, and it has seemed to him worth while to put on record some of these cases by bringing them before the members of the Practitioners' Society. These cases are by no means of common occurrence, but they seem to be increasing in frequency, and the lesions are so destructive of vision that the patients need the best skill and widest knowledge which can only come from the combined efforts of the family physician and the ophthalmologist.

The patients were all markedly gouty, were all well past middle life, and were all victims of the modern, ultrastrenuous life. In the treatment and management of these cases I was greatly assisted by the family physician, with his wider knowledge of the patient's general condition.

None of the cases of intraocular inflammation occurred simultaneously with an acute arthritic attack, but they always followed an intestinal attack, and in all of them the urinalysis showed a marked excess of uric acid, and a high percentage of indican. This would seem to prove that the general toxemia resulting from faulty metabolism is of intestinal origin, and due to fermentative processes.

The excess of uric acid present in an acute inflammatory attack of gout acts not only as a toxic agent, but also as a mechanical irritant upon the tissues. The protective cells of the body are not powerful enough to neutralize the excess of uric acid or prevent its partial absorption, and the combined toxic and irritant agent is carried into the general circulation, and may set up an inflammatory process in any part of the body. All these patients showed the well-known cardiovascular changes met with in chronic lithemia, which were well marked in the vessels of the retina and chorioid. It is a recognized fact that the continued perversion of function of any part leads to structural change. Compensatory growth has its limit, and in the altered condition of the vessels, arteriofibrosis constitutes the compensatory stage, while arteriosclerosis forms the secondary process of degeneration.

A close study of many of these cases of retinitis, chorioiditis, and secondary acute glaucoma will show that the strain of increased blood-pressure causes hypertrophy of the muscular tissue of the tunica media. The increased blood-pressure is the cause of both fibrosis and sclerosis, the latter being a degenerative process. This condition once established, time and the question of relative weakness will determine when and where the vessel-wall will yield to dilatation and rupture. Of course high arterial tension does not always mean a fully developed arteriosclerosis, for at first the results are simply functional. The occurrence of the outbreak in the eye simply represents the extension of the diseased arterial condition in one special direction.

The influence of increased blood pressure on the functions of the eye may be recognized by a loss of accommodation, transient blurring of the vision due to a diminished, intermittent blood-current, or to retinal edema; sudden impairment of vision from retinal or vitreous hemorrhage. All these are conditions of recognized toxic origin. But in all these cases, gout is not the direct cause of the vascular lesions. The diseased products of faulty metabolism are the cause of both the arterial degeneration and the gout.

An abnormally high blood-pressure is much more frequently met with in modern life than formerly. It is significant of the modern strenuous life, with its impaired metabolism, its imperfect elimination of the toxic products of metabolism, and the resulting toxemia.

These deep lesions of the retina, chorioid, and sometimes of the iris, are of grave importance, and leave lasting traces behind them in impaired vision, enfeebled or abolished function, and a tendency to degeneration and atrophy. The hemorrhages from the vessels point to the gradual degeneration of the entire vascular system, and any considerable change in the intraocular tension will give rise to hemorrhages into the retina, chorioid or vitreous humor. They may occur in one or both eyes, may be single or multiple, and may be scattered all over the fundus. A recurrence of these hemorrhages under any sudden emotional excitement, or following great physical or mental fatigue, is too often followed by the development of a secondary acute glaucoma, with its intense pain requiring immediate operative interference, with disastrous results as to vision.

It is an interesting fact that this arterial degeneration seems to be distinctly hereditary in certain families, and here the evidence of arteriosclerosis in the retinal vessels is often the first symptom of the hereditary condition, and has been seen in comparatively early life.

We also find a similar condition in the retinal veins, which is often more marked than the change in the arteries. This soon leads to edema of the retina, which is one of the constant symptoms of the early stages of the retinal disease. This edema disappears if the circulation becomes reestablished in the obstructed vessels. This phlebosclerosis is more frequently encountered in the eyes of patients who are the subjects of chronic atypical gout, than

*Read before the Practitioners' Society, November 6, 1908.

in the typical inflammatory form of the disease, and in these cases the diagnosis as to cause and effect is not always easy. The cases of acute inflammatory retinitis naturally come more frequently under the observation of the ophthalmologist, and are, of course, of a much more serious nature, because of the seroplastic exudation, and the recurring retinal and vitreous hemorrhages. The latter I have come to regard as almost pathognomonic of lithemia.

The fundus changes in these cases are retinal edema, patches of yellowish exudation, retinal and vitreous hemorrhages, and a blurring of the outline of the optic disc. The retinal arteries are diminished in calibre, and the white lines along the vessels can be distinctly traced well towards the periphery. The veins show fusiform dilatations. When vitreous opacities are present, they are either the remains of previous hemorrhages, or an evidence of coexisting chorioiditis. These changes are almost always bilateral, though they are rarely symmetrical. In the cases of chronic atypical gout, the degenerative changes in the walls of the vessels are at first very slight, and often overlooked. The hemorrhages occur in the early stage of the disease; but when the walls of the retinal vessels become thickened by deposit, they become stronger, and under ordinary conditions of everyday life, hemorrhages are less likely to occur. There is marked impairment of central vision, which is progressive up to a certain point, but never ends in blindness unless acute glaucoma supervenes.

The microscopic examination of the retina in all these cases confirms the existence of the extensive angiosclerosis, but a full description of the pathological changes would occupy too much time. It suffices to say that such an examination proves the existence of the three factors involved in the process, viz: the shortening of the tunica media, the compensatory endarteritis, and the atrophy of the muscular coat.

The great danger in these cases of retinitis or chorioretinitis is the development of an acute glaucoma. The high blood-pressure with its increased vascular tension tends at once to increase the intraocular tension beyond the normal limits and well within the danger-zone. If this occurs in a hypermetropic or very astigmatic eye, with its shallow interior chamber, the almost inevitable result is a more or less complete obstruction of the channels of filtration, ending in acute glaucoma, with its severe pain, paralysis of the sphincter iridis, engorgement of the deep episcleral vessels, cloudy cornea, and loss of vision.

In the presence of such a complication, our first impulse is to advise the immediate performance of the classical operation of iridectomy. The operation, when properly done, relieves the increased tension, stops the severe pain, and arrests the progress of the symptom-complex known as acute glaucoma. But in these cases of chorioretinitis with exudation and hemorrhages, the sudden lowering of the intraocular tension by the iridectomy almost invariably causes a sudden profuse hemorrhage into the vitreous, which again raises the tension above the normal, causes a return of the severe pain, which cannot be controlled, and ultimately necessitates the enucleation of the eyeball to relieve suffering. Moreover the operation of iridectomy is very painful in acute glaucoma and requires the employment of general anesthesia. These patients with their extensive cardiovascular changes, generally accompanied by cardiac hypertrophy and enfeebled heart action, are not fit subjects for general anesthesia, because of the danger of death during the use of the anesthetic.

It should be fully recognized that an iridectomy should never be done in acute glaucoma, which has been preceded or accompanied by retinal or vitreous hemorrhages, and where the extensive cardiovascular disease makes general anesthesia dangerous to the life of the patient. We have other means at our disposal for allaying the pain, reducing the tension, and arresting the inflammatory process, even if the eye remains permanently blind.

The treatment and management of these cases must vary with the age and general condition of the patient, the nature of the lesion, and the severity of the type. The habits of life must be regulated, of course modified in strictness by the patient's condition and environment. It must be largely dietetic, based on accurate knowledge of the patient's digestive capabilities. The administration of drugs, except to combat certain symptoms as they arise, is of secondary importance. The daily life of the patient should be rendered as quiet as possible, and there should be great moderation in eating and drinking. As an abundant meat-diet raises the blood-pressure, the amount of meat eaten should be curtailed. A certain definite amount of systematic exercise should be insisted upon, preferably in the open air, because it increases oxidation, improves the capillary circulation, and thus aids in the process of elimination. If the patient has been addicted to the use of alcohol in moderation, it is not wise to absolutely interdict its use, but it should be taken largely diluted. Alcohol does dilate the peripheral blood-vessels, but does not increase the blood-pressure to any appreciable extent. The use of tobacco should be forbidden or reduced to a minimum, as it contracts the blood-vessels and raises the blood-pressure. Water should be taken freely between meals in order to aid elimination. The products of faulty metabolism which induce hypertension only cause the toxic effects while they are circulating in the blood. The uric acid group are eliminated largely through the kidneys, and experience has taught us that the best renal eliminants are the salts of lithia, soda, and potash.

To reduce the high blood-pressure, I employ sodium nitrite as a vasodilator, but I always combine with it some reliable heart tonic. I have made it a rule, in this class of cases, to have a thorough examination made of the heart and general circulation, before prescribing any cardiac drugs. We should be especially cautious in administering any of the vasodilator drugs. A rapid, irregular or intermittent pulse, with a rapid pulse rhythm, and with a systolic murmur, probably indicate a cardiac inadequacy with high blood pressure, and in such a condition cardiac stimulants should be combined with vasodilator drugs. Experience teaches us that a high blood-pressure does not necessarily mean the need of the prompt administration of drugs, for nature often maintains a cardiac integrity in spite of the circulatory resistance, and the apparently urgent symptoms yield gradually without the use of drugs to reduce the pressure. If the blood-pressure be over 200 mm. of mercury, the vasodilator should be slowly administered, and its effect on the blood-pressure, the pulse rate, and the sensations of the patient carefully noted. I believe that the subjective sensations of the patient are a better means of judging of the effect produced than the blood pressure or the pulse rate. The administration of a full dose at once may cause very serious consequences to the patient's heart.

The local treatment of these deep-seated ocular lesions is of great importance. An exudative retinitis or chorioretinitis, with or without hemorrhages, occurring in patients of forty years of age

or over, has a tendency to increase the intraocular tension, aside from the increased intravascular tension. As a result the subjective symptoms are impaired central vision, a sense of tension at times amounting to dull pain, and more or less intolerance of light. It is not safe to use atropine for the purpose of putting the accommodation at rest because of its tendency to increase the intraocular tension and aid in the development of glaucoma. Pilocarpine in a half per cent. or one per cent. solution should be used, as it contracts the pupil, draws the iris away from the angle of the anterior chamber, and lowers the intraocular tension. The light should be modified by wearing smoked glasses, but not darker than tint No. 3.

Should hemorrhages into the retina or vitreous occur, the danger of an outbreak of acute glaucoma becomes greater, and the pilocarpine must be used more frequently and in a stronger solution. All use of the eyes must be forbidden, and the patient must be kept as quiet as possible. The danger of the development of acute glaucoma in these cases is always present, and any sudden mental or physical shock may bring it on. This is markedly so in highly hypermatropic or astigmatic eyes, for here the anterior chamber is shallow, and the angle of the anterior chamber is narrow. The onset of the glaucoma is usually sudden, starting with an acute lancinating pain in the ciliary region, which extends upwards on the forehead and inwards towards the nose, accompanied by engorgement of the deep ciliary and episcleral vessels, dilatation of the pupil, rapid diminution of vision, and marked increased intraocular tension, due to closure of the channel of filtration through Schlemm's canal by the increased pressure. The pain is very severe and resists the administration even of strong opiates.

In the uncomplicated acute glaucoma, unaccompanied by retinitis, chorioiditis, or intraocular hemorrhages, the classical operation of iridectomy should be done at once. This relieves the pain, lowers the intraocular tension, and in the great majority of cases ends the attack at once.

But the case is very different when we have to deal with an acute glaucoma, secondary to a retinitis or chorioiditis, and preceded or followed by intraocular hemorrhages. In such a case, if an iridectomy is done, it is invariably followed by a profuse intraocular hemorrhage, either subretinal or into the vitreous; by an immediate increase of the pain and total loss of vision, and enucleation of the eye must be done in order to relieve the patient's suffering. In such a case iridectomy is bad surgery and entirely unjustifiable, and would better be replaced by an immediate enucleation.

There is still another danger to be considered in these cases. The operation of iridectomy, on an acutely inflamed eye, is very painful, and cannot be satisfactorily done without general anesthesia. But in these patients with extensive vascular degeneration and marked cardiac disease, the employment of general anesthesia would be very dangerous, if not fatal to life.

Moreover in these cases of so-called hemorrhagic glaucoma, the operation can be avoided, and other means employed. In the cases, five in number, accompanying this paper, the operation of iridectomy was avoided by the following method: Under the influence of a strong solution of cocaine a paracentesis of the cornea was done, and the aqueous humor allowed to flow out, drop by drop, from the anterior chamber. In this manner the tension was lowered very slowly, and the danger of an extensive intraocular hemorrhage avoided. Two leeches were applied to the temple and allowed to fill themselves until they dropped. A solution of eserine sulphate, one grain, and of pilocarpine, four grains, was instilled every hour, until under the combined influence of the paracentesis of the cornea and the use of miotics, the eye softened and the pain grew less. As the tension subsides and the excessive pain gradually diminishes, the eserine and pilocarpine solution is instilled less and less frequently. The patient is then directed to use hot applications on the eye for half an hour at a time, and to keep these up every two hours until the pain has gone, and twenty drops of the fluid extract of Jaborandi are ordered three times a day, as an additional means of lowering the intravascular tension. Hypodermic injections of pilocarpine will bring about the same result, but in the presence of advanced cardiac disease they are dangerous. It is sometimes necessary to repeat the paracentesis several times in the same cautious way, at varying intervals, but eventually the end is accomplished. As the symptoms subside, the eserine and pilocarpine may be reduced to three times in the day.

Case I.—Gentleman, aged 85, with advanced cardiac hypertrophy and very marked arterial and venous degeneration, who had suffered from arthritic and intestinal attacks of gout for many years. He had had several attacks of transient obscuration of vision, the last one having come on two weeks before I saw him, and still persisted in the right eye. An examination showed punctate and linear opacities in both lenses, and retinitis with numerous retinal hemorrhages in the right eye. The fundus of both eyes showed the most marked case of arteriosclerosis that I had ever seen, the vascular degeneration being traceable to the extreme periphery of the fundus. The urine contained albumen and hyaline and granular casts. I first saw him in April, 1902, and at that time there was no increased tension in either eye. As a precaution pilocarpine was instilled into both eyes and his heart and circulation were carefully regulated. He had been for several years on a strict antigout diet. The symptoms of retinitis slowly subsided and the hemorrhages became gradually absorbed. There was no recurrence of the attack until December, 1903, when a similar obscuration of vision occurred in the left eye, and an examination showed a retinitis with hemorrhages. There was no increase of tension, but the iris was sluggish and the anterior chamber was shallow. The same treatment was carried out, and the patient did very well until February 10, 1904, when he had a sudden loss of vision in the left eye on the nasal side, and an examination showed a large hemorrhage at the macula and several others scattered over the fundus. This was followed the next day by injection of the ciliary vessels, iritis, and increased tension, with severe pain, and this brought on a severe attack of cardiac dyspnea, which yielded very slowly to treatment. A solution of eserine and cocaine combined with hot applications caused a diminution of the pain, but the acute glaucoma called for surgical interference. I opposed an iridectomy, against the advice of two consultants, and advised a careful paracentesis of the cornea, to be repeated if necessary, which was done. The eserine and cocaine was instilled every hour, and leeches were applied to the temple. The patient's heart action was very feeble and strong cardiac stimulants were ordered. As it was not deemed safe to use pilocarpine hypodermically, he was given 30 drops of the fl. extr. jaborandi three times a day. On February 28 there was a profuse hemorrhage into the vitreous, and the tension rose rapidly so that another paracentesis became necessary. From this

time the symptoms of pain and tension slowly subsided. On two occasions in March the patient nearly died from cardiac dyspnea, but rallied. During these attacks the intraocular tension rose rapidly but could be reduced by a strong solution of eserine and pilocarpine. I have seen this patient about once a month ever since, and at the last visit, in June, 1908, he was in good physical condition, and entirely free from pain or discomfort in the eye. The left eye is blind, but he still has useful vision in the right eye. He is now 91 years old.

Case II.—Gentleman, aged 69, a lawyer by profession. Has been an overworked man for many years and has taken but little rest. Is very gouty, and has had numerous inflammatory arthritic attacks. Has a poor digestion and has been on a rather restricted diet for years. Has cardiac hypertrophy with a mitral systolic murmur, and his heart action is very weak. I saw him first, in 1902, when he had an attack of retinitis with hemorrhage in both eyes, most marked in the left eye. As he was both hypermetropic and astigmatic, I ordered a half per cent. solution of pilocarpine and gave him sodium nitrite combined with strophanthus. The retinitis slowly subsided, the hemorrhages did not recur, and vision slowly improved. In 1904 he had a similar attack in the left eye, which yielded more slowly to treatment, and his general health was much impaired. In the summer of 1906 he had a sudden loss of vision in the left eye while away from home which passed away in a few weeks. Early in November, 1906, a similar attack occurred, accompanied by severe pain, vision was reduced to light perception and the eye was acutely inflamed. When I saw him he had all the signs of acute glaucoma, hazy cornea, dilated pupil, ciliary and episcleral injection, greatly increased intraocular tension, and in addition a large hemorrhage into the vitreous. Under the circumstances an iridectomy was out of the question. A paracentesis of the cornea was at once performed, the aqueous being allowed to pass out very slowly. Three leeches were applied to the temple and a solution of eserine and pilocarpine was instilled every two hours into the left eye, and twice a day in the right eye. The pain was lessened in the course of a few hours. The local applications were continued and four days later I did a second paracentesis of the cornea. He was also ordered 20 drops of the fl. extr. jaborandi three times a day. His condition slowly improved and at the end of a month the pain had gone. At the end of three months all signs of inflammation had subsided, and though the eye was blind he was free from discomfort.

Case III.—A gentleman, aged 62, a banker, whose life was made up of harassing cares with no relaxation. He had been a gouty subject for years, who constantly overstepped the bounds of reason in eating and drinking, and who smoked to excess. In 1903, shortly after a severe attack of intestinal gout, he had an attack of retinitis with hemorrhages in the left eye, for which he came to me. All the signs of arterial and venous degeneration were well marked in the retina of both eyes. He was highly hypermetropic, with normal vision in the right eye and only 5/200 in the left eye. He had cardiac hypertrophy, high arterial tension, and a very irregular pulse. The urinalysis showed a great excess both of uric acid and indican, with albumin but no casts. He was put on sodium nitrite and strophanthus; he was advised to drink freely of lithia water between meals; all red meats and all alcohol were cut off, and his tobacco was reduced to two cigars a day. Pilocarpine was instilled three times a day in both eyes. Within three weeks he had a large hemorrhage into the vitreous of the left eye, which was followed within twenty-four hours by acute glaucoma, with very severe pain and total blindness. As an iridectomy was absolutely contraindicated, a paracentesis of the cornea was done immediately, the needle being withdrawn very slowly, and as soon as the anterior chamber had been emptied a solution of eserine, 1 per cent., and pilocarpine, 4 per cent., was instilled into the conjunctival cul-de-sac every two hours. Leeches were applied to the temple and the fl. extr. jaborandi in 30 drop doses was given three times a day. I was obliged to repeat the paracentesis of the cornea twice at intervals of a week before producing any permanent effect. The pain ceased entirely at the end of three weeks, and at the end of six weeks the attack had passed off, with a vision of counting fingers at one foot and a good chance of still further improvement. There has been no return of the glaucomatous condition.

Case IV.—Lady, aged 70, short in stature, of slight frame, very nervous and very gouty. I saw her first in 1904. She was hypermetropic and astigmatic, with somewhat impaired vision from peripheral lens opacities. She had well-marked arteriosclerosis in the retina of both eyes, a venous pulse, and a very shallow anterior chamber. Fearing a possible development of glaucoma, I ordered pilocarpine for both eyes, and put her on a restricted diet with plenty of lithia water. She did very well for nearly two years, and then there occurred a retinitis with exudation in the left eye, which was followed two weeks later by a very large retinal hemorrhage. Within forty-eight hours acute glaucoma developed, accompanied by a severe iritis, a very unpleasant complication, as miotics used to lower the tension invariably make the iritis worse. A hasty examination of the heart by her family physician showed an enlarged and flabby organ, with a mitral systolic murmur, and a feeble and intermittent pulse. The patient's general condition was very bad. A hypodermic dose of strychnine was given, leeches were applied to the temple, and hot applications were made continuously to the left eye for four hours. I then made a paracentesis of the cornea very carefully allowing the aqueous humor to drain away slowly, and then instilled a 2 per cent solution of pilocarpine, avoiding the use of eserine because of its irritating effect on the inflamed iris. Under the combined influence of these applications the pain gradually grew less and a hypnotic gave the patient a brief sleep of four hours. The eye was blind except for light perception. The next day I began the administration of jaborandi and strophanthus internally, and the pilocarpine in the eye every two hours preceded by hot applications for half an hour. At the end of a week it became necessary to perform a second paracentesis of the cornea on account of a sudden rise of tension. From this time all symptoms of glaucoma slowly subsided, and the pain finally disappeared. About the middle of August she suddenly partially lost the sight of the right eye from a retinal hemorrhage, but there were no glaucomatous symptoms developed. I last saw her on October 16, 1908, when her general condition was very satisfactory. The right eye, the one recently affected, had a vision of 15/50 and she could read fairly small type. In the left eye, where the glaucoma developed, the vision was 15/100 and the eye was quiet and painless.

Case V.—A gentleman, aged 70, of slight frame and frail health. Has a very weak heart action, with mitral systolic bruit, and a chronic, well devel-

oped interstitial nephritis. Has been subject to gouty attacks, both arthritic and intestinal, for many years. I first saw the patient in 1904 for an attack of exudative retinitis in the right eye with several small hemorrhages. At that time an exhaustive examination of the heart and kidneys was made and the diseased condition of both recognized. There was well-marked arteriosclerosis in the retina of both eyes. He was slightly myopic with nearly normal vision in the left eye. Under duly prescribed local and dietetic treatment, the retinitis slowly subsided, the hemorrhages were absorbed and the vision improved. In 1906 some fresh retinal hemorrhages occurred in the right eye, which were very slowly absorbed. In February, 1908, he had a sudden loss of vision in the right eye, lasting half an hour, and then passing off. Three days later he had a similar attack, which lasted somewhat longer. Four days after this second attack he had a third attack in which the vision was entirely lost, and the eye has remained blind ever since. When I examined the eye after this third attack, I found the vitreous full of blood, but there was no increase of tension. Two months after the first attack in February last, he had an attack of acute glaucoma, with very marked injection of ciliary and episcleral vessels and very severe pain; and the eyeball became very hard, and this in spite of the eye having been under the influence of pilocarpine for two months. An iridectomy on such a patient, under the existing conditions, was of course out of the question. Under cocaine anesthesia, a very careful paracentesis of the cornea was made, and the aqueous humor evacuated very slowly. A solution of pilocarpine, 2 per cent., and eserine, ½ per cent., was then instilled into the cul-de-sac, and this was ordered repeated every hour. Hot applications were ordered for half-hour periods every two hours, and two leeches were applied to the temple. The pain began to diminish in about four hours, and the patient was given a hypodermic injection of pilocarpine hydrochlorate, gr. 1/50, followed by a dose of strophanthus internally. The paracentesis of the cornea was repeated on the sixth day as there was another increase of tension. He was ordered 30 drops of the fl. extr. jaborandi three times a day. Four weeks from the date of the attack the pain was gone, though it returned on three different occasions. This patient has been for nearly three months without any severe pain. The engorged vessels have disappeared. The tension is normal, and the pupil is kept contracted by eserine. Miotics were used in the left eye also as a precaution and this eye has remained uninvolved. The right eye is blind, and the lens is becoming opaque. The patient's general condition is satisfactory.

LOCAL ANESTHESIA IN MAJOR SURGERY, WITH ESPECIAL REFERENCE TO ABDOMINAL WORK.*

By WINFIELD SCOTT SCHLEY, M.D.,

NEW YORK.

SURGEON TRINITY HOSPITAL AND ASSISTANT SURGEON ST. LUKE'S HOSPITAL.

THERE is still a great deal of scepticism and actual disbelief with regard to the possibilities of operating painlessly and successfully with the local anesthetics, and especially is this true in its application to major surgery. Local and regional anesthesia in the larger surgery is not a new subject, and dates back some twelve to fifteen years, but the number of workers along these lines has not been great and their results have not attracted the attention they merit. How seldom we see or hear of an extremity being amputated by that most successful and masterful procedure of Crile and Matas by intraneural cocainization, or any other major procedure, with the possible exception of hernia, where local anesthesia the last few years has gained adherents. I believe this is all very largely due to the fact that the average use of cocaine or other local anesthetics has been more often inefficient in the production of real anesthesia. Also because the earlier use of cocaine solutions of too great strength frequently gave rise to toxic symptoms, and because general anesthesia is easier for the surgeon. The majority of operators do not seem to have the inclination, the time, or the patience to undertake this branch of anesthesia, even in cases where ether and chloroform are greatly added risks or are prohibitive. This is no plea for the general adoption of local methods in the majority of surgical cases; general anesthesia has been and must remain our chief reliance probably for some years, as at present 60 to 70 per cent. of cases seen in general work require it, but the field of local anesthesia has steadily widened with greater experience and as newer agents of lessened toxicity have been found. Its place in major surgery has come to stay, and aside from the cases in which it is most strongly indicated and those to which it is especially adapted, there are a number, now done as a routine with general anesthesia, in which the patient will have the election of the two methods of relieving pain according to his desire to escape the discomforts of general narcosis. That great development of local anesthesia, spinal cocainization, has, up to the present, I think, not proven reliable enough or sufficiently free from immediate or later bad effects to take the place of local and regional methods in their present development.

The application of local anesthesia in major surgery to-day is at its greatest usefulness where general narcosis adds distinctly to the danger, but there has been a slow and progressive development in its technique and in its extension to many cases to avoid the disturbances of general narcosis and to ensure a quicker and pleasanter convalescence. The conspicuous advantages of the local method are the greatly reduced or total absence of shock, absence of respiratory and gastric disturbance, and much more agreeable post-operative period. In abdominal work with prolonged exposure, and with much traction and rough handling of the gut, some shock may result, but I have been able to work for over an hour in a large ovarian cyst adherent to the parietes and greatly adherent to the gut without apparent shock then or later. This, too, in a small, delicate woman with a pulmonary lesion. No more than the usual care was taken, not to eviscerate, expose, or handle the gut more than necessary. This great reduction or absence of shock I believe due to the more or less complete nerve block, absence of abnormal heat radiation from the surface and lungs, and absence of the direct toxic action of the anesthetic upon the nerve tissue of the brain and spinal cord. The nerve block and the enforced rather gentler manipulation save the spinal cord from a bombardment of impulses while laboring under the effect of a toxic agent, and there is little or no fall in vasomotor tone, that first indicative of shock. I believe a further adjuvant to be the adrenalin added to the solutions, and which acts both to diminish the speed of absorption and to maintain vasomotor tone.

*Read by Invitation and in Substance before the Mt. Vernon Medical Society, and before the Surgical Section, New York Academy of Medicine, October 2, 1908.

Speed and gentleness of manipulation in operating have been the greatest factors in contributing to successful results under general narcosis, and local anesthesia is in no wise a substitute for the latter, as successful work by this method requires an even lighter degree of touch. Rapidity of work is not so necessary and sometimes not possible. We can often in this way safely operate upon many borderline cases, that with general anesthesia would be hazardous performances or altogether barred, and bring them to a successful and frequently speedy convalescence. It is remarkable to see patients, both immediately after operation and on the following day, looking rather as though they had made a spontaneous recovery than as having been through a major operative procedure.

The particular method of local anesthesia that I want to speak of at this time is neither the infiltration method of Schleich nor the neural method of Crile, Matas, or Cushing, but one of purely local anesthesia of the subcutaneous tissue and cellular planes with limited amounts of the solution of the anesthetic. My own recent work, the last year, has been more in the field of abdominal surgery, and where I believe some of the greatest triumphs and possibilities await this method.

In doing hernia operations and colostomy under local anesthesia with the necessary handling of the gut and peritoneum and its apparent painlessness, I have felt more and more convinced that the viscera with their peritoneal investment and the general space of the peritoneum could be explored and operations done as well as in these cases, provided there was not a coexistent acute inflammation. It was further apparent in bad cases of strangulated hernia that the gut could be divided and reunited with absolute painlessness. The immediate subsidence of vomiting and the excellent condition of these patients after operation was most striking. It now seemed worth attempting this method in intra-abdominal conditions, and the opportunity soon presented itself in two desperate cases of intestinal obstruction from enteroliths, in one traumatic rupture of the jejunum in a boy of thirteen years, in three operations for tuberculous peritonitis, in a complicated ovarian cyst, and in a recent case of acute pancreatitis.

The first case of obstruction in an elderly physician seventy-four years of age who entered the hospital on the fifth day of his illness was in a critical condition. Suspecting carcinoma of the colon, an opening was first made in the left inguinal region by the intermuscular method. This was closed and a six-inch median incision made, and with the hand and part of the forearm introduced a hard mass was felt in the gut, which when brought out was found to be a stone in the lower part of the jejunum. The gut was completely blocked and distended by the stone and it could not be pushed up to a larger section of the intestine. The gut was incised, the stone removed, and the opening closed with a double suture layer. The abdominal wound was closed with through and through sutures of silk worm. This patient had been in the habit of taking two grains of morphine a day for some years and he was given 20 minims of Majendie's solution prior to operation on account of restlessness. He had taken his morphine by mouth and the vomiting of the obstruction had cut him off for some days.

The second case, ten days later, occurred in an elderly woman of sixty years, who entered the hospital on the fifth day after the onset of vomiting and in a critical condition. A median six-inch incision and exploration disclosed a hard mass in the intestine, which was found to be a stone in the lower part of the ileum some eight inches from the ileocecal junction. This was treated as in the previous case. Both of these patients made a perfect recovery and were discharged in excellent condition. The cessation of vomiting and the remarkable absence of shock were striking, and it would be impossible to tell from their appearance the following day that they had been through an operation.

The boy with ruptured jejunum was brought in about two and a half hours after the accident and in profound shock. A rock of 100 pounds had fallen on the upper part of the abdomen, and with the rigid wall and the signs of peritoneal effusion I believed that we had to deal with a rupture of the liver or intestine, with hemorrhage. It seemed wise to operate immediately, and he was given a sixth of a grain of morphine and an intravenous saline of 800 c.c. Notwithstanding his youth and the probable difficulty of managing him, I decided to try local anesthesia, using ether if necessary later. A five-inch incision was made through the left rectus close to the median line and above the umbilicus. The peritoneum was filled with bile mixed with blood, the liver and spleen were not ruptured. The upper part of the intestine was looked for and the jejunum was found divided completely across and an inch into its mesentery just two and a half inches from the duodenojejunal junction. It was reunited with a Murphy button reinforced with a peritoneal stitch. The pelvis and abdomen were flushed out with hot saline and the wound closed with through and through sutures. This boy's shock was scarcely appreciably augmented and he made an excellent recovery.

An Italian boy of nineteen years upon whom it was necessary to do three successive laparotomies for advanced tuberculosis of the peritoneum, had a cough and apical trouble, and all three operations were done under local anesthesia. The first two were for the evacuation of large amounts of fluid and the last for supposed perforation and localized abscess. At the first operation he complained much of pain until an Esmarch mask was put over his face and a small amount of alcohol dropped on it, after which he remained entirely quiet and neither moved nor spoke. It was possible to get this patient out of doors promptly and he was fed increasing amounts of cream. To-day he is scarcely recognizable as the former patient of six months ago. He has been in the country for two months and comes down for observation occasionally. I am sure that he could never have stood the three operations under general narcosis, or if perchance he had, would not have shown so quick and satisfactory improvement from such an advanced condition. It was entirely possible in this case through a five-inch incision to explore the abdomen, swab the peritoneum with camphonapthol, and handle the viscera without evidence of pain.

Another case of great interest, kindly referred to me by Dr. Merriam Myers, was that of a very large ovarian cyst. This patient, a small, delicate woman with a chronic bronchitis of tuberculous suspicion, had so large a cyst that not only was the abdomen filled, but pressure upon the lower ribs had caused eversion of the costal margins. The pressure upon the diaphragm was so extreme that the chest capacity was greatly reduced and the patient could not overcome the chest complication. The pressure had also caused complete prolapse of the bladder and uterus. The operation upon the cyst was undertaken with the double purpose of removing the tumor and of allowing chest expansion. General anesthesia seemed completely contraindicated, and it was determined to attempt the local

method. I had hopes that it would prove a unilocular cyst and not greatly adherent, but neither of these conditions was fulfilled and we had to deal with a multilocular cyst that was everywhere adherent and by a broad vascularized band to the sigmoid. The adhesions were partly caused by tuberculous deposits in the peritoneum. It was necessary to make a twelve-inch incision through the thin distended abdominal wall and to introduce the whole forearm into the abdominal cavity to separate the adhesions gently and to turn out the tumor, dividing and ligating the larger adhesions and broad pedicle. This patient was conscious throughout and frequently replied to questions. There was no apparent shock and she left the table with a lower pulse rate than when she went on. To a question after operation as to whether she had felt pain, she replied that she thought we had been trying to catheterize her, a procedure sometimes necessary because of her complete prolapse of uterus and bladder from the great intraabdominal pressure. This patient unfortunately later succumbed to the process in the chest, which continued to advance, and we were deprived of the fruits of our labors. This is, I think, a fair example of the extent to which we can go in selected cases. The tumor weighed over 50 pounds.

Another very recent case of interest was complicated by intraperitoneal inflammation. Prior to operation the diagnosis lay between perforated gastric ulcer and acute pancreatitis. This patient had been in the hospital several weeks before upon the Medical Division with a diagnosis of gastric ulcer, and the sudden onset of pain in the present illness with the rigid and tender abdomen and the evidence of considerable fluid in the peritoneum favored the former diagnosis. The leucocyte count was 31,000 with a differential of 94 per cent., and the woman was evidently acutely ill. Under local anesthesia a five-inch incision was made in the median line above the umbilicus. There was a large accumulation of turbid fluid in the peritoneum that suggested a perforation of a viscus, but on examining the stomach nothing was found. Upon lifting up the great omentum and transverse colon an intensely reddened and injected area was found about the duodenum, and the transverse mesocolon and mesentery and peritoneal coat out to the hepatic flexure were markedly edematous. No duodenal perforation could be found. The whole pancreas, but especially the head, was enlarged, indurated, and tender to touch, but with gentleness could be entirely explored. There were no demonstrable areas of softening and it was not interfered with. The omentum was studded with small areas of fat necrosis and several were removed for study. Traction upon the stomach and upper part of the jejunum, as also the moderate pressure necessary to replace the omentum and colon, was painful as one would suppose in so intense an inflammatory condition. This, however, was never more than the patient could well stand, and although she had no general anesthetic whatever, was operated upon in the general amphitheater before an audience, and shortly after her admission she went through the ordeal perfectly and never interfered for a moment with the work. The wound was closed with through-and-through sutures. There was no apparent shock and the patient looked the next day rather better than before operation. With starvation for a few days and abundant rectal saline she made an uninterrupted recovery. The persistent vomiting which had been a feature of her illness lasted for two days after operation, and I am confident that the absence of general anesthesia contributed much to her comfort if not to her safety in the presence of so severe an upset to the chemical metabolism.

In regard to the method of preparing the patient and anesthetizing the tissues the procedure has been as follows: An hour before operation (if possible) a hypodermic of one-fourth to one-third grain of morphine is given and the patient is told that it will not be necessary to resort to ether or chloroform and that the necessary work can be done under cocaine. This is after a frank confession of the nature of the trouble. Some are incredulous but willing to try, some are happy and reassured, and some apprehensive, preferring general anesthesia. The latter class are usually managed with the assurance that they may have their ether if they have pain, but that it is unpleasant and they will be much better off afterwards and make a quicker recovery without it.

The anesthetic agent has been the novocain-adrenalin mixture as reported in an earlier paper this year.* After many experiments I was satisfied that novocain was only one-sixth as toxic as cocaine, and that when *combined with adrenalin* it had anesthetic properties and a suitability much above cocaine when injected hypodermically. Also that the combination was even less toxic than the novocain solution alone. A four or two per cent. solution, to which has been added one-fifth or one-sixth the bulk of adrenalin (1-1000), is used to raise a continuous line of blebs along the line of the proposed incision. It is only in this way I believe that we can get a perfect and lasting anesthesia of the skin and subcutaneous tissues. At intervals of one-third to one-half an inch along this line of injection a needle is introduced perpendicularly to the skin and to the depth of the tissue to be anesthetized, and five or six minims of the solution are injected each time as the needle is withdrawn. Special paraphernalia or syringes are not required, an ordinary aseptic hypodermic being sufficient. Sharp needles are essential and make the first prick painless. The remarkable diffusive power of this combination does its own infiltration and the longer we wait the better the anesthesia. I have not found it necessary in hernia, for instance, to inject the nerves separately as the perineural contact has apparently been sufficient. We have the advantage of operating through tissues that are not edematous and sodden, but are dry and comparatively bloodless, and in which the larger vessels stand out in contrast to the paler surroundings. We have the further advantage over cocaine in that we can use stronger solutions and in much larger quantity, and so secure more lasting anesthesia and over a larger area. I believe it will last, with 4 per cent. novocain solution with adrenalin, for two hours, depending upon the vascularity of the area injected, and have found the anesthesia deeper at the end of an hour than at the beginning of an operation and extending over a much greater area. I have usually waited fifteen minutes after completing the injections before starting the incision. The maximum quantity used has been 140 minims of the combination of 4 per cent, novocain and adrenalin; 110 of the former and 30 of the latter.

Morphine prior to the operation and occasionally an Esmarch mask with a few drops of ether or a mixture of alcohol and ether have always enabled me to operate in this way, the patient's face being usually screened from the operation. These patients should receive just enough of the ether to feel slight constitutional effects and a slight confusion of mind. A little only is required, as too much abolishes the

N. Y. State Journal of Medicine, December, 1907.

will, a certain amount of which we must depend on, and is apt to cause mental and muscular excitation. A number of patients will not require even this slight aid of a general anesthetic. In the first obstruction case, in the case of ruptured jejunum, and in the case of ovarian cyst, small amounts of the ether and alcohol were used, as I wished every aid in carrying them through without inducing unconsciousness by resorting to general narcosis.

It may be in order to remark here that this method of local anesthesia has apparently never interfered with healing, and I have never seen secondary hemorrhage in over seventy operations with its aid. In a few of the earlier cases and in one abdominal case there was suppuration in the wound, apparently due to talking with the patient while over the field of operation. Since using a gauze face mask there has not been the slightest trouble and healing has been primary in every respect.

So far I have not attempted this anesthetic method in operations requiring extensive dissection, as in malignant breast cases, multiple and extensive glands of the neck, most of the operations for malignant disease, etc., but believe it is practicable in a number. In many abdominal cases I think local anesthesia will find one of its greatest fields of usefulness, believing as I do in the insensitiveness of the peritoneum of the viscera in a noninflammatory condition. Gastrotomy and gastrostomy have been done and gastroenterostomy and gastrectomy I am sure are as possible. It will save great discomfort and some risk in these cases, many of which are done to allow a few months longer of tolerable existence. Exploratory measures for suspected tumors, obstructions, and perforations may be especially well accomplished, and there is nothing to contraindicate general anesthesia at any time it may be found wise or necessary, and the amount required will be much less than normally.

It would not be fair to local anesthesia not to repeat that we must reserve our local anesthesias for selected cases: character of the disease, character of the patient, and the surroundings are the factors that must determine the choice of anesthetic. Patients at home or in a private operating room will generally be more easily managed than when they are in an amphitheater with spectators and the necessarily increased paraphernalia, passing about, and noise. Quiet contributes much in nervous cases, but, as before said, the more adept one becomes at this method and the more successful he is in reassuring and carrying through his patients, the more does his field widen. That we have here a method that can save great discomfort I know, and that in many of the desperate borderline cases we can save lives, I am sure.

A number of the cases mentioned above, and others with extraabdominal conditions, were operated upon in St. Luke's Hospital on the first Surgical Division, that of Dr. Robert Abbe, to whom I am indebted for the operations and the recording of those cases.

24 West Forty-fifth Street.

TUBERCULOSIS IN HOSPITALS FOR THE INSANE.*

By RICHARD H. HUTCHINGS, M.D.,
OGDENSBURG, N. Y.
SUPERINTENDENT ST. LAWRENCE STATE HOSPITAL.

The object of this paper is to present in a concise form the present position of American Hospitals for the Insane with reference to the prevalence of tuberculosis among the inmates and the measures which have been adopted to control it, together with some suggestions for further limiting the spread of this disease among the insane.

*Read at the International Congress on Tuberculosis, Washington, D. C., October 2, 1908.

Tuberculosis is one of the chief causes of death in our asylums and the rate of mortality is higher among the insane than among the population at large. Last year there were 140,343 deaths from all causes in the State of New York and of this number 14,027, or ten per cent. resulted from tuberculosis.*

During the same year the State Commission in Lunacy reported 2,071 deaths among the insane in custody in that State of which not less than 345, or sixteen and two-thirds per cent., were attributed to this disease.†

In the State of Massachusetts more than fourteen per cent. of the deaths among the inmates of the hospitals for the insane was attributed to tuberculosis.‡

In the Government Hospital for the Insane at Washington, D. C., during the past twenty-one years, 2,102 autopsies (representing sixty per cent. of the deaths) showed tuberculosis in active form in 432 cases, or more than twenty per cent., and latent lesions in a still greater number.

In the St. Lawrence State Hospital, Ogdensburg, N. Y., in a series of 828 autopsies active tuberculosis was met with 119 times, or in fourteen per cent. of the cases.

With reference to the prevalence of the disease among asylum inmates it will be found from an examination of the reports of the American institutions that there is a wide diversity with reference to the prevalence of the disease in the institutions in different sections of the country, as well as different institutions of the same State. From inquiries made by the writer during the present year it was ascertained that there are in the fifteen State hospitals in New York State 28,623 insane patients in custody, and of this number there are no less than 872 in whom a definite diagnosis of tuberculosis has been made.

The following table gives the prevalence of tuberculosis per thousand of the insane in custody in various representative States from which complete information was obtained:

Minnesota	20 per thousand
Massachusetts	23 per thousand
Pennsylvania	23 per thousand
Mississippi	27 per thousand
Iowa	28 per thousand
New York	30 per thousand
Georgia	32 per thousand
Virginia	38 per thousand

In many individual hospitals the ratio is much higher than the maximum given above, but this is due in some cases to the practice prevailing in several States of transferring tuberculous patients to certain of the hospitals where special provision has been made for their care. It was ascertained that in one large hospital in the United States about thirty per cent. of the patients were regarded as tuberculous; and the superintendents of several institutions reported an entire absence of this disease.

In the following States special provision has been made for the care of tuberculous insane with the object of removing them from contact with others and providing modern treatment:

Tuscaloosa, Ala..... A separate ward for women.
Mendocino, Cal..... Tent colony for men.

Kingston, Ont.	Shacks.
Hamilton, Ont.	Separate building accommodating 24 patients.
Penetanguishene, Ont.	Tents.
Quebec, Can.	Separate building.

The sources from which our institutions recruit tuberculosis are two: (1) The patients who are admitted with the disease which may or may not be recognized at the time. (2) The cases which develop in the institution. The relative importance of each source is difficult to gauge—they doubtless differ in different institutions depending on the one hand upon the communities from which patients are received, whether from the congested districts of large cities or from the rural and farming regions; and on the other hand upon the local conditions existing in the hospital as the presence of overcrowding, the ventilation, and the general standard of care maintained.

At the St. Lawrence State Hospital, in 1907, 38 patients were transferred to the pavilion set apart for the treatment of tuberculosis of whom 15 were recognized as such on admission and 23 had been residents of the hospital for a length of time as follows: Less than one year, 7; between one and five years, 4; more than five years, 12.

Where the disease made its appearance during the first year of asylum residence it may have been present and unrecognized at the time of admission. This is probable where the general physical condition was much reduced and the patient did not gain in strength. Where the disease makes its appearance after a year or more of fair physical health the hospital may fairly be charged with aiding and abetting the disease, if not with originating it. It is impossible in the majority of insane patients to diagnose tuberculosis in its incipient stages; the nice cooperation on the part of the patient to elicit the crepitant râle can rarely be obtained and one may be pardoned for failure to discover fairly well marked foci in many insane persons. It is only when coarse physical signs as consolidation and bronchial breathing are present that one can be sure of his diagnosis in many cases. Among the insane the constitutional symptoms have less value than among the sane; fluctuations in weight and temperature and even sweating are not conclusive as they are frequently concomitants of an abnormal condition of the nervous system, and cough is sometimes absent when the disease is well advanced. These facts emphasize the importance of careful observation of newly admitted patients to the end that the patient himself may receive proper treatment and the health of the household be safeguarded. There are no conditions under which the use of such diagnostic aids as tuberculin is of greater value than among the insane, and it should be employed in every case where satisfactory physical examination is impracticable at the time of a patient's admission or on any subsequent occasion.

Turning now to the cases which appear to originate in the institution, it is the experience of the writer that there is great diversity in the classes of patients among whom it makes its appearance. At the St. Lawrence State Hospital there are two detached cottages accommodating each 70 men patients who are regularly employed at farm and garden work, and during the past fifteen years no case of tuberculosis has originated in either cottage. In some other wards one or more cases have developed nearly every year. Those wards in which it is most frequently found are occupied by the demented and untidy classes, and the so-called disturbed. These are the wards in large public hospitals which tend to become overcrowded even when in the institution as a whole the overcrowding is not great. This is due in part to the desire of the officers to remove objectionable patients from the better wards, thereby rendering them more attractive to the intelligent patients, and partly for the reason that individuals of this class cannot take part in occupations which would remove them from the ward during the working hours, and many on account of their physical condition cannot even be taken out for exercise, hence they lead a comparatively inactive and an indoor life. The mere fact that the ward is crowded renders rather urgent the necessity of keeping people in their places; the requirements of good order are too frequently construed by nurses and attendants as having patients seated in their places and to discourage all activity. Those patients who can be employed and who, therefore, are off the ward a portion or the greater part of each day, unless crowded in sewing rooms and shops, are usually in a healthier condition and freer from tuberculosis than those remaining on the wards. As most institutions for the insane have farms or large gardens where patients may be employed it is comparatively easy to find suitable employment out of doors for men and difficult to provide work for women except housework and indoor occupations as sewing, rug making, chair caning, and other more or less sedentary tasks. Let us see how the prevalence of tuberculosis differs in the two sexes, bearing in mind this well recognized difference in the employment and modes of life of our hospital inmates. In the period 1888 to 1906, according to the report of the New York State Commission in Lunacy, there were 28,106 deaths from all causes in the New York State Hospitals for the insane. Of these 15,242 were men and 12,864 were women.

Among the men 1,463 died from tuberculosis, 9.5 per cent., while among the women there were 2,596 deaths from tuberculosis, which is 20.1 per cent.—more than twice the death rate among the men from this cause. The death rate among the men in State hospitals is slightly less than that of the State at large, among the women it is more than twice as high as that of the State at large, and what is more significant, more than twice that of the men in the same institutions. Inquiries made in other States show that the conditions are virtually the same throughout the United States. In almost every State in the Union the number of cases of this disease among women greatly exceed those among men.

The following table shows the form of insanity of the 119 cases in which active tuberculosis was found post mortem in a series of 828 autopsies: Terminal dementia, 51; chronic mania, 11; chronic melancholia, 12; senile insanity, 11; epilepsy, 9; acute melancholia, 7; general paralysis, 8; acute mania, 3; imbecility, 3; organic dementia, 1; paranoid, 1; miscellaneous, 2.

In the above series of 828 autopsies 447 were on men and 381 on women. Among the women active tuberculosis was found 62 times, or 16.2 per cent.; among the men 57 times, or 12.7 per cent.

There are a few large public hospitals for the insane in the United States in which the disease is almost if not wholly unknown. I refer to the State Hospital at Provo City, Utah. The superintendent, Dr. Calder, informs me that there is not now nor has there been for the past five years a single case of tuberculosis among the 353 inmates. Practically the same may be said of the State Hospital at Reno, Nevada, where the disease is unknown except for an occasional patient admitted with it, and there have been no deaths from it for several years past. It is interesting in this connection to notice that the altitude of these institutions is 4,560 and 4,500 feet respectively above the sea level, but Dr. Calder adds another significant remark when he says: "In this altitude we are able to have all of our patients, except now and then a bed patient, out of doors a part of each day, almost all of the year. During the spring, summer and fall they spend on an average five hours each day in the open air."

Prevention of Tuberculosis.—It is now generally recognized that among the insane as elsewhere tuberculous patients should be removed from contact with the healthy and afforded the treatment which can only be given in special structures of one sort or another as pavilions, tents, and sheltered porches. To this end no patient should be admitted to the general wards of an institution until the presence of the disease has been excluded. Overcrowding in wards and dormitories should be avoided, and particularly those departments occupied by the demented and inactive classes. The writer realizes fully the difficulty in accomplishing this very evident precaution, but believes that when we can go to the legislature with stronger objections to overcrowding than mere difficulties of administration we will be more likely to obtain the relief which we seek. All patients physically able should be exercised and when possible employed in the open air daily. When patients are in the wards they should be warmly dressed and fresh air should be admitted through open windows in such quantities as to effectually do away with any suggestion of foul air in the rooms. The clothing worn by one patient should not be used by another until it has been sterilized. The danger here is particularly in the use of shawls, hoods, and wraps for the neck. The same rule should apply to the use of blankets and bed linen. Care should be exercised that infection is not conveyed through cups for drinking water. The wards for women as well as those for men should be supplied with cuspidors of appropriate type and the patients taught to use them.

It is worthy of remark that those institutions which have provided separate pavilions or have adopted the use of tents have almost uniformly reported a decrease in the prevalence of tuberculosis in the institutions. Some of my correspondents have characterized it as a remarkable decrease. I have no figures to present except the result of the work of the tuberculosis pavilion at Ogdensburg, which to us have been extremely gratifying. During the first year of its operation, from January 26 to September 30, four of the patients were discharged from custody, apparently cured of tuberculosis, and three of them recovered from insanity, and the fourth much improved. Fourteen others improved to such a degree that all active symptoms subsided and physical examination was either negative or showed only diminished resonance over the affected area. During the second year nine of the patients were discharged from the pavilion to other wards of the hospital as not requiring further treatment, and five others were returned to their homes in a condition to resume their occupations. During the second year the number of deaths declined from 34 to 19, the lowest in seven years, and tuberculosis, which has heretofore occupied first place in the causes of mortality, has been reduced to fourth.

ETIOLOGICAL INDICATIONS IN THE TREATMENT OF PNEUMONIA.

By H. B. KNAPP, M.D.,

WICONISCO, PA.

To attempt to review all the methods used in the treatment of pneumonia would carry us beyond the limits of this short paper. A glance at the history, however, of a disease, the mortality of which has been increasing in recent years, rather than diminishing, does not inspire us with anything like the enthusiasm we need to cope with it. But few maladies have taken so little notice of the various measures brought to bear against it.

The brilliant results of specific remedies lauded by some fail to materialize when the same remedies are tried by others. It might be expected that the serum treatment would give us the long-looked for remedy, but the results do not warrant us as yet in placing too great reliance in it. Anders has collected 535 cases treated by this method with a mortality of 18.3 per cent. Other reports show the mortality as high as 25 per cent. To attempt to account for the apparent failure of this rational form of treatment might lead us too far into speculation. Welch has pointed out that the present stage of progress does not hold much hope for a protective antitoxin owing to the low vitality of the pneumococcus in culture media, and further, what is clinically recognized as pneumonia may be caused by a variety of different organisms, or by a mixed infection, which we are at present rarely able to determine positively or promptly. This fact probably in part accounts for the very varied conclusions which have been arrived at by different observers who have employed different kinds of therapy.

We have at present no specific for pneumonia, so that the thoughtful physician is compelled to adhere to lines of treatment based on sound physiological principles derived from our knowledge of the action

of the organism and the reaction of the host. Musser and Norris say that the action of the organism is that of an invasion of the body inducing a general infection, a local inflammation, and a secondary toxemia. A favorable reaction of the host is seen in the ability of the body to take care of the inflammation by physiological means; and, to neutralize, eliminate, or withstand the effects of the toxins. As to the invading organism after infection has taken place, but little can be done by the therapeutist save to limit the inflammation or prevent reinfection. As to the host we must aid every line of defence provided by nature, in other words, treat the individual and not the disease.

The morbid manifestations of pathological states which are commonly known as disease not only result from the immediate or exciting cause, but there must be a preparation of the soil, a lessening of the natural resistance. For example, the tubercle bacillus is not able to establish itself in the thoroughly healthy individual, but thrives only in the body which is out of physical training on account of some of the many unhygienic habits so often due to modern civilization.

Probably the greatest natural defence the human body possesses is the blood. "The blood is the life," declares the Good Book. A limb may be deprived of its nerve supply, both motor and sensory, yet life is maintained through the vital circulating fluid being carried to it through its vessels. Cut off the blood supply, and death occurs almost instantly.

In considering the various ways by which the salient forces of life may be enhanced let us review some of the recognized methods of improving the physiological powers of the body and especially of the blood.

Aerotherapy.—The short, labored breathing of the patient suffering from pneumonia gives a clue to one of the indications to be met, viz., ventilation. Fresh air stimulates the heart and makes respiration effective, thus relieving air-hunger. It promotes sleep and quiets restlessness. Fever patients cannot catch cold. The great amount of fear manifested by the laymen, and I might also add some of the profession, amounts almost to aerophobia. We must make the anxious relatives and friends see that we are dealing with a condition where only a part of the vital lung capacity is available for breathing purposes, hence the great need of adequate ventilation. William Gilman Thompson reports 47 cases of pneumonia ending in recovery, in which the patients received absolutely no medicinal treatment, and in which the principal reliance for recovery was placed in an abundance of cold, fresh air. They were placed on the roof or on balconies, kept there day and night, with the temperature of the air hovering around the freezing point. He says: "Not all patients need digitalis, because not all have weak hearts; not all need aconite or nitroglycerin, because not all have the initial high tension pulse and full arteries; it is well enough and time enough to employ these measures when they are indicated; but what every pneumonia case needs is a plentiful supply of fresh air that has never been in the lungs of anyone else." To give canned oxygen such as is found in the average bedroom, especially in the winter, does not seem any more rational for a case of air-hunger than to give salt meat and canned vegetables in a case of scurvy. Northrup aptly states that we should not make the patient breathe five times when three will accomplish the same effect. Give him air, fresh air, cold air, and in unlimited amounts.

Hydrotherapy.—Possibly the next most important method of aiding the defences of the body is by means of hydrotherapy. Musser says that greater confidence can be placed in hydrotherapeutic measures than in other forms of treatment. By the use of water in some of its varied physical forms we are able to produce a variety of favorable effects when intelligently applied.

The skin has been aptly termed a harp of a thousand strings, upon which one who is master of the necessary means can play in such a way as to produce almost any desired physiological or therapeutic effect. The skin is the keyboard, and the nerves and the nerve centers are the internal mechanism. It has been shown experimentally that the pulmonary vessels are supplied by vasomotor nerves through the roots of the second to the seventh dorsal nerves. Hence a positive effect upon the vasomotor supply of the lung may be produced by applying the cold compress to the chest down to the level of the umbilicus.

Baruch says, in Osler's "Modern Medicine": "When the cold compress is applied there is a rapid contraction of the cutaneous vessels which raises the tension at once, but eventuates in a tonic dilatation of these vessels evidenced by the ruddy hue of the skin. The dilatation differs decidedly from the relaxed condition of the cutaneous vessels which is produced by warm poultices. The latter relaxed condition produces a paretic condition of the vessels, or a stasis, while the cold applications stimulate the vasodilators, giving rise to an active dilatation, with the maintenance of the tone of the vessels, an active hyperemis through them." The heart is thus relieved, not by augmenting the *vis a tergo*, but by relieving the load by broadening the blood stream. "Arterial tension is increased, as evidenced by the tonometer as well as by the better filling of the radial arteries. The right heart is indirectly aided by the enhancement of the general tone of the vascular apparatus, and may thus expend more force upon the pulmonary circulation, whose vessels contract more effectively by reason of the dilation of the superficial vessels."

Several varieties of the chest pack may be employed. One of the more convenient methods is as follows:

The Roller Pack.—Take a strip of old linen or cotton cloth 6 to 8 inches wide and 6 to 8 feet long. Roll it into a roll and wring quite dry from cold water at 40° to 60° F. With the patient sitting, apply the bandage in a figure of 8 fashion as follows: Place the loose end of the roll under the right arm and carry the bandage upward obliquely across the front of the chest over the left shoulder; thence obliquely downward across the back, under the right arm; horizontally across the chest in front, under the left arm, and obliquely upward across the back and over the right shoulder to the place of starting. Next a bandage of heavy flannel, a little wider and longer, is applied over the moist bandage in precisely the same way, care being taken to cover the wet compress completely so that no wet edges protrude to become cold and clammy. The pack should be changed every hour or half hour when the temperature is 102° F. or above, and may be discontinued when the temperature is below 99.5° F. To increase the effect of these cold compresses hot fomentations should be administered every three or four hours, after which the cold compress should be reapplied.

The Cold Wet Sheet Pack.*—This extremely useful and easily applied procedure consists in enveloping the body with a wet sheet and preventing

*Kellogg's "Rational Hydrotherapy."

evaporation by careful protection with dry wrappings. A double blanket is spread upon the bed or couch where the treatment is to be given. A linen or old cotton sheet is next wrung out of water at a temperature of from 60° to 70°. This may be easiest accomplished by two persons grasping the sheet at each end and twisting it in opposite directions until it is as dry as possible. The sheet is then quickly spread upon the blanket. The patient now is placed upon the sheet so that its upper edge extends three or four inches above the shoulders. With the arms raised above the head one side of the sheet is snugly wrapped about the body, tucking it well up under the arms and about the leg on the same side. Next have the patient lower the arms to the sides and with the other loose side of the sheet wrap the arms in, care being taken to make the sheet fit snugly about the neck to prevent draughts of air from cooling it. The blanket is now quickly wrapped about the whole body in such a way as to bring the coverings in close contact with the body everywhere. For additional warmth another blanket or quilt may be laid over all and tucked in close about the neck and legs.

Rendu prefers the wet sheet pack to the Brand bath in acute febrile disorders, not only because it aids in the elimination of the toxins present, but because of its quieting effect on the central nervous system. In pneumonia it is one of the best procedures available because of the relief it gives to the heart through the tonic action upon the vasodilators, and the derivative effects upon the congested lung. For its antipyretic effects the pack may be repeated by rewringing the sheet from the cold water. The sheet need be changed only when it has reached the temperature of the patient's skin, which may easily be determined by slipping the hand between the wet sheet and the skin. For its eliminative effects the patient may be left in the pack from one or two hours, or longer. For tonic or antipyretic effects 10 to 20 minutes should be the time.

Cold Friction.*—By this term is designated a procedure which consists in the application to the surface of the body of a series of partial wet rubbings, one part after another being taken in systematic order until the whole body surface is brought into cutaneous reaction. Two or three Turkish towels and a bowl of cool, cold, or very cold water, and a mit consisting of rough material such as Turkish toweling or mohair cloth, are required.

The head and face and neck should first be wet with the cold water, or a cloth wet in cold water is placed over the face. With the mit on the hand and dipped in the cold water begin with a small portion of the body surface, preferably an arm, and proceed to rub the surface until it is reddened, redipping the mit one or more times. When a good reaction takes place as manifested by a crimson redness, the part is quickly dried, friction being used to still further aid reaction. Next proceed with the other arm, the chest, abdomen, legs, and back, securing complete reaction in each part before proceeding to the next.

The effect of stimulating the peripheral nerves by cold friction is to produce profound reflex effects upon the nervous system, the heart, and the glandular structures; and, according to Winternitz, cold applications increase the number of blood corpuscles both red and white, the increase being due not to the sudden creation of new blood-corpuscles, but to the contraction of the visceral blood-vessels whereby a great number of corpuscles which have collected in the liver, spleen, and other organs, are driven out into the general blood stream.

*Kellogg's "Rational Hydrotherapy."

Crawford has shown that cold baths increase the contrast of color between the arterial and the venous blood, the natural result of increased tissue activity and oxidation. That general cold baths increase the alkalinity of the blood has also been demonstrated by Strasser.

Elimination.—In dealing with the etiological indications for treatment in pneumonia measures which act as diaphoretics, diuretics, and laxatives should be considered. As a diuretic, water internally in amounts of four to eight ounces every two hours. If it cannot be taken by mouth, enemata of normal salt solution may be given high into the colon, or by the constant method of Murphy. Of diaphoretics citrate of potassium in hot water, hot lemonade, hot water bags, mustard foot baths, all are useful in stimulating perspiration.

When the apex beat is feeble the first sound weak, and the accentuation in the pulmonary area begins to weaken, stimulation in the form of the ice-bag to the precordia should be resorted to. While alcohol, the commonly used drug for heart stimulation in pneumonia, lessens the work of the heart by its action on the vasodilators, according to Hare's experiments, it also lessens the ability of the heart to do the work. Digitalis, on the other hand, while it increases the strength of the heart beat, also increases the load on the heart by its action on the vasoconstrictors. Cold, however, increases the working power while at the same time it diminishes the work.

In concluding this brief and perhaps one-sided paper, I do not claim to have covered anything like all the therapeutic indications of a disease that is so many sided. I have not attempted to go over the list of drugs which must be made use of to meet the symptoms as they appear. However, with the free use of rational measures I claim that there is less indication for medicinal treatment, and if medicine must be given to satisfy the friends or relatives it would be better to give a placebo than to drug needlessly.

It is not claimed that fresh air and hydrotherapy will cure every case, but the advantages to the patient as enumerated above are very great and are easily obtainable.

DIAGNOSTIC POINTS IN THE RECOGNITION OF PERFORATED GASTRIC AND DUODENAL ULCERS.

By BENJAMIN T. TILTON, M.D.,

NEW YORK.

While the early recognition of perforation of an ulcer or abscess into the general peritoneal cavity is essential to successful treatment, we must not be satisfied with this diagnosis until we have determined also the location of the perforation. It is not sufficient to know that a general peritonitis is developing or has developed as the result of some perforation. We should determine with all possible care the exact starting point of the peritonitis. This is of great practical importance for the outcome of our operative measures. If we know the exact location of the perforative lesion we shall waste no time in enlarging a wrongly placed incision in the abdominal wall, in making perhaps a second or even third incision, and in searching blindly about through the abdominal cavity for the site of the perforation. We shall spare the patient unnecessary mutilation and shock from manipulation and exposure of the abdominal contents. We shall also be better prepared to treat what we expect to find.

Perforation of the appendix or of an appendicular abscess has now become an easy condition to recognize. Its great frequency, together with the usually typical symptoms that accompany it have made the diagnosis a comparatively simple matter. Next to perforation of the appendix, that of a pyosalpinx is probably the most common cause of general peritonitis. The recognition of this also offers little difficulty. Third on the list, but far less frequent, is perforation of a gastric or duodenal ulcer. Its frequency is, however, much greater than was formerely thought, and to-day it has to be taken constantly into consideration in determining the cause of a general peritonitis.

The recognition of perforation of a gastric or duodenal ulcer is sometimes easy, at other times very difficult. This difference is due in part to the obscureness or prominence of previous ulcer symptoms and in part to the presence or absence of certain manifestations characteristic of perforation. It is easy, for example, to make a diagnosis of perforation in the case of an ulcer which has been recognized and is under treatment. On the other hand, it may be difficult in a latent or unrecognized ulcer where there have been perhaps no symptoms to draw the attention to the real site of trouble. In the same way it may be easy to diagnose a case of perforation which has been observed from the beginning and in which all the cardinal symptoms are present. This is not true of cases which come under observation 24 hours after perforation with the initial and typical symptoms obscured by those of peritonitis.

The importance of the history in these cases cannot be too strongly emphasized. When there is the least probability that an ulcer of the stomach is present and has perforated, the patient and his friends should be very carefully questioned as to previous stomach symptoms typical or not of gastric or duodenal ulcer. Superficial questioning of the patient before operation often gives negative results as regards a gastric history, and the stomach is not thought of as the point of origin of the perforative peritonitis. The result of the history-taking is often very different after the operation when we have found an old ulcer of the stomach or duodenum that has perforated. Questioning now the patient or his friends we can usually get a history of digestive disturbances which may or may not be typical of ulcer and which may have been present years before and perhaps almost forgotten.

This vague history may be that of pain in the epigastrium associated with the ingestion of food, occasional vomiting, and very rarely vomiting of blood. In some instances these dyspeptic symptoms may have required treatment, in others not. The patient may have completely recovered from them months or years before the perforation or he may have had occasional attacks of the same indefinite kind up to the time of the perforation. Perforation of an ulcer that has never given rise to any gastric symptoms is, I believe, extremely rare. Careful questioning of the patient or his family either before or after operation will almost always bring out some facts, forgotten perhaps, suggestive of ulcer. It is more common for an ulcer of the duodenum to perforate in an individual in perfect health than is the case in ulcer of the stomach. The former is rare in women.

The history of the onset of the symptoms is often very characteristic and should be obtained in complete detail. There is usually a sudden sharp excruciating pain in the epigastrium. Dieulafoy calls it "le coup de poignard péritonéal." When it comes out of a clear sky, as it usually does, its onset is very striking. This initial symptom may occur when the patient is at rest or may be preceded by a strain, muscular effort, blow, etc. One of my patients was in the act of hanging up a window curtain when seized with the pain. Another was lifting a heavy weight. It is easy to understand that an impending perforation can be hastened by any factor which produces a contraction of the abdominal muscles. The mere fact that such a slight traumatism precedes these stormy symptoms of perforation suggests the presence of some pathological condition within the abdomen such as an ulcer.

The location of this sudden and severe pain is almost constantly the epigastrium or its vicinity. The site of the perforation may determine the exact location of the pain. If situated at the pylorus, or in the duodenum the pain is most likely to occur to the right of the median line. In perforations of the cardiac region the pain is felt on the left side. It is the initial location of the pain that is important as it later becomes generalized with or without a point of greatest intensity. This point is usually the epigastric region in perforation of the stomach, while in duodenal perforation it is often the right iliac fossa. For this reason the resemblance to appendicitis may be marked. Associated with the pain there is always more or less collapse. This may be a very pronounced symptom and persist up to the time of death. "The rapid appearance of collapse following sudden excruciating pain in the epigastrium in an individual in perfect health compels the diagnosis of perforation of the stomach or duodenum" (Auffray).

Examination of the abdomen shows it to be usually retracted (scaphoid) and palpation reveals a marked rigidity of the muscles. Particularly the recti above the umbilicus show this marked contraction which is board-like in character. The retraction of the wall seems to be particularly marked in perforation of the stomach. This may be due to the intimate connections of the latter with the diaphragm, which being maintained in forced expiration by the same reflex action which contracts the muscles of the parietes draws the stomach upward. The latter thus rests fixed and immovable between two tense muscles (Roux). This retraction does not last long—it disappears after 24 hours and often before. The muscular rigidity, however, persists.

Tenderness on palpation of the abdomen is usually marked. Like the pain it is at first localized over the site of perforation but some hours later becomes more diffuse. Even now a point of greatest tenderness can usually be made out in the epigastrium. If the point of initial pain and the point of greatest tenderness are located in the epigastrium, it is highly probable that the stomach is the affected part. On the other hand, the stomach must not be eliminated whatever may be the site where the symptoms are most marked. A careful comparison of the different regions should be made in order to determine the important diagnostic point of the location of the greatest tenderness. In duodenal perforation this point may be in the right iliac fossa resembling acute appendicitis.

Disappearance of the liver dullness is of limited value in the diagnosis of perforation of the stomach or intestine. It is of no importance after 24 hours as it can be caused then by interposition of a distended intestine between the liver and abdominal wall. Persistence of the liver dullness is perfectly possible with perforation of the stomach. The amount of gas that escapes through the small perforation may be so slight that it does not make its

presence evident. Furthermore, the existence of adhesions may make it impossible for an appreciable amount of gas to collect between the liver and the abdominal wall.

It is a striking peculiarity of perforation of an ulcer of the stomach that vomiting during the first 24 hours is a rare symptom. If it does occur, it is most likely to take place at the outset and then stop. Brunner found initial vomiting in a third of the cases, Stadwell in 70 per cent., Finney in 40 per cent., and Fenwick in 29 per cent. The vomiting that occurs after 24 hours is due to peritonitis. Traube thinks that the absence of vomiting in perforation of the stomach is due to the fact that the patient vomits, so to speak, into his peritoneal cavity instead. It is difficult to estimate the diagnostic value of this absence of vomiting, but it certainly should be noted and taken into consideration particularly if other symptoms point toward the stomach as the site of the perforative lesion. The persistence of vomiting is, of course, not incompatible with the diagnosis of perforation of the stomach.

The presence in most acute cases of a "free interval" is of diagnostic importance. There is during this period an improvement in or cessation of all symptoms. The patient has recovered from the shock, his pain is slight, there is no vomiting, the pulse is slow and of good volume, the expression is good, and there seems to the inexperienced a marked change for the better. This condition of affairs is most deceptive and it is easy to be led into the error of postponing operative intervention. There is great danger in this, however, as this usually represents the most favorable time for operation and delay means the gradual progression of a peritonitis. There is one symptom that can be relied upon even now to make the diagnosis, viz., the muscular rigidity in the abdominal wall. This is invariably present and should be given great weight. It is at this time too that the history of the sudden stormy onset and the location of the pain should be given due consideration.

Early diagnosis of perforation of a gastric or duodenal ulcer renders the prognosis of operative interference decidedly brighter. Statistics show that early operation is followed by much better results than late ones. Körte, for example, operated on 10 cases from 1890 to 1900 with a mortality of 90 per cent. These cases all came to him at a late stage with well-developed peritonitis. From 1900 to 1907 he operated on 17 cases with a mortality of only 23.5 per cent. These cases had been diagnosed, as a rule, at a much earlier period. Of the 14 cases that have come under my observation, 8 were operated on within 12 hours with 5 recoveries—a mortality of 37.5 per cent. The other 6 cases did not come to operation until from 12 to 72 hours after perforation. Of these 2 recovered—a mortality of 66 per cent.

It is thus evident that nothing will improve so much our statistics for the operative treatment of this, the most serious complication of gastric and duodenal ulcer, as an early diagnosis. With our present knowledge of this condition such a diagnosis should be possible in almost every case, provided the case is seen early before the development of a general peritonitis which obscures the clinical picture. It is in the hands of the general practioner then that the fate of the patient really rests, and it is to him that we must appeal for earlier diagnosis in order to secure still greater improvement in our operative results.

121 East Thirty-eighth Street.

NOTES ON THE HOSPITALS, TAKEN DURING A VISIT TO SCANDINAVIA.*

By J. B. BOUCHER, M.D.,

HARTFORD, CONN.

SURGEON TO ST. FRANCIS' HOSPITAL.

If Americans visit the Scandinavian Peninsula, and expect to find it behind the other European nations, they will be very much disappointed. It was the writer's good fortune during the past summer to visit the three capital cities of Norway, Sweden and Denmark, which are not only equal to, but in many respects superior to many of the other European cities.

After a pleasant voyage of eleven days from New York, we landed at Christiania, the capital of Norway. It is a city of about two hundred and fifty thousand. It is beautifully located on the Christiania Fjord, at the foot of pine-clad hills. The buildings are large and substantial, the streets broad and clean, and the whole air of the city one of prosperity. The University of Norway, founded in 1811, by Frederick VI, is located here, and is a very flourishing institution. It has about fifteen hundred students in attendance. The city is well supplied with hospitals. The Municipal Hospital, of four hundred beds, is a modern building, and doing excellent work. It is supported by public taxes and charitable donations. A visit to this institution enabled us to meet Dr. Franze, the surgeon in charge. A morning spent with him convinced us that they were doing modern, up-to-date work. He showed us through the hospital and spacious operating rooms. My attention was particularly called to the large number of tuberculous surgical cases in the wards. I have never seen as large a proportion in any hospital which I have visited.

The State Hospital is the oldest institution, has about five hundred beds, and is connected with the University. Prof. Nicholison, now seventy-four years old, the senior surgeon, has retired. His successor has not yet been appointed. Prof. Strumm is the other surgeon, and a man of recognized ability and fine reputation. His first assistant showed us through the hospital and described their work on surgical cases, which is quite equal to the other hospitals which I have visited in Central Europe.

Besides this institution, there is a large Sisters' Hospital, where all physicians are allowed to treat patients. It is also a modern and well regulated institution.

The visitor to Norway is at once impressed by the large number of tuberculous cases which seem to be present everywhere. Likewise, the numerous sanatoria for the treatment of tuberculosis, one of which is situated on the hill a few miles above Christiania, at Holmenkollen. It is reached by trolley car, plus a short walk. It is in a most beautiful location, the road leading to it, for the most part, being cut through solid rock, and commanding a beautiful view of Christiania and its harbor. The sanatorium situated on this mountain, overlooking the city and bay, seems to be an ideal place, as it is surrounded by forests of hemlock, but the sun shines through the broad, glass windows of the piazzas. The treatment there consists of fresh air, sunshine, and wholesome food. I doubt if I have ever seen a place where the combination could be more enjoyed or better attained.

The great prevalence of tuberculosis, not only in Norway, but all through Sweden and Denmark, may be accounted for in part by the long, cold winters,

*Read before the Surgical Section of the Hartford Medical Society September 28, 1908.

which necessitates living indoors most of the time.

A ride of twelve hours in a comfortable train, with good sleeping car accommodations, took us from Christiania to Stockholm, the capital of Sweden, and by all means the most beautiful and charming city in Scandinavia. In fact, I would class it as being the second or third city in Europe, in point of location and general beauty. It is the seat of government and has a population of about three hundred and fifty thousand. The city is beautifully located on islands, plain and rocky hills, surrounded by water in all directions which has given it the name of the "Venice of the North." This beautiful city, composed of such fine buildings, palatial homes, and magnificent theaters, is not behind in its hospital appointments, either in quality or in quantity. The hospitals of Stockholm deserve as high a place as those of any city in Europe. Many of the larger medical buildings are situated at Kungsholen, the Western suburb of the city.

Among the many hospitals in this city, the writer visited the large hospital Serafirma Lazzarette, which contains several hundred beds and is connected with the University and Medical School all in the same square. It is a modern institution, made up of a large number of buildings, the medical, surgical, and various departments being kept separate, but all in the same square. Prof. John Berg of international reputation, is the senior surgeon. He is now sixty-one years old. He retires at sixty-five on a pension, that being the law in Sweden, unlike Norway, where they can retire at pleasure. I had the pleasure of meeting this polished gentleman, who showed me through the whole institution, the medical schools, and spacious laboratories, the large dispensary; and also had the pleasure of seeing some of his work. He speaks good English, his grandmother having been an Englishwoman. He not only inherits the language, but many of the good traits of the English. I had the pleasure of visiting his clinic three days, where I saw splendid, up-to-date work by his associate, Dr. Key. Among the various operations which I witnessed were two for resections of the stomach, one for hourglass contraction, and several cases of joint and bone surgery, as well as general abdominal work. When he resected the stomach, only a small portion being left, he did the anterior long loop, plus the Roux enteroanastomosis. One of the cases was of special interest. A woman about thirty-five years of age had been treated several years for gastric ulcer, and had been given silver nitrate, and her tissues had been so stained that she was of a dark slate color from head to foot. An interesting point about the case was that when the abdomen was opened, the stomach and all the internal organs were of the same dark hue, but not as marked as the skin. I believe this discoloration will be permanent. I am sure the picture presented will deter me from the use of this agent in medical treatment.

In this same institution they have the most complete *x*-ray apparatus I have seen. The work is under the charge of Dr. Gosta Forssoll, whose entire time is devoted to it. He showed me a number of skiagraphs, by which he was able to diagnose tuberculosis of the kidneys. The picture even showed the ureters. I saw a number of cases of stones in the kidney, ureter, and bladder which were so clear that they could not possibly be mistaken. One patient, a pregnant woman, was photographed that day, as she had had a symphyseotomy a few years before and they wished to determine if there had been osseous union. The *x*-ray showed that it was not, so they decided the case could go on without interference.

Another case was one in which he made the diagnosis of hourglass contraction of the stomach and located the contraction perfectly. He gave the patient one-half pound of bismuth, and took a picture which showed it in the fundus, along a narrow streak (the contraction), and finally in the pyloric portion, which made the picture complete. He then drew a diagram with blue pencil, and sent it to the operating room, where the diagnosis was confirmed by operation. Dr. Forssoll has invented a special light box in which the light is evenly distributed and adds materially to the view of the picture.

We also visited the Sabbatsburg Hospital, and witnessed several gynecological operations by Dr. Forstner; one, an ovarion cyst in a very old lady, which was done successfully with spinal anesthesia. A short visit to the Deaconess' Hospital, in charge of Dr. Toll, formerly of Minneapolis, was much enjoyed. We saw him do a nephrectomy; he then took us through the building, which is a strictly modern institution, supplied with all the modern apparatus, and various baths, Turkish, spray, etc. Much attention is paid to hydrotherapy in this institution. They have a beautifully arranged operating room and special boilers with coils which lead into the operating room. From these coils they can draw at the correct temperature not only sterilized water, but sterile salt solution. The hospital is managed by a church society. It commands a position on a high ledge overlooking the city.

The medical training in Scandinavia is very exacting, especially in Sweden. Prof. Berg informed me that it required from eight to ten years' study for the average man before he could practise. While there are three other medical schools in Sweden, all students must spend a certain number of years in the University of Stockholm, regardless of the medical advantages obtained in other Swedish institutions. A visit to the city impresses the American traveler with the thoroughness of their work, and leaves an indelible remembrance of the able physicians and of the kind and courteous treatment received.

Twelve hours by rail, on a comfortable train, brings us to Copenhagen, the capital of Denmark, which has been properly termed, "The Athens of the North." It is certainly entitled to this distinction, when one considers the collections of art, not only the great collection of the famous Thorvaldsen, which cannot be surpassed, but the magnificent donations of private citizens which have enriched her museums and mark the loyalty of the Dane for the fatherland. Here again, the beautiful capital of Denmark is not backward in the care of its sick. Our first visit was to the Friedericks Hospital, the largest and oldest in the city, built about one hundred and fifty years ago. The hospital has about six hundred beds. This hospital is a venerable relic of bygone days. It is past its present usefulness and is about to be replaced by a large and modern building, which, it is estimated, will require about four years for its completion. Professor Rovsing is the surgical leader in Denmark. He is the senior surgeon at the Friederick Hospital. I did not see him operate there, but accepted an invitation to visit his private hospital which has about forty beds. It is located on the outskirts of the city, near the Finsen Hospital, and is surrounded by shady lawns and rich foliage, where patients can spend their days of convalesence in comfort. He is doing a high class of work. His technique is perfect, but like the rest, or at least, most of European surgeons, he has little regard for incisions, as five to seven inches is not uncommon in a clean case of appendicitis. He has his catgut

arranged on a frame so that it can be sterilized, and not touched, even by the nurse. He cuts it off, one strand at the time, so that no one touches the gut but himself. He is a clever diagnostician, an able surgeon, and a most obliging and courteous gentleman. He showed me his well-appointed laboratory, his *x*-ray outfit, also one of the largest collections of stones of the kidney, bladder, and gall-bladder that I have ever seen. He keeps them in large, glass cases in dishes, where one can see all shapes and sizes. In two dishes he has gallstones of pearly whiteness, the first of that color which I have seen.

The next day we visited the Municipal Hospital of one thousand beds, in charge of Prof. Tscherning. It is built in the form of the letter "H" with an extra bar across the top. While the building is over forty years old, it is a fairly modern institution and doing good work. They have twenty-four resident physicians and a training school for four hundred nurses and different departments for medicine, and the specialties. Prof. Tscherning, with one other surgeon, looks after the entire work. They are paid by the city and receive about four thousand krone, or one thousand dollars, a year. Evidently, the income of noted men in that country is very limited. In a visit with him through the wards, I was surprised to see him dressing patients, applying bandages, and sterilizing the field of operation, etc., the work done by our internes. I saw him do several operations, in one of which I was especially interested—the removal of the Gasserian ganglion. He did it very nicely and completed the work in less than one hour without hurry or worry. In fact, no one seems to be in a hurry. Back of all the surgeons a high stool is placed, as much of a fixture as the operating table. Chairs are located in front of the wash stands, where the surgeons and assistants sit leisurely while washing and sterilizing their hands, which they do in a most thorough manner, averaging not less than fifteen minutes in washing and preparing before each operation. Most surgeons wear rubber gloves, but not at Prof. Berg's clinic in Stockholm. The surgeons seem to have ample time for everything and always time to treat the visiting American with every kindness, courtesy, and attention, which becomes almost distressing to the visitor. For example, Prof. Birg's assistant, Dr. Waldenstrom (who has visited America) telephoned personally to the hospitals in Stockholm every evening, obtaining a list of the work and the men operating the following morning, and then sent a special messenger to my hotel every morning with a list of my work marked out for the day and a nice little note expressing the wishes of the head of the clinic to meet me. This note, I found under my bedroom door every morning, so that my work was mapped out for me before leaving my room.

In all my travels abroad, I have never had the same amount of courtesy and attention shown me. They inquire about our American methods, and while I do not think they are prompt in accepting all our newer ideas, they have a great deal of respect for American surgery and Americans surgeons.

The last hospital to visit, but by no means the least, was the famous Finsen Hospital at Copenhagen, which has attained such a world-wide reputation for its light treatment of lupus. This institution is located among shady trees on the edge of the town, and surrounded by private villas. It consists of two buildings, the laboratory, and the clinical building. At the left one sees a little red building, hardly noticeable, where Finsen worked out his ideas.

I had the good fortune of sitting at the table beside Dr. Rehm, who has charge of the institution and sees all patients daily. They pass up to him after being photographed. He looks at the lesion with a glass and marks (with a wax pencil) the exact spot to which the light is to be applied. The patients are then taken to the treatment rooms, after which bandages are applied. They have treated some fourteen hundred cases of lupus. Their percentage of recoveries is as follows: In the recent superficial cases they cure eighty to ninety per cent.; in chronic deep-seated cases, with bone involvement, about fifty per cent. They see about three hundred cases a day. The treatment varies, but many of the cases are long and stubborn and require from one to two hours daily exposure with the Finsen light. While it is true some cases are cured in a few weeks, it requires from months to years in many cases.

The light is applied to a small place each day, not larger than a silver half dollar. A nurse holds the light in position, her eyes being protected with glasses; they keep their attention constantly on the field. Therefore, it is not only a tedious treatment, but a very expensive method. They give treatment to thirty-five or forty in the same room at one time. There are seven of the light machines in one room. Each of the machines consists of a certain electric arc which furnishes light for four long, brass tubes fitted with quartz lenses. A bed, on which the patient lies, is wheeled under each tube. The ringed area on the face of the patient, to which the rays are to be applied, is first covered with a water compress to prevent burning, and then the light is kept constantly on the spot for one hour or more. The institution is branching out in its work, treating eczema, acne, and many other skin lesions by light. They have in the last two years been treating heart and arterial lesions with a high power light of one hundred and twenty amperes. The naked patients are placed near the light, which is so powerful one cannot enter the room without being protected by dark glasses. The light is allowed to penetrate the body for about five minutes until the skin becomes red and congested. They are then given baths. The length of treatment is increased from five to fifteen minutes. Thirty-four patients can be accommodated in the building besides the large number that come there for treatment. This treatment has been carried on for over two years, and while it is somewhat experimental, they claim good results. In going about this institution, it is surprising to see the deformities and horrible facial expressions. Many without noses or ears have been going about for years. Some with the mouth gone, with only a ragged hole left. An army of sufferers from this hideous disease swarm to this life-saving institution. Scores of people are met daily on the streets with their faces all healed, but with the marks of the horrible condition that made them seek this haven of relief. Dr. Rehm informed me that they had practically given up the use of *x*-ray treatment in cancer, excepting a few superficial epitheliomas of the face, but in cancer of the lip, breast, and deep cancer, they advise immediate surgical operation, and then follow with the *x*-ray treatment after the growth and glands have been removed. He assured me that not only in their work there, but from what he had seen in his travels in England, Germany, and France, he felt the *x*-ray must be considered a failure in the treatment of cancer.

As the visitor beholds the great work done at this institution, it recalls for a moment the history

of its founder and its master hand. A visit to the room laid out as a museum for the early works of the master is well worth seeing, and has in it a pathetic side. There we behold the picture of the founder, who died at forty-three of heart disease, over which he had experimented for some time, with his light treatment. His last manuscript, unfinished, lies on his desk. Around the room are arranged the different apparatus with which he experimented and developed step by step from the sun glass to the present complicated mechanism. We recall how he won the Nobel prize in 1903, of thirty-eight thousand dollars, with which, and all the rest of his means, he built the present institution. In the early morning of his life, so full of promise, he was cut off, leaving a wife and four children penniless, the oldest ten, and the youngest two. They are today cared for by admiring friends. When he knew his hours were numbered and the end was in sight, he called together his assistants and calmly laid out the work for each—the completion of which required three years.

It is unnecessary to say his memory is cherished by the Danish people and by the hundreds of wretched victims who have been cured of their ailments; mankind has been benefited because he lived.

THE LYMPH PROPULSION AND EXCHANGE.*

By GEO. N. JACK, M.D.,

BUFFALO, N. Y.

This subject as here presented has been worked out by injecting the peritoneal region of dogs with highly colored solutions. Five minutes only being allowed for this paper, deductions and conclusions will be reserved for future opportunities.

In studying the lymph propulsion it must be borne in mind that the lymph, unlike the blood, does not go rapidly coursing through the body through fixed and unobstructed channels with a high reserve pressure back of it. It therefore is more appropriate to use the word *propulsion* rather than *circulation* in studying or speaking of the forces that propel, and of the movements of the lymph.

The lymph then, unlike the blood, goes slowly through the tissues of the body, on its mission of nutrition and body-waste absorption, slowly finding its way, or being slowly propelled, from lymph space to lymph space, between tissue cells, or by chemotaxis, exosmosis, capillarity, diffusion, or dialysis, through thin animal membranes or connective tissue, as its chemical composition changes, as a result of stagnation or partial absorption to favor one or all of the above named laws of transudation, until finally it finds its way, through a slow but physiological propulsion, to the great lymph and blood center of the body, or the lung tissue and lymphatics of the thoracic cavity. Just as sap works its way from the root of a tree to its leaves for oxygenation and vice versa, so does lymph work its way from the uttermost extremities of the body to the lungs.

The forces that tend to keep up this normally procrastinating, sluggish, chemical change-awaiting, lymph propulsion, are: (1) Absorption. (2) The muscular contraction or activities of the body and the force-pump-like action of moving articulations on the synovial cavity fluids. (3) The lymph-aspirating action of the thoracic cavity upon the thoracic and other lymphatic ducts and vessels.

*Read at a meeting of the Medical Society of Erie County, October 12, 1908.

(4) Last, but, although never before mentioned, not the least of the physical, chemical, and mechanical forces at work to perfect the propulsion of the lymph, is the anatomical and physiological fact that during respiration some lymph is aspirated into the mediastinum through the peritracheal, periesophageal, and perivascular lymph spaces of the trachea, esophagus, and the veins that enter the mediastinum, the chief of which are the inferior vena cava and the right and left innominate veins.

The lymph thus conveyed to and aspirated into the mediastinum and other midpleural lymph spaces, also that reaching the same region through the lymphatics of the diaphragm, is absorbed by the pulmonary parenchyma or glandular lung tissue, through the open stoma or lymph mouths of the visceral pleura.

Some of the lymph is aspirated into the lung tissue from the peritracheal lymph spaces along the peribronchial lymph spaces. The rest of the lymph reaches the lung tissue directly through the blood as that conveyed by the thoracic duct.

In the lung the lymph is mixed with the blood and soon again through the glandular action of the lung tissue is separated or classified; some remaining in the blood, to be taken on by the blood current; some being absorbed by the lung lymphatics and conveyed to the mediastinal and bronchiotracheal glands; and finally some finding its way along the perivascular spaces of the pulmonary arteries, reaches or is aspirated into the pericardium from which it is forced, together with the lymph that reaches the pericardial space by absorption through the pericardium, with each heart beat along the perivascular lymph space of the aorta and its arterial branches, to feed or nourish the tissues of the body.

The propelling force imparted to the lymph along the periarterial lymph spaces by the action of the heart in the water-bag like pericardium is encouraged and kept up throughout the body by the aspirating or propelling effect that the pulsating arterial walls have on the lymph in their periarterial lymph spaces, said pulsation accompanying each heart beat or arterial pulsation that can plainly be felt at the uttermost extremities of the body.

Structurally this lymph propulsion and exchange is encouraged by the peritoneum being adherent to the surface of the diaphragm below, and the pleura closely adherent to the upper surface of the diaphragm, and the two connected by lymphatics and other openings or holes through the diaphragm, with the fact that the visceral pleura and sponge-like absorbent lung tissue are closely held to the diaphragm by the midpleural vacuum-like pull and the bands of the pericardium.

Pathologically this law of diaphragmatic lymph propulsion and gland-like lung tissue exchange can be illustrated no better than by the relief from the dyspnea of the toxic asthmatic through a compensatory diarrhea, and by the following post-mortem and clinical findings:

1. The pulmonary tuberculous infections that have been traced from the intestine and peritoneum.
2. The septic pulmonary conditions following abdominal operations.
3. The secondary pulmonary complications of appendicitis, or other inflammations of the bowels or a suppurative peritonitis.
4. The pneumonia following puerperal infection.
5. The respiratory conditions secondary to typhoid fever.
6. The right side pleurisies produced by the cholecystitis of gallstones.

7. The subdiaphragmatic abscesses and other abdominal morbid states that progressively involve the serous surfaces on first the abdominal and second the thoracic sides of the diaphragm and ultimately result in a basic pneumonia, pleuropneumonia, empyema, pyopneumothorax, or a pulmonary tuberculosis.

8. The rapidity with which certain pleural effusions are absorbed by the pleura and lung tissue.

9. The chylothorax following a chylous ascites.

10. Chylopericardium or milky effusions into the pericardial sac that are the result of a transudation from a chyliform effusion present in the left pleural region.

11. "The fact emphasized by Byron Robinson that the peritoneum is a great lymph-sac explains the quick absorption of septic material and the rapid spread of infectious processes. If the exudate clots and blocks the lymph channels, absorption is slow and life may be saved. If it does not clot, absorption is rapid and death is certain. Whether it clots or not, depends on the nature of the bacteria present. Fowler, impressed by the fact that absorption takes place *most rapidly from the diaphragmatic region* and least rapidly from the pelvic region, advises placing the victim of peritonitis in bed, with his head and body elevated.

"The lymph from this region reaches the mediastinal or diaphragmatic glands. The serus surface of the diaphragm is the region chiefly efficient in absorption from the peritoneum, and *there is a current in the peritoneal cavity directed toward the diaphragm*. Absorption is very rapid from the peritoneal cavity. Fluid equalling from 3 to 8 per cent. of the body weight can be absorbed in one hour." (Gray's Surgical Anatomy.)

A NEW METHOD FOR ADMINISTERING ETHER AS AN ANESTHETIC.

By A. L. Soresi, M.D.,

New York.

I wish to bring before the medical profession a method of administering ether which, from the little experience I have had with it, appears to have many advantages. I will first describe the method and subsequently expose its merits.

A special mask is used, which is made of small metal tubing, which through perforations on its inner surface carries the vapor to the patient's mouth and nose. The mask is connected by means of rubber tubing, with a Wolf's bottle containing warm water and the vessel of ether, and the latter, by means of a glass Y-tube, with a tank containing oxygen and one containing compressed air. The ether is contained in a Wolf's bottle of good size, so that the pressure of the air may not force out any liquid ether in this way. Before entering the mask, the ether passes through warm water, thus becoming saturated with vapor.

The anesthesia is started by opening the can containing the oxygen, and placing the mask uncovered over the patient's mouth and nose. When the patient begins to lose consciousness, the bottle containing the ether is placed in warm water, the oxygen is shut off, and the mask is covered with a towel.

The patient is now receiving only pure ether vapor. When he is completely under the anesthetic, the bottle containing the ether is removed from the hot water, and the can containing compressed air is opened, the amount being regulated as required.

The Y-tubing shown in the illustration between the vessel containing warm water and the other can is to facilitate the giving of oxygen direct if needed. Ordinarily the open end is closed with a cork. The illustration is more or less schematic; in actual practice the ether and warm water bottles are attached to the cylinder of compressed air so as to make the apparatus more compact and portable.

The advantages of this method are:

1.—The patients are anesthetized more easily than by other methods, some even escaping the excitation stage.

2.—There is very little, if any, irritation to the air passages.

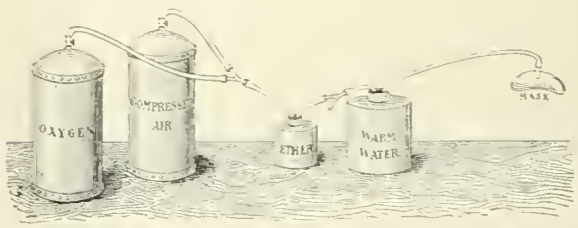
3.—There is no need of employing any other anesthetic to usher in the anesthesia.

4.—At the beginning of anesthesia, the mask is open, thus avoiding the feeling of suffocation which so many patients experience with a closed mask.

5.—There is a minimum of ether inhaled by the patient, which is proven by the fact that as soon as the ether is stopped the patient becomes conscious.

6.—With this method of administering ether, the patient is always inhaling the vapor in definite proportion, while in other methods the patient at times, that is, when ether is introduced into the inhaler, receives too much ether, and at other times too little.

7.—In operations on the upper part of the body, the anesthetist does not disturb the operator or his assistants, as his presence at the head of the patient



is not necessary, either to hold the mask or to replenish the ether can.

8.—This method of administering ether is so simple and so devoid of danger, that any intelligent person can continue the administration after the patient is once under. This is an advantage in rura districts where an experienced anesthetist, or even a physician to give the anesthetic, is not available.

9.—In operations on the face, a sterile mask may be employed, and at the proper time can be covered with a sterile towel.

10.—The patient's face or eyes are not injured.

11.—If the patient needs oxygen, there is no trouble in administering it.

12.—With my open mask, the patient receives only ether and pure air, and does not breathe any of the impurities coming from his own respiration, which in my belief is one of the most active causes of vomiting.

13.—The anesthetist has no trouble with the dropping of the anesthetic, replacing and holding the mask, refilling bottles, etc., but can give his entire attention and help to the patient.

40 Washington Square, South.

Researches on the Hemolytic Power of Placental Extract.—G. Ballerini has made experiments on the hemolytic power of placental extract as compared with extracts of other tissues. The existence of this power is undoubted in placental extract, manifested not directly but after passage through animals. This power does not appear to differ from such power as found in the other tissues so as to be of any practical value.—*Annali di Ostetricia e Ginecologia.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 19, 1908.

THE WORK AND NEEDS OF THE NAVAL MEDICAL CORPS.

THE annual report of the Surgeon-General of the Navy for the fiscal year 1908, recently issued, shows a most gratifying improvement in the general health of the naval service over last year. There was a great increase in the number of enlistments during the year, caused in part, it may be, by the report of the coming cruise of the Atlantic Fleet around the world, but chiefly by the business depression which threw so many men out of work. Nevertheless, in spite of this increase of over 2,000 men, from 41,690 to 44,083, there was a decrease of admissions to the sick list for the year of 2,038, or a decrease in ratio per 1,000 of 91.83. It is interesting to note that the morbidity rate was least among those at sea, somewhat greater among those on shore duty at home, and greatest among those on shore duty beyond the continental limits of the United States. The most frequent cause of disability was, as usual, venereal disease, next coming traumatisms of various sorts, then tonsillitis, epidemic catarrh, malaria, bronchial affections, rheumatism, gastro-enteric disorders, the exanthemata, and finally other infectious diseases.

The number of vacancies in the Medical Corps is 51, a slight improvement over last year, when there were 58. It is believed, however, that the greater inducements for service provided by Congress last spring will attract an increasingly greater number of men so that before many years the Corps will have been recruited to its allotted strength. Notwithstanding the need of more surgeons there has been no letting down of the bars by making the examinations easier, as may be seen by the fact that of 97 candidates presenting themselves for examination during the year only 39 received appointments. The examination is not, however, so difficult as this number of failures might imply, for 27 of the applicants were rejected for physical disabilities. One wonders whether this proportion of nearly 28 per cent. of the unsound prevails among recent graduates in general, or whether there is some peculiar reason why the physically unfit should be attracted by the naval service. Very likely some men in delicate health were led to apply for naval service in the hope that sea life might better their condition. The increase in the Medical Corps during the past five years has been in the three lower grades, and there is now the same number of medical directors and medical inspectors with a corps of 345 as there was in 1883, when the corps numbered only 171 all told. This shortage in the upper grades, which Congress seems strangely unwilling to remedy, has caused much inconvenience, necessitating the shifting of work belonging properly to medical inspectors to the surgeons, their proper duties being in turn imposed upon passed assistant surgeons. The Surgeon-General regards the grade of acting assistant surgeon, created in 1898, with considerable favor and wishes it continued. One great advantage accruing to the service from the existence of this grade is that it is often the means of recruiting the commissioned ranks with young men of excellent attainments and fine character who might otherwise have looked upon a naval career as beyond their reach. The services rendered by the newly appointed members of this grade were very satisfactory, and most of them passed through the probationary period in general service and under instruction at the Navy Medical School with a creditable showing.

The Navy Medical School in its development and in the routine work accomplished has fully justified the wisdom of its foundation. During the session of 1907-8 there were, as heretofore, two terms, the first of six months, the second of three. The first, or winter term, was attended by a class of 35 officers, the second, or spring term, by one of 11 officers. Most of the latter had just returned from a full tour of sea duty and were thus given an opportunity to brush up in laboratory technique and in the most recent diagnostic and therapeutic methods. This school, General Rixey says, "represents one of the most potent influences for good which the service possesses. Indeed, the growing efficiency of the work of the medical department in every direction must be evident to all, and this is certainly due in great part to the school. The Bureau's aim is not only to give a finishing touch to the education of young doctors entering upon a naval career and to prepare them for an intelligent application of their professional attainments, but to broaden their knowledge and practical capabilities to include those peculiar responsibilities which devolve upon the naval surgeon. It is believed that the school accomplishes this end."

The first steps have been taken to establish a corps of female nurses in accordance with the authority granted in the naval legislation of the Sixtieth Congress. Miss E. V. Hasson was appointed superintendent of nurses, and it was expected that by October a corps of twenty nurses would be organized and assigned to the several naval hospitals after preliminary training in the Naval Medical School Hospital in Washington.

A bill is to be introduced into Congress reorganizing the naval militia so that it may occupy a position in relation to the navy, which will be in the nature of a reserve, and in such case its medical department will share in the changed statute and will constitute a reserve medical corps for the navy in time of need. Other than this, however, and the force of the National Red Cross, there is no organized body of medical men available for service in the navy, in war or in any other emergency. This, the Surgeon-General thinks, is most regrettable, since it means that in case of war or other emergency there will be no one familiar with the conditions and requirements of the naval service who

can be called upon to come to the assistance of the medical department, which is barely sufficient, or rather actually insufficient, for the needs of the navy in time of peace. It is felt that the important duties of the medical department of the navy should not be left dependent upon an uncertain personnel, and General Rixey therefore urges that, in addition to the limited possibilities of expansion which would be represented by the medical department of the militia under the conditions of its proposed reorganization, there should be a "Medical Reserve Corps of the Navy" similar to that provided for the army. "The creation of such a corps would not add discernibly to the required annual naval appropriation, but it would add materially to the resources of the medical department in the matter of assured efficiency. By such a corps the bureau would find it more feasible to inaugurate that greatly needed change of requiring all applicants for the regular corps to pass through the course of instruction at the Naval Medical School before being eligible for permanent commissions; and by it also the Navy Department would be able to keep in touch with the medical profession throughout the country, and insure adequate and efficient medical services in the navy no matter how great the demand." It is the intention to submit to the department for approval the draft of a bill providing for a reserve corps.

BACTERIOLOGY OF THE COMMON COLD.

Colds are among the most frequent of all the so-called "minor ailments," and are perhaps especially frequent in this country. The reasons for this prevalence of catarrhal states in America have been variously stated. One cause, and possibly the chief cause, is that the houses and offices and public buildings of every description are generally overheated, and especially that the air in them is overdry, rendering those who spend a great part of the day under such conditions peculiarly susceptible to the influence of variations of temperature. It is curious to note that the majority of people look upon the complaint known as catarrhal fever as trifling. "Only a cold," is a stock figure of speech and few realize that from so trivial a source spring diseases which kill and incapacitate thousands.

In the *Lancet* of November 28 and December 5, R. W. Allen has an article which deals with the bacteriology of the common cold, in which the subject is treated in an interesting and to some extent original manner. When defining colds Allen avoids the term "fever," "inasmuch as any rise of temperature is more often than not local and not general; indeed, the true body of temperature obtained either per rectum or by means of the urine is more often than not subnormal." Another feature of some moment in connection with colds is that they are always acute at the outset, but may go on to a chronic stage, persisting for even twenty years, punctuated at intervals by acute exacerbations.

The bacteriology of colds was investigated by the writer with care and patience and his conclusions, though necessarily not definite and even somewhat confusing, throw some light on the matter. The influence of three bacilli and of one micrococcus was traced, *Bacillus friedländer, B. influenzæ, B. septus,* and *Micracoccus catarrhalis.* In the trachea, throat, and nose, several other organisms were isolated, but Allen decided that the above-named were those fruitful of harm.

Little need be said regarding the capacity of *Bacillus influenzæ* and of *Micrococcus catarrhalis* to produce colds, as both these organisms have been definitely shown to be capable of so doing. The claims, however, of the other microorganisms mentioned as a causative factor in the origin of colds have not up to the present time been thoroughly examined.

Among other reasons for Allen's belief that *Bacillus friedländer* is an important factor in causing colds is that an emulsion of the bacillus was spilt in the laboratory where three individuals were working and within a few hours each developed a mild catarrhal attack during which the bacillus was found in the nasal mucus. Other evidence tending in the same direction is given and the investigator seems to have brought forward a fairly strong case against this organism. Allen places the Friedländer bacillus, indeed, in the front rank as the originator of the ordinary cold and furthermore holds the view that this bacillus is probably the sole cause of a chronic nasal catarrh and that the risk of the involvement of the Eustachian tube, middle-ear, and accessory sinuses being considerable, the prognosis in the case of this organism should be very guarded and much greater care should be taken by the patient. The claims of *Bacillus septus* are not so great, as many previous investigators have endeavored to show, though the writer believes that this microbe is the etiological factor in the production of a certain percentage of colds.

In the treatment of colds Allen regards quinine as theoretically about the most useless of any drug in the pharmacopeia, though in practice, especially in combination with ammonia, he thinks it may possibly do some good. The most useful drugs, however, are in his opinion the oil of cinnamon and the oil of eucalyptus, the former being preferable by reason of its better odor and better taste. It should, however, be given in generous doses—20 minims in milk every hour for three hours, then two doses of 15 minims at intervals of two hours, and finally several doses of 10 minims at three or four hour intervals.

He puts most reliance, however, upon vaccine therapy. The best time for dealing with an acute attack is either at the onset or on the third day; inoculation between these times is not advisable as it may produce considerable constitutional disturbance. The appropriate doses are 250,000,000 of *B. septus*, and 125,000,000 of either *B. friedländer* or *Micrococcus catarrhalis.* Should an accurate diagnosis of the infecting organism not be possible, a combined vaccine of the several "cold" organisms may be given. Repetition of the dose is not usually necessary, but should it be, then 500,000,000 of *B. septus* or *M. catarrhalis* may be given at the end of a week, or 250,000,000 of *B. friedländer* at the end of a fortnight.

To secure immunity against colds the author advises the administration of a dose of 250,000,000

of each of the several organisms every four to six months, the first being given three weeks after recovery from the acute attack.

THE SIGNIFICANCE OF AGNOSIA IN THE INTERPRETATION OF PSYCHOSES.

In discussing the pathogenesis of delusions of negation, Denis and Camus believe them to be due to direct cerebral modification. They exclude from consideration the influence of peripheral modifications of the cenesthesia on the ground that the patients they have studied show, with the exception of the delusions, no other loss of the sensibility derived from the viscera; for they manifest appetite and thirst, and respond to the normal calls of urination and defecation. The facts that they react only feebly to the passing of an esophageal sound, that they are sometimes incontinent, and that they often refuse to eat, are attributed by these authors not to a true anesthesia but to the presence of the idea of contrariety or the fixed idea of negation of their organs.

Now this explanation begs the question, for we cannot legitimately exclude peripheral modifications of all the modalities of sensibility in the organs because some of them are conserved. A study of agnosia demonstrates this; for though the earlier observers were content to attribute to the derangement of a special cortical center the failure to recognize objects by palpation, yet later observations tend to show that this incapacity is always a residuum of, and probably therefore due to, a deficiency of one of the modalities of sensibility (Déjerine), even though these latter have become insusceptible to other means of clinical demonstration than that signified by the agnosia. Hence, we may infer that the agnosia which remains is of peripheral source, though its exact components are at present beyond our power of analysis. Before therefore excluding the peripheral causation of ideas of negation, one would either have to prove definitely their origin in the cerebrum, or at least to exclude partial peripheral limitation of the sensibility of the viscera similar to that now known to be at the root of agnosia.

It may be as well to add that we are not here considering the function of symbolia, which is due to a more complex, and indeed intellectual, process. A symbolia, of course, may be contributed to by the lack of information from the periphery; but on the other hand, it often originates in defective cerebration.

Maldescended or Undescended Testicle Complicating Inguinal Hernia.

While not a common associated phenomenon, undescended or improperly descended testicle is not a rare complication of inguinal hernia, and opinions differ as to the etiology of the disorder, as well as to the indications for surgical intervention and the best mode of procedure. As a result of observations made in 126 cases of this kind operated on and of a careful study of the reports of other surgeons, William B. Coley, writing in the *Annals of Surgery* for September, 1908, concludes that the undescended testicle is almost invariably of little or no functional value. It is often the source of considerable pain and it is more susceptible to inflammatory attack than the normally descended testicle and possibly, though not certainly, more susceptible to malignant disease. In Coley's opinion the undescended testicle should never be sacrificed in the case of children and rarely in that of adults, as it is possible to effect a radical cure of the hernia without removal of the testicle. In childhood the testicle is of value in determining the male characteristics of the child, as well as in promoting the general health; while in the adult it should be retained for its influence on the mental state of the subject if for no other reason. Coley recommends that operation for undescended or maldescended testicle should seldom be performed at an earlier age than eight years unless demanded by the accompanying hernia, for the reason that in a considerable number of cases the testicle descends spontaneously on the approach of puberty. Bilateral abdominal ectopy of the testicle had better be left untreated, inasmuch as operation is difficult and by no means free from risk. According to Coley, the main principles of any operation likely to yield satisfactory results must comprise free opening of the inguinal canal, thorough freeing of the testicle from adhesions or peritoneal bands, even with sacrifice of some veins if necessary, bringing the testicle into the scrotum, and suture of the canal without transplantation of the cord. Bilateral failure of the testicle to descend should not be permitted to persist to puberty.

Typhobacillosis.

One of the rarer conditions resulting from the tubercle bacillus is denominated by Landouzy "typhobacillosis." It simulates a typhoid fever very closely, and many authors claim that in reality this condition results from a typhoid infection which in its convalescent stage takes on a tuberculous infection. Landouzy thinks otherwise. In the *Presse Médicale* for October 24, 1908, this author gives the differential diagnosis as follows: the temperature curve in acute tuberculosis simulating typhoid fever is more irregular, it oscillates from day to day, being sometimes higher and sometimes lower, instead of being progressively higher as in typhoid; the pulse is ordinarily much less rapid than the height of temperature would lead us to expect; there is a complete absence of any symptoms of visceral lesions and of catarrh of the pharynx, bronchial tubes, and intestine; the rose spots are never seen; the spleen is not enlarged. Furthermore that the two conditions are distinct is proved by the fact that on autopsy no lesions are found in the intestines. The course of the disease also varies in these two conditions. The tuberculous condition tends to convalescence which, however, is not perfect, and the tuberculous lesions then go on increasing, with more prostration than should exist in a convalescent from typhoid. The good appetite of the typhoid convalescent is not present, and instead of growing stouter the tuberculous patient grows progressively thinner. Signs of consolidation generally appear at the apices. Many patients observed by Landouzy were attacked by typhobacillosis in the spring, without any local manifestations of the disease, and died the following winter with pulmonary cavities, after ten months of fever, having never been out of bed at all in the interval. When there is any question of the diagnosis in these cases, it may be perfectly established by the use of the Widal test, by microscopic examination of the feces, by blood cultures, and by inoculation tests.

News of the Week.

Tuberculosis Exhibition.—While the success of the tuberculosis exhibition was anticipated, it was hardly expected that such general interest would be shown, or that crowds of such large numbers would visit the Museum of Natural History where it is on view. Because of the great crowds on the first Sunday, the exhibition hours have been made from one to ten on Sundays instead of from one to five. December 13 was Labor Union Day and 30,000 invitations were sent out. January 2 has been set aside for East Side Day and a mass meeting will be held on that afternoon under the auspices of the United Hebrew Trades. On December 9, special invitations were extended to medical students, and about 2,000 listened to addresses by Drs. T. Adolphus Knopf, Woods Hutchinson, Hermann M. Biggs, Walter B. James, and others.

The State Charities Aid Association and the New York State Department of Health have combined their efforts to make Monday, December 21, which has been designated New York State Day, notable in the history of the exhibition. It is hoped that many throughout the State who were unable to attend the exhibition in Washington during September will avail themselves of this opportunity, for which special rates have been offered by the railroads. During the morning an informal conference of representatives of the State Charities Aid Association's local committees on the Prevention of Tuberculosis, and representatives from other associations throughout the State, will be held. In the afternoon at two, George A. Canfield will preside at a meeting at which city officials from Schenectady, Syracuse, Rochester, Troy, Buffalo, and Yonkers, will tell of the work which is being done in their respective cities, and the county work will also be described. At the evening meeting, the Hon. Joseph H. Choate presiding, Bishop Nelson will tell of the campaign in Albany, and Dr. Gibson of the work in Utica. The State Commissioner of Health, Dr. Porter, will talk of the work and plans of the State Department in the struggle; the State Commissioner of Labor, Mr. Williams, will discuss the relation of factories and mercantile establishments to tuberculosis; Dr. Hermann M. Biggs will advance the need of a uniform policy throughout the State for the care of moderate and advanced cases of tuberculosis; Mr. Martin E. McClary will tell of the needs of the State Hospital for Incipient Cases of Tuberculosis at Ray Brook, and the Hon. Joseph F. Alling, President of the Rochester Health Association, will give the business man's point of view in the campaign against the disease.

Health Matters in the President's Message.—President Roosevelt in his annual message to Congress makes the following recommendations in regard to a National Health Bureau: "It is highly advisable that there should be intelligent action on the part of the nation on the question of preserving the health of the country. Through the practical extermination in San Francisco of disease-bearing rodents our country has thus far escaped the bubonic plague. This is but one of the many achievements of American health officers; and it shows what can be accomplished with a better organization than at present exists. The dangers to public health from food adulteration and from many other sources, such as the menace to the physical, mental, and moral development of children from child labor, should be met and overcome. There are numerous diseases, which are now known to be preventable, which are, nevertheless, not prevented. The recent International Congress on Tuberculosis has made us painfully aware of the inadequacy of American public health legislation. This nation cannot afford to lag behind in the world-wide battle now being waged by all civilized people with the microscopic foes of mankind, nor ought we longer to ignore the reproach that this Government takes more pains to protect the lives of hogs and of cattle than of human beings. The first legislative step to be taken is that for the concentration of the proper bureaus into one of the existing departments. I therefore urgently recommend the passage of a bill which shall authorize a redistribution of the bureaus which shall best accomplish this end."

The message contained also the following recommendation regarding hospital ships for the navy: "Two hospital ships should be provided. The actual experience of the hospital ship with the fleet in the Pacific has shown the invaluable work which such a ship does, and has also proved that it is well to have it kept under the command of a medical officer. As was to be expected, all of the anticipations of trouble from such a command have proved completely baseless. It is as absurd to put a hospital ship under a line officer as it would be to put a hospital on shore under such a command. This ought to have been realized before, and there is no excuse for failure to realize it now."

Institutional Improvements Recommended.—Among other things, President Busse, of the Cook County Board, made the following recommendations in his message to the Board at his reinauguration, December 7: The establishment of an institution for the care of those in the early stages of tuberculosis; the extension of the facilities of the various charitable institutions to reduce overcrowding; better facilities at the insane hospital; improvements at the county morgue; a pathological department and a bureau of statistics at the County Hospital; a psychopathic ward either at the Detention Hospital or the County Hospital; a place for the care of the alcoholically insane; the placing of a physician in charge and nurses at the Juvenile Court.

Typhoid Epidemic Checked.—Reports from Reading, Pa., indicate that the situation in regard to the epidemic of typhoid fever there is now under control. Nearly six hundred cases developed. The engineers of the State Board of Health have made an investigation of the watershed for sources of pollution, and the Commissioner of Health has taken active steps to abate the nuisances. The local Board of Health has also appointed officers to inspect the vaults and cesspools as well as the alleys and yards throughout the city.

Increase in Immigration.—Following the panic a year ago, a considerable drop in the number of immigrants arriving at the port of New York was noticed, but recently the arrivals have increased, and, on December 8, 5,057 immigrants passed through Ellis Island. This is a record for any single day, the largest number arriving on any day previously being 3,126.

Destruction of Spoiled Food Stuffs.—The Chicago administration has been greatly strengthened in its warfare against decayed and unwholesome food products by a decision of the United States Supreme Court. It practically gives to the city the needed authority to suppress the marketing and retaining in cold storage of food products which have begun to decompose. The right to destroy spoiled material wherever found not only makes it easier for the officials of the health department, but has a strong deterring effect on any dealer who might wish to impose upon the public.

New York's Death Rate.—The death rate in the city continues to show a decrease as compared with 1907 which is considered remarkable by the health officials. During the week ending December 5, 1908, there were 1,213 deaths, a rate of 14.1 per thousand of population, while last year there were 1,403 deaths, a rate of 17.40. There was a falling off of deaths from all causes except heart disease, diphtheria, and violence. These all showed a very slight increase.

Cholera in Russia.—It has been found necessary to reopen some of the cholera hospitals in St. Petersburg, as the number of cases have increased considerably during the last two weeks.

Dr. Roswell Park on December 7 celebrated the twenty-fifth anniversary of his professorship in the University of Buffalo, at a dinner given in his honor, by the medical profession of Buffalo, as an evidence of their appreciation of his abilities as teacher and surgeon.

Col. William C. Gorgas, who is one of the ten delegates from the United States appointed to attend the Pan-American Scientific Congress at Santiago, Chili, on Christmas Day, will present a paper on the Control of Yellow Fever in the Tropics.

Dr. Stephen Balderson has been appointed health commissioner of Evanston, Ill., vice Dr. Wm. R. Parkes, resigned.

Harvey Society Lectures.—The sixth lecture of the Harvey Society will be delivered by Prof. A. B. Macallum of the University of Toronto, at the New York Academy of Medicine, 17 West Forty-third street, on December 19, at 8:30 P.M. The subject of the lecture will be Osmosis, and all persons interested are cordially invited to attend.

Free Medical Lectures.—On Sunday, January 3, the course of free medical lectures given by the Faculty of Medicine of Harvard University will be inaugurated, and will be followed by lectures on every Saturday evening and Sunday afternoon, until April 25.

Bellevue Hospital.—Dr. S. F. Goldwater, Superintendent of Mt. Sinai Hospital, has been appointed sanitary expert to supervise the construction of the surgical wards at the new Bellevue Hospital. He will retain his place at Mt. Sinai. It is estimated that the new hospital will be ready in about five years.

Charitable Gifts.—By the terms of the will of Mrs. Grace M. Kuhn, who died in Lenox last October, Harvard University will receive $175,000 to endow a department of biological chemistry. The Massachusetts General Hospital also receives $10,000.

Philadelphia County Medical Society.—At a stated meeting held December 9 the following resolution was adopted: "The Philadelphia County Medical Society, as the exponent of the recognized profession in this teaching center, declares its belief in the right of a physician to use mental, chemical, mechanical, electrical, manipulative, dietetic, or any other legitimate means of treating disease; the same holds true of dosage, small or large. Furthermore, the society embodies the modern spirit as to professional fellowship, and points with pride to its record for broadminded liberality in election to its membership. Graduates of various schools of practice have been and are now on its rolls."

The Norwegian Hospital Alumni Association.—The ninety-ninth regular meeting of this Association was held at the residence of Dr. Arthur Longstreet on December 9. Dr. Robert E. Coughlin was elected *President,* Dr. John H. Ohly *Vice-President,* and Dr. Louis Stork *Secretary and Treasurer.* The hundredth meeting of the Association will be held in January at the home of Dr. Sewell Matheson. It will be celebrated in a manner fitting to the occasion.

Alumni Association of the New York Skin and Cancer Hospital.—A meeting of this Association was held in New York on Wednesday of this week under the presidency of Dr. H. H. Whitehouse. The program included papers by Dr. B. Merrill Ricketts of Cincinnati, on "Lupus and Epitheliomata, Their Treatment by Excision and Paste;" Dr. R. M. Vermilye, on "Influence of Gravity on Lesions of the Skin"; Dr. J. Francis Aitken, on "The Practical Physician *vs.* the Para Pathologist"; Dr. Jerome Kingsbury, on "The Conjunctival Tuberculin Reaction in Certain Diseases of the Skin;" and Dr. James T. Gwathmey, "Anesthesia for Plastic Operations on the Face."

Joint Society Meeting.—The New York Pathological and the New York Surgical Societies held a joint meeting in Hoosack Hall of the New York Academy of Medicine, on December 9. Dr. John Howland read a paper giving the results of studies made by Dr. A. N. Richards and himself on the pathology and metabolism of cases of delayed chloroform poisoning in dogs, which was illustrated by the projection of microscopic sections from the liver and other organs. Dr. George E. Brewer discussed the clinical aspect of such cases, and Dr. James Ewing and Dr. C. G. L. Wolf discussed the scientific side.

The Southern California Public Health Association held its semi-annual meeting in Santa Ana, on December 2, and passed a resolution indorsing the establishment in Southern California of a bacteriological laboratory as a branch of the State laboratory. The following officers were elected for the ensuing year: *President,* Dr. C. D. Ball, Santa Ana; *Vice-President,* Dr. W. H. Jones, Long Beach; *Secretary-Treasurer,* Dr. W. W. Roblee, Riverside.

The Oakland County (Mich.) Medical Society at its annual meeting on December 2 elected the following officers: Dr. C. J. Sutherland, Clarkston, *President;* Dr. T. E. McDonald, Holly, *Vice-President;* Dr. J. T. Bird, Clarkston, *Secretary* and *Treasurer;* Dr. E. A. Christian, Dr. N. B. Colvin, and Dr. M. W. Gray, *Board of Directors.*

The Rolla District (Mo.) Medical Society held its sixty-seventh semi-annual meeting on December 3, and elected the following officers for the ensuing year: Dr. E. L. Hume of Bourbon, *President;* Dr. J. C. Welch of Salem, *Vice-President;* Dr. W. H. Breuer of St. James, *Secretary* and *Treasurer.* The next meeting will be in St. James in May, 1909.

The Douglas County (Minn.) Medical Society, at its sixth annual meeting held on December 2, elected the following officers: *President,* Dr. John Baird; *Vice-President,* Dr. Lewis Moody; *Secretary* and *Treasurer,* Dr. T. J. O'Leary; *Censor,* Dr. L. B. Shehan.

The St. Charles (Mo.) Medical Society held its annual meeting on December 2 and elected officers for the ensuing year as follows: *President,* Dr. J. R. Mudd; *Vice-President,* Dr. D. C. Dunn; *Secretary,* Dr. F. J. Taintor; *Treasurer,* Dr. Carl Bitter; *Censor,* Dr. B. P. Wentker.

The Baltimore City Medical Society, at its annual meeting on December 1 elected the following officers: *President,* Dr. Jacob H. Hartman; *Vice-President,* Dr. William D. Booker; *Secretary,* Dr. William E. Magruder; *Treasurer,* Dr. William S. Gardner; *Censor,* Dr. Randolph Winslow.

The San Mateo County (Cal.) Medical Association held its annual election of officers on November 9. The election resulted as follows: *President*, Dr. H. C. McLenehan of Belmont; *Vice-President*, Dr. D. B. Plymere of South City; *Treasurer and Secretary*, Dr. F. M. Seibert of San Mateo.

Cook County Tuberculosis Hospital.—The work on the new million dollar tuberculosis hospital for Cook County (Illinois) is to be begun in a few days. A building permit has already been secured.

Obituary Notes.—Prof. Oliver Walcott Gibbs of Boston died in Newport on December 9. Dr. Gibbs was born in New York in 1822, and graduated from Columbia College in 1841, and from the College of Physicians and Surgeons, New York, in 1843. During the Civil War he was a member of the United States Sanitary Commission, and in 1863 was appointed Rumford professor at Harvard University, an office which he held until 1897, when he was made professor emeritus. He was one of the founders of the Union League Club of New York, and a charter member and president of the National Academy of Sciences. He was well known for his original investigations and had received honorary degrees from Berlin and London, as well as from Columbia, Harvard, Toronto, and Pennsylvania Universities.

Dr. John T. Wheeler, who died at his home in Chatham, N. Y., December 3, 1908, at the age of 58, was not only a leading man in his profession but had been a good citizen, especially interested in the village schools of which he was a trustee for almost thirty years. He had been the first president of the Third District Branch Society and was at the time of his death vice-president of the State Medical Society. His community testified to their sense of bereavement by closing all places of business the day of his funeral and by gathering with a wide circle of friends to pay the last tribute to his memory. He was director of the Division of Communicable Diseases of the State Department of Health at the time of his death.

Dr. Bethuel Lewis Dodd, one of the oldest practitioners of Essex County, New Jersey, died at his home on December 5, after a short illness. Dr. Dodd was born in East Orange in 1825, and was graduated from the College of Physicians and Surgeons, New York, in 1852. During the Civil War he was examining surgeon for the Thirteenth and Twenty-sixth New Jersey Volunteers, was at one time surgeon-in-chief of the Pennsylvania Railroad, was for ten years county physician, and had also served as police surgeon for the city of Newark. He had practised but little for some years past.

Dr. George H. Bicknell of Omaha, Nebraska, died at the Methodist Hospital in that city on November 28, of peritonitis, aged 44 years. Dr. Bicknell was graduated from the Omaha Medical College in 1895, and for the past two years had been associate professor of ophthalmology and otology in the Medical Department of the University of Nebraska.

Dr. Editha Root of De Kalb, Illinois, died at her home on November 26. Dr. Root was graduated from the Woman's Medical School in Chicago in 1875, and had practised in Denver, Colorado, until a year ago.

Dr. William E. Walker of Fairhaven, Massachusetts, died on November 30 at his home, after a short illness from pneumonia. Dr. Walker was born in 1874, and was graduated from Amherst, and from the Harvard Medical College in 1902.

Dr. Norval Smith of Bridgeport, Connecticut, died at the Bridgeport Hospital on December 1, of cerebrospinal meningitis. Dr. Smith was graduated from Queen's University, Canada, in 1904, and had practised in Bridgeport for the last two years.

Dr. Frank Russell Baker of Brooklyn, New York, was instantly killed on December 11, by falling from a fourth-story window of his house while trying to remove a tightly wedged window screen. Dr. Baker was born in 1869, and was graduated from the College of Physicians and Surgeons, New York, in 1889. He was a member of the American Medical Association and of the Kings County Medical Society.

Dr. Rush J. Shank, a well-known physician of Lansing, Mich., and a veteran of the Civil War, died on November 25, of peritonitis, aged 60 years. Dr. Shanks was graduated from the University of Michigan in 1871, and was a member of the Michigan State Medical Society.

Correspondence.

APPENDICITIS AND RHEUMATISM.

To the Editor of the Medical Record:

Sir:—In the *British Medical Journal* of November 28, 1908, page 1601, is an article by Dr. Eustace Smith, entitled "Remarks on the Rheumatic Origin of Certain Serous Inflammations." Dr. Smith concludes his article as follows: "I have seen not one, or two, but many cases of appendicitis in which the question of operation was being considered which underwent such rapid improvement under antirheumatic treatment that all idea of surgical interference was quickly set aside. If the treatment fail—that is, if no improvement be noticed within thirty-six hours of taking the first dose of the salicylate (which should be of substantial quantity and given every three hours), the assumption of a rheumatic origin for the inflammation may be definitely ignored." It is almost unnecessary to add that this statement comes from a prominent physician of large and long experience, and who is very favorably known to physicians throughout the world.

To many among my colleagues it is also well known that similar judgment has been passed during many years by myself, and I have never had up to date any reason to believe that my statements, written as well as oral, in regard to the not infrequent rheumatic causation of appendicitis, are at all erroneous. I should not recur to this subject, were it not very important, practically. To those who fail to remember my former article on this subject, I would refer them to the Medical Record, September 14, 1895, pages 373-374, "Rheumatism as a Cause of Appendicitis."

Beverley Robinson, M.D.

New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—HORACE DOBELL LECTURE ON LATENT PERSISTENCE OF BACTERIA—WHY NOT PRESERVE THE APPENDIX?—TRANSFUSION IN TOXEMIC STATES—ACTION OF SALINE PURGATIVES.

London, November 27, 1908.

The General Medical Council met on Tuesday and Sir Donald Macalister delivered his presidential address. He began by remarking that the Council that day entered on its second half century—a remark which suggests the many hopes which have been frustrated, the many efforts that have been fruitless, and the little good that has resulted. The presidential addresses alone would be a sufficient library on the subject of medical reforms advocated without effect. Sir Donald said the register was the instrument devised by the Legislature to enable persons to distinguish qualified from unqualified practitioners. In a sense it has done this, but so cumbrous and expensive a body was not required to supplant a medical directory which was tolerably correct. In fact, the Council proposes now to issue a circular with a view to correct the errors of the register—a proceeding carried out yearly by the directory.

The Council has also at enormous cost produced the Pharmacopœian for the United Kingdom, which is certainly better than having one for each division.

But the three colleges previously supplied the materials and might have unified their work at a fraction of the expense incurred by the ponderous body set up fifty years ago. Sir Donald held that the Council had kept before it its original purpose—the safeguarding of the public health—and to that end had pursued in a remarkable degree the improvement of the profession. It is not the custom of the Council to criticise the presidential addresses or it might be hoped that one of its members would have called in question this statement.

In the evening the Council celebrated its jubilee by a dinner and invited thereto their surviving predecessors.

The behavior of bacteria in the body, whether pathogenic or not, is a large subject, and one side of it was stated in a luminous manner by Dr. Leonard Dudgeon, pathologist and bacteriologist to St. Thomas' Hospital in the Horace Dobell Lecture at the Royal College of Physicians, which he delivered on the 12th inst. The part he took up was the "latent persistence and the reactivation" of the pathogenic bacteria. He said the *Staphylococcus epidermidis albus*, shown long ago by Welch to be a normal inhabitant of the human skin, is now known to be very closely allied to other staphylococci met with in infective processes. Organisms belonging to this group are of frequent occurrence in wounds which heal by first intention. Probably their presence in normal tissues is an important source of suppuration. The *Staph. albus*, is important in peritoneal infections, having often been found in the blood-clot of intraperitoneal hemorrhage, as well as in acute peritoneal infections. The similar organism called *Micrococcus neoformans*, which has been found in malignant growths, is very likely identical, as suggested by Andrewes and Gordon. If so, it would appear that malignant neoplasms become infected by normal bacteria, *i.e.* autoinfection is a more important agent than infection from without.

Furunculosis is a well-known example of autoinfection, through *Staph. pyogenes aurcus*, to which also the lecturer has himself suggested most cases of osteomyelitis are due. To autobacterial infection of injured parts excessive formation of callus in some fracture cases has also been attributed by no less an authority than Shattock and Battle. Scar tissues also are liable to be inflamed from no known cause unless these organisms which are latent had become reactive. The investigations of Andrewes and Horder show that malignant endocarditis is due to streptococci and in overwhelming preponderance to the salivary and fecal types. They are all either absolutely identical, or closely related in their reactions with the commonest saprophytic streptococci of the mouth and gut. Turning to the diphtheria bacillus, the lecturer held, with Graham Smith, that the organisms found in the throats of healthy persons are virulent and do not lose their virulence when persisting a long time in the throat and nose. In a few instances he admitted they had diminished in virulence, but in the great majority full virulence was noted up to the time of disappearance. In one case virulent bacilli were found after 335 days. So then these bacilli can remain in the tissues of healthy people without giving rise to any symptoms, but may yet retain their virulence.

The *Bacillus coli* is a normal inhabitant of the intestinal tract in both man and animals, and give rise to no symptoms. But it is the commonest organism in the bacteriology of peritonitis—especially that due to appendicitis. It persists in the appendix after subsidence of the acute stage and after operation may give rise to diffuse peritonitis. This bacillus may also be found in the urinary tract and in such enormous numbers as to have been called bacilluria without setting up any symptoms whatever, or in other cases causing slight pyrexia, or again it may produce a condition indistinguishable clinically from typhoid fever. With regard to this disease we now understand by typhoid fever a state due to infection with various microorganisms of the coli group—not necessarily the *Bacillus typhosus*. Still further, we may be infected with the typhoid bacillus without having any of the clinical manifestations of typhoid fever. Typhoid is, in fact, a group disease produced by a group of organisms.

As to the interesting question of typhoid carriers, the lecturer did not limit the consideration to carriers of the *Bacillus typhosus*, but to the group of organisms described by Major Statham as capable of originating disease indistinguishable from typhoid fever. There are: 1. *Bacillus fecalis alcaligenes*. 2. *Bacillus typhosus*. 3. *Bacillus paratyphosus*, A. 4. *Bacillus paratyphosus*, B. 5. *Bacillus coli*. He thinks infection due to the persistence of the first of these in the tissues for long periods is probably of greater import than in the case of the others. It is well known that the feces of convalescents from typhoid may be infective for months, or even years, the general idea being that this is due to infection of the gall-bladder. About 3 to 4 per cent. are estimated to become carriers and a small proportion of contacts may excrete the bacillus temporarily. Then persons who had never had an illness considered to be typhoid may have paratyphosus bacilli in their feces. Moreover, there are persons who seem to be temporary carriers, not such as might be thought to discharge their bacilli intermittently, nor even cases of ambulatory typhoid. So it has been shown that bacilluria may last a long time and be a source of infection. Epidemics have been traced to such a source. There is some evidence, too, that autoinfective attacks may occur to persons who have been carrying the bacillus for long periods. The lecturer gave some illustrative cases. One was a man admitted with jaundice. He had had that complaint thirty years previously and "influenza" twenty years ago. An operation was done and the gall-bladder was found in a suppurative state with thickened walls. The paratyphosus B. was obtained in pure culture. At the post mortem carcinoma of the gall-bladder was found. This man had never been known to have typhoid and the only illness likely to have been caused by the paratyphosus found might be the "influenza" of his record. He was admitted to the surgical ward for suppuration in the biliary passages. In such a case danger of infecting patients or nurses is a possibility. The question arises whether the bacillus persisted in the biliary passages as a saprophyte and became reactivated and gave rise to suppuration in a carcinomatous growth, or had it only recently entered?

The lecturer had isolated bacilli of the paratyphoid group from three private patients in the last two years. In two the *Bacillus coli* was also present, and the patients had pyuria as well as bacilluria. All three had had "influenza," but none typhoid. In two definite urinary symptoms occurred soon after the influenza, suggestive of the disease so diagnosed being an infection with *Bacillus paratyphosus*. The latent persistence of the paratyphoid group is very important. That organisms can live in our tissues and have periods of activity and when discharged enter and infect another host and so give rise to serious epidemics may suggest a reconsideration of our facts as to these infections. Our knowledge of bacterial growth and multiplication within our tissues must be further compared with their activity outside our bodies.

Mr. C. B. Keetley in a paper in the Surgical Section (R. M. S.) asked how and why the surgeon should attempt to preserve the appendix, and reported a number of cases to show its value. Macewen had shown it was not useless, and Mr. Keetley extolled it as a channel of ingress and egress to and from the intestine. Cases of colitis, intussusception, hemorrhage, distention, or toxic conditions, typhoid, constipation, etc., could be reached by this channel. In his opinion transplanting the appendix so as to imbed it or the major part in the abdominal wall was to be preferred to removal. Concretions, kinks, twists, and strictures could often be cured without excision, and non-recurrence could be assured. Through the appendix the large intestine could be regularly washed out from end to end.

Mr. Bidwell admitted that he had seen Mr. Keetley's method successful in intractable constipation, but he was not convinced that a twisted or kinked appendix was worth preserving in the abdominal wall.

Mr. Kirkby-Jones testified to the value of the plan in constipation. But Mr. Mummery said the cause of constipation must be sought, though in some cases appendicostomy was the ideal treatment. Mr. Spencer looked at the appendix from a developmental aspect, and could not see such a shrunken remnant was of any use. Mr. Hertz said it was easier to wash out the colon through the rectum. Mr. Rowlands said it was better to remove an inflamed or sloughing appendix. Mr. Waterhouse said that in future appendicostomy would certainly be the operation for ulcerative colitis and most cases of mucous colitis. In his reply Mr. Keetley said to leave the stump of an appendix in the peritoneal cavity was quite as dangerous as to insert it in the anterior wall of the abdomen.

In the Therapeutical Section Professor Dixon related some experiments showing that in animals toxemic states of a general character drugs were without effect, but transfusion of large quantities of saline solution gave good results. Dr. Fawcett remarked that in young children dying of diphtheria the difficulties of this treatment were too great. So, too, he said strychnine could not be injected without danger, for he had seen twitchings brought on by small doses. Dr. Hertz afterwards described experi-

ments to show that saline purgatives only acted after absorption, as long ago asserted by Aubert and MacCullum. The drug acted, he held, on the neuromuscular mechanism of the colon, increasing both motor and secretory activity. Analysis of the watery stools showed very little excess of salines. The salt was mostly excreted the next day when the stools were solid. Prof. Cushny could not accept this view without further consideration. One difficulty was that intravenous injections of purgative salts were without effect. It is difficult to think they act immediately on muscular tissue. Prof. Dixon said he had often injected small doses of magnes. sulph. into the veins. Larger doses paralyzed the heart, and the effect of small ones was nil. He believed the watery constituents could pass down in half an hour. If the action was due to absorption of a minute quantity of the salt, why should doubling the dose produce greater effect? Dr. Hertz replied and acknowledged that he had no explanation of the negative effect of intravenous injections. But experiments on animals were not free from possible fallacy as the conditions were not normal. As a matter of practice he did not think doubling the dose doubled the purgation; nor if his view were accepted did he consider it necessary to think that the effect of small and large doses could not differ.

TWELFTH SESSION OF THE FRENCH ASSOCIATION OF UROLOGY.

(From Our Special Correspondent.)

PARIS, October 15, 1908.

THE twelfth session of the French Association of Urology took place at Paris, October 8 to 10, 1908, under the presidency of Drs. Legueu of Paris, and Tedenat of Montpelier.

The question considered by this Congress was the so-called "Essential Incontinence of Urine," and those who presented papers were Bazy of Marseilles and Marcel Deschamps of Paris. These authors defined the subject of their papers by saying that essential incontinence is that which occurs involuntarily and unconsciously during sleep, without any lesion of the urinary apparatus to explain it. Essential nocturnal incontinence of urine is more frequent among boys; it is a malady of childhood; the personal antecedents of the patient are unimportant, but in regard to hereditary antecedents we generally find a neurotic heredity. This incontinence is manifested sometimes continuously every night, sometimes in irregular periods; the child may pass several nights without urinating, and sometimes unusual exciting causes may be found, as in the case of a child who always wet the bed after eating potatoes. The influence of deep sleep and of the amount of liquid ingested appears to be real, although not constant; the flow of urine is not continuously, drop by drop, but by several acts of micturition during the night. The incontinence seems to be independent of the quantity of the urine, since by measuring the daily and nightly quantity of urine Guinon found that the nocturnal excretion was less than the diurnal, as is the case in normal individuals.

Troubles of sensation are often noticed in these patients, such as hyperesthesia, abolition of the pharyngeal reflexes, abolition or exaggeration of patellar reflexes, epileptoid trepidation, tics, tremors, stammering, rhythmic twitching of the eyelids, dermographia, or hyperidrosis. This kind of incontinence often disappears at adolescence; its periods become less and less frequent, and it finally disappears entirely. On the other hand, it may persist into adult life, and even continue up to thirty years of age.

Among the causes which have been invoked to explain nocturnal incontinence of urine is congenital atresia of the meatus or urethra; other causes may be active, such as epilepsy, idiocy, and mental degeneracy. There are several types of children that are more subject than others to nocturnal incontinence of urine; some need only pride to cure them, and these are very intelligent; others are lazy, and urinate in bed because it is disagreeable to arise. In others incontinence is a psychic trouble, and here dreams have an important place in the pathogeny of the condition; still other cases are physiological and proceed either from vesical hyperexcitability, or, as Guyon has said, from paresis or insufficiency of the urethral sphincter.

Nocturnal incontinence of urine should be divided thus: (1) Incontinence of nervous origin (hysteria, epilepsy). (2) Incontinence of urinary origin (retention, prostatic, stricture, spasm).

The modifications of the urinary chemism should also be distinguished, for when the urine is concentrated it is a cause of vesical irritation, and may produce pollakiuria and incontinence, especially in nervous subjects. In practice the most frequently observed cause is hyperacidity of the urine; in other cases alkalinity may be mentioned. Inflammatory affections of the bladder and kidney may any of them be accompanied by incontinence from local irritation; this may be observed in pyelitis and pyelonephritis, benignant or tuberculous. We must also remember the malformations of the urinary organs, as phimosis, atresia of the meatus, hypertrophy of the valve of Guerin, polypus of the meatus, adhesions of the clitoris, and congenital stricture of the urethra. Lastly should be mentioned incontinence of urine of peripheral origin; such as incontinence resulting from polypus of the rectum, rectal fistulæ, rectal prolapse, colitis, fistula in ano, and intestinal worms. Sometimes incontinence is provoked by cutaneous eruptions, such as herpes, impetigo, enlarged tonsils, or nasopharyngeal polypi.

The prognosis of incontinence of urine is good, since it has a natural tendency to cure; some reserves should be made, for the incontinent, on account of the repulsion which surrounds them, the annoyances, and corrections to which they are exposed, may become hypochondriacal, and sometimes even commit suicide. In reference to treatment we may make two classes: (1) Empirical measures: (*a*) psychical measures, threats of correction, of operation, and violent emotions; (*b*) mechanical measures of two kinds, such as close the urethra more or less completely; as compresses in the form of rings about the end of the penis; such as are intended to cause light sleep—making the patient sleep on a hard bed, or putting foreign bodies in the bed at night; (*c*) hygienic measures, consisting of diminution of the quantity of fluids ingested, and even denying supper entirely. Lastly, the child may be awakened at a fixed hour to urinate.

(2) Internal treatment consists of antispasmodics, such as belladonna, chloral, or antipyrin, and the opposite excitants of the nervous system, as strychnia.

(4) Electrical treatment is designed to combat atony of the sphincter or inhibition of the cerebral center. The most generally used application is faradization of the sphincter urethræ. A current of ten milli-amperes may be used with sixty interruptions per minute, for two or three minutes; again galvanization may be combined with faradism.

(5) Psychical treatment consists of attempting a cure by suggestion, in the course of a hypnotic sleep, or in the course of natural sleep.

(6) Treatment by punctures and injections of the spinal canal. Epidural injections should be mentioned among these, which have given some success; also retrorectal injections, consisting in the injection of 100 to 150 cubic centimeters of artificial serum into the cellular spaces between the rectum and the sacrum. These last injections have for object the elongation of the hypogastric plexus, and especially of the sacral sympathetics, which are found in the rectorectal space. Lastly, lumbar puncture with the removal of 15 c.c. of the cerebrospinal fluid.

(7) Surgical treatment: Bloody surgical procedures are applicable only to cases of incontinence caused by malformations, or of peripheral origin.

To sum up: It is seen that measures proposed to remedy incontinence are very numerous. The prime therapeutic condition is an exact diagnosis; followed by elimination of all the conditions that may cause the involuntary emission of urine. This affection should never be treated by internal medication, according to the authors; simple means should first be tried, suggestion in the form of threats of operation, and if these means fail, catheterism, instillations, electrization, punctures, or injections, and above all, hygienic measures, less drinking of alcoholics, less meat, avoidance of physical and intellectual fatigue, and a life in the open air.

Among the other communications should be mentioned that of Noguès of Paris, on Early Diagnosis of Urinary Tuberculosis. While direct microscopic examination of the urine after centrifugation often fails, inoculation of guinea pigs gives good results; however, this last method has the inconvenience of demanding five or six weeks, a lapse of time that is too great. The author thinks the best means of ascertaining the urinary contents is to inoculate a female guinea pig in the udder with the urinary deposit during lactation. This method gives a rapid response, since the bacillus appears in the secretion of the mammary gland on the eighth to the twelfth day.

On the subject of transvesical prostatectomy, Escat of Marseilles is a partisan of early operation. This measure ends the danger of catheterization and cures the patient. It is very difficult to judge of the resistence of the patient for anesthesia and for operation. Michon of Paris thinks that an exact indication for operation is found in chronic incomplete retention with great distension. In such prostatics catheterism is a danger, and operation is no longer serious. Lagueu believes it best to do a prostatectomy in two sittings. At the first operation the bladder should be opened and disinfected and in a second operation the prostate may be removed.

Progress of Medical Science.

Boston Medical and Surgical Journal, December 3, 1908.

The Method of Administering Antimeningitis Serum.—C. H. Dunn lays down the following rules: (1) Perform lumbar puncture, prepared to give the serum, as soon as meningitis is suspected. If the fluid is cloudy, give the first full dose of serum at once, without waiting for the bacterial examination, although further doses are only to be given in case the diplococcus intracellularis is found in the cerebrospinal fluid. The serum is of no value in other forms of meningitis. (2) At every dose give as much as possible. Always withdraw as much cerebrospinal fluid as possible. Give 30 c.c. in all cases in which the amount of fluid withdrawn is 30 c.c. or less, unless a distinctly abnormal sense of resistance is encountered after as much has been injected as has been withdrawn. In all cases in which the amount of fluid withdrawn is more than 30 c.cm., give as much serum as the quantity withdrawn. In very severe or fulminating cases, in which the amount withdrawn is between 30 c.cm. and 45 c.cm., give 45 c.cm. unless abnormal resistance is encountered. (3) In very severe or fulminating cases, repeat within twenty-four hours as soon as the patient begins to get worse again, or at twelve-hour intervals. (4) In average cases, repeat daily, until four full doses have been given in all cases. (5) If diplococci persist after four full doses have been given, continue the injections until they have disappeared. (6) If subjective symptoms, any impairment of the mental condition or fever persist after diplococci have disappeared, or after four full doses have been given without progressive improvement, wait four days if the condition of the patient is stationary. At the end of four days, or at any time if the patient's condition is getting worse, repeat the treatment with four daily full doses, and continue as if this were the original attack. (7) When a relapse occurs, either by reappearance of diplococci in the cerebrospinal fluid or by a reappearance of symptoms, give four daily full doses and continue treatment as if this were the original attack. (8) Treatment along these lines should be continued until the patient is symptom free, without diplococci in the fluid, or until the chronic stage is established. (9) In the chronic stage, watch for possible reappearance of diplococci by doing occasional lumbar punctures. If diplococci reappear, resume treatment with the serum as outlined above. In chronic cases, with excessive cerebrospinal fluid under marked pressures, try daily lumbar puncture without the injection of serum.

Electrotherapeutics in the Treatment of Tuberculosis.—J. F. Wallis says that static electricity has no special value in tuberculosis beyond stimulating respiration and aiding metabolism, but claims considerable value for the high-frequency current. The latter tends to stimulate the eliminative organs and has some effect in retarding the growth of the bacillus and may alternate the virulence of the toxins. The author also refers to the *x*-ray, the Finsen light, etc., but presents nothing new. All of these methods, says the author, have properties in common. They all stimulate the nutritive functions, but the chemical action of the rays of the sun or the light of the high-power electric lamp and the high-frequency current alone stimulate all these functions, including digestion, absorption, secretion, excretion, respiration, and circulation of the blood. We also learn that pathological processes are arrested, pain is relieved, expectoration is facilitated, bacteria are destroyed, toxins are eliminated; the absorption of oxygen, the elimination of carbonic acid, sleep, and rest produced; appetite increased and nervous symptoms so distressing to the patient greatly benefited.

New York Medical Journal, December 5, 1908.

Peritonitis Due to Appendicitis.—F. Torek considers this question with special reference to diffuse suppurative peritonitis and notes the various procedures which have been followed in the past. His own method of operating consists in making a large median incision, extending generally two inches above the navel. The appendix is rapidly exposed and tied off. The pus exposed in these manipulations is at once rinsed off with saline solution, so that the appendix removal may be done in a territory not too much soiled. Then follows the careful cleansing of the peritoneal cavity by pouring saline solution from bottles or pitchers. This is done systematically, taking up one region after another, for instance, first the region of the appendix, then the pelvis, then the left lower part of the abdomen, finally the parts higher up. During these manipulations the intestines must be treated as tenderly as possible. The wound then is closed completely with through-and-through silk sutures, no drainage being employed, unless it has been impossible to close the stump of the appendix, in which case a drain is introduced down to the stump through a separate small lateral incision. Furthermore, the author does not employ Fowler's posture and avoids inducing peristalsis during the first five days. The large median incision facilitates access to all parts of the peritoneal cavity. Cleansing by irrigation leads to gentleness in handling the inflamed tissues. As the pus is widely spread already, no harm comes from flushing. The closure of the abdominal cavity without drainage rests upon the fact that the peritoneum, after it has been washed clean, is well able to cope with what little infectious material may yet be left. Furthermore, it is impossible to drain the peritoneal cavity. The author has drained in only two instances when the point of origin of the appendix could not be properly closed owing to extension of the gangrene to the cecum. This was done by the introduction of a strip of gauze through a separate lateral opening. The indication for drainage in those cases was not the presence of diffuse peritonitis, but the expected escape of feces.

Restoration of Sight After Nearly a Month's Blindness from Glaucoma.—The notable feature of the case reported by J. L. Minor is expressed in the title of his paper. His patient was a woman of 57 years, whose illness began with a sudden and severe pain in the left eye, lasting thirty-six hours. A few days later a similar attack occurred in the right eye and vision became blurred in both eyes. In due time an iridectomy upward was done in both eyes, they both having become totally blind, with more or less continuous pain. The bulk of the paper is taken up with details of treatment. One week after operation she could see sufficiently to tell the time by a watch and see the hands of the clock across the room. Five years or so later she could see fairly well, though there was a permanent lessening in the range of vision.

The Value of the X-Rays in Chest Diagnosis.—A. L. Gray writes of his experience in cases of thoracic-aneurysms, pleuritic effusions, tumors, enlarged glands, and tuberculosis. He says that with modern apparatus, isolated tubercles, minute calcified glands, and thickenings at the roots of the lungs can be clearly made out. In advanced tuberculosis, in which there is considerable consolidation, the areas may be studied and progress or recession of the disease determined by comparing radiographs made from time to time. Cavities in the lungs, their size, location, and whether or not they are being walled off are all points that may be shown by a good radiograph. In chest examinations for tuberculosis it is not sufficient, as is often done, to make a single picture with the plate behind the thorax, for images of small, solid areas in the anterior portion of the lungs may be indistinct by reason of their distance from the plate. In order to obtain a clear impression it is of equal importance that a picture be made with the plate in front. Restricted motion to the diaphragm on the affected side (Williams's sign), which was formerly considered of great value in the diagnosis of early tuberculosis, has been proved to be unreliable. This is easily demonstrable by an *x*-ray examination, but is not always present in the earliest manifestations.

Late Report of a Case of Fracture and Dislocation of the Second Cervical Vertebra.—C. D. Fox notes that fractures and dislocations of any of the three upper cervical vertebræ are generally fatal. His own patient was a man of thirty-two years, on whose vertex a heavy weight fell, forcing his head backward. He was unconscious for several hours. The case was under observation for a long period and the history of symptoms during this time is given in great detail. After a full consideration of all the facts in the case, the signs and symptoms and the use of the *x*-ray, a diagnosis was made of an old fracture dislocation of the second cervical vertebra, complicated by an ancient depressed fracture of the skull. In addition, the patient suffered from major epileptic attacks, without any focal symptoms, and petit mal. His recent attack would seem to be an acute cerebrospinal meningitis of unknown type and origin. The medicinal treatment received was almost exclusively with bromides for the possible relief of his convulsions. Hypnotic suggestion, carried to the stage of somnambulism, was employed for over four weeks, with no apparent effect on his convulsions, but being of great benefit in the relief of insomnia, pains, and other symptoms. This was

most noticeable during the attack of meningitis, for on several occasions, when the headache and pains were almost unendurable, he was kept in the hypnotic state for a half hour, and on one occasion as long as two hours. Immediately upon the production of hypnosis his pains would entirely disappear and would not return for perhaps twelve hours.

Journal of the American Medical Association, December 5, 1908.

The Treatment of Locomotor Ataxia.—A. McL. Hamilton deprecates the general tendency to give an unfavorable prognosis in cases of locomotor ataxia, which has a tendency to send the patients to the pretentious quacks, only, of course, to be disappointed in the end. He recognizes two classes of cases, one including about 60 per cent. of all patients and in which the disease is a parasyphilitic affection, progressive and usually incurable, though subject to favorable modifications and even arrest by intelligent treatment; the other 40 per cent. includes patients who are not only capable of being greatly helped, but often of being cured. Of course, evidences of destructive neural disease is of unfavorable signification. Considering the larger proportion of luetic cases, specific treatment is suggested, and he finds that in about 20 per cent. the use of mercurials is of advantage, especially the bichloride. The treatment of special symptoms is of great importance, and he calls attention to the effect of barometric conditions on the ataxic pains, which are for this reason often considered rheumatic. If this influence can be determined, the use of the salicylates and hydrotherapy is often of value, and he thinks that, with the judicious control of the physician, the use of morphine is comparatively safe. Dietetic regulation should be instituted for the gastric crises which are often associated with intestinal disturbances and autointoxication. The use of counter-irritation is also mentioned. For the ataxia the Frenkel systematic exercises may do much good in cases in which there is not too much pain, gastric crises, or excessive friability of the bones. Over-exercise and fatigue, however, should be avoided. When there is plantar anesthesia, perhaps causing the ataxia, he has found surprising benefit from the high-frequency current applied directly to the sole by means of a spark electrode. He has no faith in other forms of electricity for this purpose. For the urinary difficulties occurring in about half the cases, lavage of the bladder at regular intervals, used for a long period, is important. A warm winter climate is useful in tabetic cases, and, preferably, dry climates. Cases due to shock, trauma, or hysteria are often curable by very simple means, if there is no syphilitic basis.

Loss of Appetite in Children.—I. M. Snow calls attention to a group of symptoms observed in children from two to ten years of age, characterized by capricious and lacking appetite in spite of the most correct regimen and attractive food, irritability, lack of nerve, irregular and unfreshing sleep, and general deterioration in physique. All this may be the case in spite of tonic, fresh air treatment, and sometimes rapid growth without corresponding increase in weight. The condition is to be distinguished from the anorexia nervosa of Gull, which is a type of hysteria with loss of weight without organic lesion and with delusions and marked hysterical manifestations, which are lacking in these cases. Snow insists on a thorough examination in these cases excluding all organic diseases, and finds the efficient treatment only in putting the child to bed and keeping him there for two weeks with plenty of ventilation and fresh air. The body should be sponged off and well rubbed morning and evening and a suitable nutritious diet, well cooked and attractive, may be given without any special restrictions. The rest treatment should be continued until there is considerable gain in weight, a good appetite and natural sleep for ten or twelve days. These being satisfactory, the child is dressed and given an hour's perfect freedom, out of doors if preferred, and if improvement continues this may be increased by an hour each day until the child has six hours in the middle of the day, and, if still delicate or not quite normal, the short day should be continued for several months. At this time, change of air, country or seashore, with restrictions as to violent exercise, will be of service. After from two to four months, restraint is no longer needed, the child can live its normal life. Of course there are borderline cases in which all the details are not required, but if the condition has lasted for months any short or partial rest-cure is a waste of time; the invalidism will recur and the result probably will be an impairment of health that may be felt in after life.

Gonorrhea and Marriage.—F. C. Valentine and T. M. Townsend describe their method of testing for latent gonorrhea in candidates for marriage. Assuming that the patient has had one attack of gonorrhea, he is instructed to bring about as much irritation as he can by eating freely of articles likely to disturb his digestion, drinking more champagne or beer than usual, but not to the extent of producing inebriety; if an abstainer he is advised to drink freely of carbonated beverages. These measures should be kept up for a week or ten days, to the extent that they can be endured. If any perceptible disturbance is perceived, such as a slight increase of urethral secretion or discomfort on urinating, he is ordered to present himself before voiding his first morning urine. The urethra is then stripped, and if this fails to bring any excess of urethral secretion to the meatus, the urethra can be curetted with a sterilized platinum loop and the results spread on a flamed cover-glass for future examination, slants of Loeffler's serum being also inoculated and placed in the culture oven at once, and kept at a temperature of 99°. The patient is then instructed to half fill a 12-inch ignition tube (180 c.c) with urine and to fill entirely as many more tubes as are needed nearly to empty the bladder; the remaining amount is passed into a final tube. Each tube is immediately stoppered with sterile cotton and marked with the patient's name and numbered. If the urines between the first and last tubes are perfectly clear and the first and last suffice for exhaustive microscopy, the intervening tubes may be discarded. The first and last, however clear, should be sedimented and the result prepared for microscopic examination. If the preliminary preparation has not caused any recrudescence, the prostate may be massaged and the seminal vesicles stripped for specimens in addition to those taken from the urethra. If no secretion is immediately obtainable by massage, etc., the patient is instructed to walk about for a few moments; a slight oozing then usually appears. If this does not occur, the urine passed within five or ten minutes thereafter will be found in most cases to be loaded with the secretion that has not escaped. This will be available for microscopy. If within three days autoreinfection of the urethra has resulted, the discharge must be taken for examination. If no reinfection has occurred, exhaustive urethroscopy is demanded, and even then, if no gonococci are found, their existence cannot be entirely excluded and, for additional safety, all the procedures should be repeated two days after the urethroscopy. Both sets of examinations proving negative, further steps are indicated. An anterior irrigation with mercury bichlorid, 1 to 5,000, generally sets up rather a severe urethritis, easily controllable by a few irrigations when no gonococci are present. In case the urethra is tolerant of bichlorid of mercury, a 1 per cent. solution of silver nitrate, retained for five minutes, will usually succeed. The microscopic detection of gonococci in the discharge, of course, settles the question here considered. When examination of all genital secretions or hypersecretions fails, the examination of the urinary sediments may reveal the germs. The site where they are held residual must be determined by repetition of the researches described. All the tests proving negative, the series should be repeated a month or two later, and then failing we can assume, in the present state of our knowledge, that it is safe for the patient to marry.

Cerebellar Symptoms in Hydrocephalus.—J. H. W. Rhein reports the case of a boy, aged 8, presenting the characteristic symptoms of cerebellar disease, vomiting, headache, tremor, and uncertainty of gait, in whom at autopsy there was found hydrocephalus, involving all the ventricles, distending the lateral recesses of the fourth ventricle and causing cysts at both cerebellopontile angles. The syringomyelia extended in the spinal canal from about the second cervical to the eighth thoracic segments, and there was with it marked alterations, cavities, etc., chiefly in the posterior horns. At the decussation, the medulla appeared nearly normal. He discusses other similar cases reported in the literature, and is inclined to account for the cerebellar symptoms in his patient by the increased intracranial pressure, exerted more particularly on the cerebellum at the localities at which the apparent cysts were found. Such cysts may be easily overlooked at autopsies, as they tend to collapse on the escape of the cerebrospinal fluid. They were due in this case, he thinks, to the obstruction of the foramina of Majendie and Luschka, which were not found open at autopsy. The existence of syringomyelia without the characteristic symptoms in children is not, in itself, so great a rarity, and its possible existence in hydrocephalus, Rhein says, should always be kept in mind.

The Lancet, November 28, 1908.

The "Effective Periods" of Typhoid "Carriers."—By this term D. S. Davies and I. W. Hall refer to the periods during which the typhoid carriers are possibly infective to those about them. Why such carriers do not always have the fever bacilli in their feces we do not know. The effectiveness is intermittent. It is almost uniformly absent during the early months of the year. What, asks the authors, is the significance of this period in which the carrier fails to be "effective"? Is it simply coincidence, or shall we find it appearing uniformly when a larger number of cases are available for reference? Has it anything to do with periodicity in the virulence of the bacillus? Does the organism live a "hibernant" existence in the intra- and extra-hepatic biliary passages during these months, and become actively parasitic on reawakening for the remaining months of the year? Has this "period of effectiveness" anything to do with the type of food taken, or with the general tissue metabolism, or with the heat regulation apparatus? Does this "seasonal effectivity" offer any explanation of the "waves" of endemic enteric fever, the May revival starting the supply of fresh infections which subsequently develop by extension into the autumnal burst? All these questions cannot be answered in the light of our present knowledge. Speaking with reference to the immunity of the carrier, the authors say it must vary considerably from time to time. It may be possible to raise it by injections of vaccines. A typhoid carrier should not be considered as cured until daily examinations of the feces have determined the absence of the bacilli during a period extending at least from April to November.

Sterilization of Potable Waters by Means of Calcium Hypochlorite.—The paper of J. C. Thresh is largely taken up with descriptions and tabulations of results of chemical experiments undertaken along the line suggested by the title. In his experience he has met with no water which two parts of chlorine per million failed to sterilize. The amount of chemicals added is so small that they do not affect in any way the character of the water. The chlorine and hardness are only increased by a minute fraction of a grain or degree per gallon. There is no practical difficulty in adding the chemicals and no special apparatus is required. The hypochlorite can be added as the water enters a tank of suitable capacity and the sodium bisulphite for the removal of the chlorine as the water leaves the tank to flow into a reservoir. If the experiment shall work out on a large scale as laboratory results seem to indicate, we shall have a sanitary agent of the utmost value, particularly as the chemicals employed are in no wise expensive.

Herpes Zoster Frontalis Associated with Glaucoma.—A. A. Bradburne notes that most of the textbooks say that in glaucoma the pupil is dilated and often pear-shaped. He maintains, however, that the malady can be associated with a contracted pupil when the iris is fastened down to the lens capsule behind, thus shutting off the posterior from the anterior chamber of the eye. In the case here narrated, that of a woman of fifty-three years, the interesting fact was that, although there was undoubted increase of ocular pressure, the pupil was not dilated; such a combination of symptoms is quite compatible with an iritis in which the plus tension is due to congestion and swelling of the iris and increased viscosity of the aqueous fluid. What made the case still simulate iritis was the marked swelling of the upper lid and the accompanying intense conjunctival injection; in fact, a superficial preliminary examination presented a typical picture of iritis, and had not the eye been most carefully scrutinized the instillation of a mydriatic would have seemed urgently necessary. On account of the edema of the upper lid making recognition of increased intraocular tension difficult, this feature, contraindicating the use of a pupil-dilating agent, could easily have been overlooked. Had, therefore, a mydriatic been instilled, as symptoms seemed to call for, a most unfortunate result would assuredly have followed. The cultivation of a faculty for observing minutiæ of detail is the secret of making correct diagnosis in eye affections. A colleague had not only correctly estimated the presence of increased tension, but had further noted that there was an absence of the rose-red ring of ciliary injection around the corneoscleral margin which is always present in inflammation of the iris and ciliary body. He had also noted that the cornea was clear and bright and the iris markings were not obscured, and the pupil was fairly mobile. During the course of the disease the eye condition changed, it becoming free from pain, photophobia, and sensitiveness to touch. The tension was subnormal, the anterior chamber deep, the pupil semi-dilated and immobile, and the texture of the iris was partially obscured. The explanation of these altered appearances was simple. There was evidently a thin viscid but transparent mucoid secretion present in the aqueous, which accounted for the loss of transparency of the media and obscured the texture of the iris. The minus tension could be attributed to the defective secretory function of the ciliary body due to the paralyzing effect of the affection on the long ciliary nerves. These symptoms indicated the urgent necessity of preventing adhesions forming between the iris and the lens capsule which the viscid mucus in the anterior chamber of the eye tended to produce. The use, therefore, of a mydriatic was obviously required now as much as it was contraindicated in the early condition, and under this treatment the eye rapidly recovered.

Berliner klinische Wochenschrift, November 23, 1908.

Effects of Hypertrophy of the Prostate.—Tandler and Zuckerkandl oppose the usual view that sees the source of changes in the urinary organs in prostatics in the increased pressure in the kidneys and ureters caused by the retention of urine in the bladder. Autopsy material always shows that the mouths of the ureters retain their normal calibers however great may be the distension of the ureters themselves or of the kidneys. Dilatation of the ureters, too, is not proportionate to the amount of hypertrophy in the prostate but may appear when the increase in the size of the gland is very moderate. The distension of the ureters and kidneys is usually coincident with and proportionate to the dislocation of the trigonum of the bladder upward, and this is caused by changes in the middle lobe of the gland. The ureteral dilatation, however, is seen to begin only a certain distance from its mouth and that point is marked by its crossing with the vas deferens. The cause of the dilatation is the change in the relative position of these two structures, the ureter being angulated at the crossing by the changes in the position of the trigonum. The retention of urine, then, affects not only the bladder but likewise the last portion of the ureter. This causes increased muscular contractions of the ureteral walls with subsequent hypertrophy and dilatation. This explanation makes it very improbable that the usual "surgical kidney" results from an infection from below; rather, the cause of it is hematogenous infection that easily attacks the kidney or the ureter weakened by the preceding changes of hypertrophy, dilatation, and retention of urine. It may be that section of the vas deferens may prove an operation of value as a palliative measure in hypertrophy of the prostate with secondary changes in the kidneys and ureters.

Effect of Cholesterin on Pregnancy.—Hofbauer says that the placental tissues are very rich in lecithin which seems to be a very important factor in the nutrition of the fetus. He found that feeding pregnant animals with cholesterin causes the accumulation of this substance in the blood and the substitution of it for the lecithin of the placenta. Such feeding always led to death of the fetuses and to widespread changes in the placentæ, granulation and necrotic tissues taking the place of normal structures. The cause of these phenomena Hofbauer sees in the lack of lecithin. He thinks that the habitual death of the fetus in parental syphilis may be explained in the same manner. Wassermann has shown the avidity of syphilitic products for lipoids, among them especially for lecithin, and the binding of lecithin of the placental villi by the syphilitic products may cause death of the fetuses just as the substitution of cholesterin for lecithin does in experimental work.

Mechanism of the Action of Bier's Hyperemia.—R. Tarantini has experimented on animals to ascertain the manner in which Bier's method produces its effects. He gives us his conclusions as follows: The lymphatics, in the neighborhood of the part treated are affected; showing pigmentation when a colored fluid is injected, while immediately under the bell the lymphatics show no pigmentation. The hyperemia of stasis prevents the entrance into the circulation of foreign bodies injected under the skin. The effects last one half hour after the application. Immediately after the application the hyperemia prevents entrance of substances into the circulation by the action of a mechanical obstacle, later phagocytic action and new formation of connective tissue continue this effect. Hyperemia confers its benefits by exalting the natural means of defense of the organism.—*Il Policlinico.*

Book Reviews.

Medical Record Visiting List or Physicians' Diary for 1909. New Revised Edition. New York: William Wood & Co., 1909.

Every physician requires a visiting list, and the one now under notice is well known and is admirably adapted to its purpose. It contains the usual pages for visiting list, consultations, obstetrical engagements, vaccination and death records, addresses of patients and of nurses, and for cash accounts. Among much useful information of a general sort we note a list of remedies with the maximum adult doses given in both apothecaries' and the metric systems. The volume is of handy size, is handsomely bound, and can be had in various styles to suit the pockets and practice of all physicians.

The Physician's Visiting List (Lindsay & Blakiston's) for 1909. Fifty-eighth year of its publication. Philadelphia: P. Blakiston's Son & Co., 1909.

This is a handy leather covered note-book arranged for twenty-five patients per day or week. It contains, in addition to the blank pages, the equivalents of metric and apothecaries' measures, a table for calculating the period of gestation, a list of doses in both metric and the English systems, and such other information as is usually found in a physician's visiting list.

Psychotherapy. A Course of Reading in Sound Psychology, Sound Medicine, and Sound Religion. Edited by W. B. Parker. New Mork: The Centre Publishing Company, 1908.

This is the first of a series of twelve monthly publications intended to deal with the whole field of mental healing and suggestion. The course is prepared mainly for the general reader, but the physician who is interested in this new-old movement of mental healing will find it by no means elementary or too simple to claim his attention. The first number of the contemplated series contains the following articles: "The American Type of Psychotherapy," by Dr. Richard C. Cabot. "The Philosophy of Psychotherapy," by Professor James J. Putnam of Harvard. "The History of Healing in the Old Testament," by Rev. L. W. Batten, Ph.D. "The Mind and Body," by Professor James R. Angell of the University of Chicago. "Some General Conceptions of the Nervous System," by Frederick T. Simpson, M.D. "Psychotherapy at Northampton—An Account of Personal Experience," by Rev. Lyman P. Powell. The medical reader will be thoroughly in accord with Professor Angell, who says: "The great danger of the movement toward mental healing in the hands of non-medical men is that of getting away from constant contact with the neurologist, who can detect the danger symptoms which the untrained man cannot" (p. 69); and with a quotation from Dr. Llewellys F. Barker that "No one who is not skilled in all the modern refinements of diagnosis should undertake the practice of psychotherapy unless his work is controlled by a diagnostician who exhausts the best methods in the study of his case before beginning the therapy" (p. 97).

Sonnenblicke vom Lateinischen Amerika. Eine Kreuzfahrt nach Westindien, Columbien, Panama und Costa Rica (Von Carl Beck, New York). Berlin: Leonhard Simion, Nf., 1908.

The prime interesting feature of this elegant book is that it is written by an eminent surgeon. One of its most important features is in teaching colleagues the need of an occasional holiday. The trend of the book appears to be essentially humorous, while it contains many matters of medical and surgical interest. Ethnology, botany, cosmography, linguistry, and even poetry appear to flow from the author's pen as easily as do his well-known contributions to medical literature. In matters rhythmic, Beck is guilty of a translation of an apotheosis on Jamaica by Ella Wheeler Wilcox; the other contents of the book carry the conviction that he will be forgiven. Like many travelers, the author sees the humorous aspects of things non-scientific; however, he never sacrifices fact for fun. "Sonnenblicke" is perhaps the best contribution to the leisure which but few practitioners can obtain. There is compensation, not only in its entertaining information, for the time spent in reading it, but also in scientific facts, which Beck knows so well acceptably to present. The mechanical part of the volume, the type, paper, and illustrations, do credit to the publisher.

Anatomy und Mechanismus der Skoliosis. By Carl Nicoladoni. Berlin and Vienna: Urban und Schwarzenberg, 1909.

Nicoladoni, at the time of his death in 1902, a. o., professor in the University of Gratz, is well known in this country as the originator of tendon transplantation. The present monograph is an abstract of a more comprehensive article which was printed in the *Bibliotheca Medica* in 1904. It was prepared by the author of the *Deutscher Chirurgie* in which, however, it did not appear. It is now published by his sister in the hope that it may reach the readers for whom it had been intended.

The work is essentially a record of the dissection of two scoliotic subjects, an adult female and a child. The changes in the external organs, secondary to the deformity; in the gross and intimate structure of the spine and of its component parts are carefully described and illustrated. In the final chapter the leading theories are reviewed. The question of therapeutics is not considered. Students of the subject are indebted to Miss Henriette Nicoladoni for this memorial to her distinguished brother.

Die Komplikationen der Stirnhoehlenentzuendungen; Beitraege zur Anatomie, Pathologie und Klinik der Stirnhoehlen. Von Dr. P. H. Gerber, Professor der Koenigl.-Universitaets-Poliklinick für Hals und Nasenkranke in Koenigsberg. i. Pr. Berlin: Verlag von S. Karger, 1908.

The extent to which the literature of nasal accessory sinus disease has been carried is shown by the appearance of this book on the complications of one single pathological condition. Some of rhinology's greatest triumphs of the last decade have been won in the surgery of the sinuses. That the problem is a weighty one and that the dangers of surgical intervention are real is shown by the mass of information here collated and representing five years of careful study by the author, whose labors have been carried out with characteristic German thoroughness. After some remarks on the frequency of complications and nomenclature, he takes up the changes in the bony structures affected, mechanism of infection, bacteriology, and then passes on to consider the complications in the oculo-orbital and intracranial structures, such as meningitis in its various forms and intracranial abscess. General considerations on etiology and therapy follow, and the book closes with a complete index of authors consulted. The book is well-printed on good paper. It is, in fact, an analysis of the entire literature of the special topic of which it treats and represents a most careful and thorough investigation of original contributions, by one who is not only a library student, but an accurate and careful clinician. The book should be in the library of every worker in diseases of the accessory sinuses. It reflects credit on editor and publisher alike.

Contributions to the Physiological Theory of Tuberculosis. By Charles Creighton, M.D., Sometime Demonstrator of Anatomy, Cambridge Medical School; Author of "Bovine Tuberculosis in Man," etc. With 64 illustrations in the text. London: Williams & Norgate, 1908.

The book before us is a monograph detailing the original views of the author in regard to the pathogenesis of the lesions that characterize infection with the tubercle bacillus. Dr. Creighton claims to have shown that tubercle bacilli injected into an animal coagulate the blood in the small vessels of the lungs, and lead to plasmodial organization of the thrombi in these vessels as well as in those of the liver and spleen; the epithelioid cells of tubercle tissue he traces to the normal tissue cells changed by assimilation of disintegrated blood. A tubercle is for him a "rodent neoplasm" and he devotes an interesting chapter to the analogous "rodent neoplasm" seen in normal placental tissue. The last portion of the book is devoted to the consideration of spontaneous tuberculosis and the attempts to fortify the theory of pathogenesis founded on experimental work by the findings in human beings. The book has many well-drawn illustrations and ought to prove of interest to the pathologist; whether the original views of the author in regard to the nature of the tuberculous process will find acceptance remains to be seen.

A Laboratory Guide for Histology. Laboratory Outlines for the Study of Histology and Microscopic Anatomy. By Irving Hardesty, A.B., Ph.D., Associate Professor of Anatomy in the University of California. With a Chapter on Laboratory Drawing by Adelbert Watts Lee, M.D., Assistant in Anatomy in the University of California. With 30 illustrations, two of which are in colors. Philadelphia: P. Blakiston's Son & Co., 1908.

This book consists of a very practical chapter on laboratory drawing, followed by complete outlines for the preparation and study of histological material. The directions given are short, yet simple, and are followed by questions intended to call the student's attention to the important points to be noted by him. Each chapter is followed by a classified bibliography of the subject considered; this bibliography is much more extensive than is usually given in elementary texthooks and forms a most valuable feature of the book.

Society Reports.

THE NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held October 6, 1908.

THE PRESIDENT, DR. B. SACHS, IN THE CHAIR.

The Seat of Consciousness.—Dr. FREDERICK PETERSON, who read this paper, said that consciousness was a word in everybody's mouth. We used it glibly, as if we knew all about it. Psychologists, metaphysicians, physiologists, and physicians had all written a great deal concerning it, but if they had said anything of any great significance, it had eluded his observation. The most tangible thing that he had been able to grasp in reading their works was that consciousness was a stream, a flow, a flight, a current, a thread, an "orderly succession of changes." He took it for granted that whatever consciousness might be, it had a seat. It was assumed that if the body be removed portion by portion, first the legs and the arms and then the trunk as far as the base of the skull, that consciousness, if the circulation and oxygenation be kept up, still persisted in the head, and that its seat was in the brain. Such an experiment in effect had often been performed for us in broken necks and other spinal cord lesions. Those who had dared to surmise further had intimated that consciousness was diffused throughout the brain, or even that it was an attribute of the cortex of the brain alone.

With this preliminary statement, Dr. Peterson said, he would take a plunge at once into a subject that he knew as little about as anyone, not so much with the hope of establishing any new fact as for the purpose of provoking a discussion that might lead to some light in so much obscurity. In his opinion, the seat of that power which produced the manifestations of consciousness was in the basal ganglia (probably the corpora striata), and consciousness was a peculiar summation of energy at that point, capable of being directed like the rays of a searchlight into this or that portion of the brain. In pointing out the lines of reasoning which had led him to this conclusion, the speaker first referred to the daily physiological variation of consciousness in the condition of sleep, which was certainly a reduction in consciousness from the highest summation of energies to some lower level. Sleeping and waking were to be observed in a vast group of animals that had little or no cerebral development. Furthermore, the phenomena of sleep were observed in newly born human infants, despite the fact that the cerebrum was quite empty of experiences and anatomically still much undeveloped as to its connections with the rest of the brain. They were also observed in children born without a cerebrum, and even in dogs deprived of their hemispheres. In innumerable cases of extensive loss of cerebral substance, of a hemisphere, as in infantile cerebral palsies, a frontal lobe in the crowbar case, etc., consciousness itself seemed unimpaired throughout life. These observations seemed to show that consciousness, at least as regarded its variations in the condition of sleep, did not reside in the cerebrum. Another argument of a similar bearing was the fact that every individual with a brain stored full of all the experiences of a lifetime was only actually awake at any one time around some particular small group of functions or ideas that occupied consciousness.

Passing now to another series of pathological conditions, the one disorder which had led him to think much of this subject was epilepsy, in which disease loss of consciousness was the most extraordinary and often the only symptom. He alluded chiefly to such remarkable conditions as the *tic de salaam* and other forms of *petit mal*, in which the patient dropped suddenly to the floor with loss of consciousness, and quite as suddenly rose again in full possession of his faculties. The loss of consciousness was complete and often lasted but a fraction of a second. How could we account for such a phenomenon? If consciousness were a diffused attribute of the whole brain, what spasm of blood-vessels or other physical process familiar to us could act and be readjusted with such speed? The question now arose, what portion of the brain was so constructed as to be, apparently, in intimate connection with every other? The corpora striata. There was no part of the brain that we knew so little of. As Edinger said, here we had "a mighty portion of the brain that must be of enormous significance; otherwise it would not be always present, from the fish up to the man."

MR. HENRY RUTGERS MARSHALL said that a few years ago it would have been a matter of surprise to find such a subject presented for discussion before a body of neurologists, as it would have been considered to belong more particularly to the field of psychology. The speaker thought the thesis presented by Dr. Peterson open to discussion, in that it attempted to describe consciousness in terms of energy. We had become more or less accustomed to similar descriptions since the appearance of Ostwald's work, in which he had attempted to define consciousness in terms of energy, but since the publication of that work psychologists and philosophers had been endeavoring to bring meaning into his statement, but without success. There was one interesting point, Mr. Marshall said, to which he desired to call attention. The word consciousness, as commonly employed, had two diverse meanings. For instance, when we referred to the consciousness of plants, of which Darwin had lately spoken, we referred to psychic existence, as such. When, on the other hand, we stated, for instance, that we had gone to the theater and met an old friend who so engrossed our attention that we were not conscious of the play, we used the word consciousness with an entirely different meaning. We here referred to a state of "awareness," and that was entirely different from "psychic existence, as such." When we spoke of the seat of consciousness we might mean either the seat of psychic sense in man, or the seat of awareness. This latter was probably the form of consciousness to which Dr. Peterson referred. When we inquired as to the seat of consciousness as psychic existence, as such, we dealt with quite a different question. The evidence at our command at present favored a very broad and exceedingly general seat of consciousness, as thus considered. In the case of the epileptic, to whose sudden loss of consciousness Dr. Peterson referred, there was also a momentary paralysis—a sudden cessation of activities. That distinction was important, because it brought into relation with our states of clear consciousness all those states of what were commonly called our "subconscious" mental life; those states which might better be called "subattentive consciousness." Mr. Marshall said that under the view he held, waking and sleeping were objective signs of the same conditions which from another point of view were described respectively as clear consciousness and the lack of clear consciousness.

PROFESSOR FREDERIC S. LEE said that while Dr. Peterson had presented a very interesting idea, his paper gave rise to a considerable number of important questions. First, as to the nature of consciousness itself: whether, for example, it represented a special form of energy or not? The speaker thought that most physiologists would hardly agree with the idea that consciousness represented energy. It had seemed to him that the best working hypothesis for the physiologist was that consciousness was something of unknown nature which merely accompanied the activity of certain brain structures. He did not like the term "epiphenomenon" to express that idea, but since that was the common and accepted term, he would use it. Consciousness, then, was an epiphenomenon accompanying the activity of certain brain structures; or, rather, it was one of the modes of manifestation of their activity, just as chemical, thermal, and electrical phenomena were other modes. Consciousness could not put into activity the brain structures. He would not necessarily confine consciousness to the activity of the cerebral cortex only, although he was inclined to believe that consciousness was

more particularly associated with the working of cortical cells. Bechterew claimed that in early life, certain parts of the brain below the cortex acted consciously, and that as the tracts between these and the cortex became myelinized and functional, conscious activity came to be preeminently associated with cortical activity. He asked Dr. Peterson how, on the theory that the corpus striatum worked through the mediation of the cortex, he would interpret the behavior of one of Goltz's dogs, from which the cortex had been entirely removed.

Dr. Adolf Meyer said the thesis of Dr. Peterson brought back to us the proposition which Dr. P. Carus advanced about thirteen years ago in the *Journal of Comparative Neurology*, which was based largely on the argument that the corpora striata formed a large, bulky part of the brain to which at the present time no other function could be assigned. Gall in turn assigned the function to the optic thalamus. Ignoring entirely the question of what we meant by "consciousness" as a positive function, it seemed that the evidence that Dr. Peterson had brought forth could best be summed up as evidence of vulnerability of mechanisms of consciousness by a lesion in the basal region. It was evidence in favor of the possibility of localizing the lesions in some types of unconsciousness. As soon as we tried to make positive inferences, *i. e.* as to the "seat of consciousness," we were bound to meet quite a number of difficulties, and one of them was this: contrary to Dr. Peterson's assumption, the corpora striata had relatively very obscure connection with the rest of the brain. This was one of the greatest stumbling-blocks to the theory advanced that the corpora striata should be of such fundamental importance. So far as we knew, their connections with the cortex were extremely scanty, and with the rest of the base their connections were essentially those with the hypothalamus. On anatomical grounds alone it would be very difficult to explain any connection with the corpora striata and the "seat of consciousness," not to speak of the question whether the "seat of consciousness" could be a safe problem to-day.

Dr. Smith Ely Jelliffe said that in very general terms, consciousness might be regarded as the instreaming of all the sensory functions, and with the cutting off of the sensory or perceptive functions, a loss of consciousness followed. To illustrate that point we need not consider the effect of an anesthetic, because in alcohol we had an agent, *por excellence*, which cut off, one by one, the different sensory perceptive functions, little by little, until we had a non-conscious residuum. So far as the seat of consciousness was concerned Dr. Jelliffe said that in his opinion the corpora striata simply acted in the capacity of a cut-off by reason of the anatomical distribution of the fibers in that region. Instead of being the seat of consciousness, he looked upon this part of the brain as a gateway through which the fibers passed, and any injury in that area would be apt, therefore, to have a widespread effect.

The Serum Diagnosis of Syphilis in Its Relation to Nervous Disease. The Development and Character of the Wassermann Test.—Dr. C. F. Bolduan, after a brief review of Ehrlich's theory of antitoxin production and cytolysis, described the Wassermann test, which was now being extensively employed in the serum diagnosis of syphilis. The Wassermann reaction, briefly outlined, was as follows: Two tubes are prepared with the following contents: *Tube* 1. Extract of the liver and spleen of a syphilitic fetus, representing the syphilitic organism (or antigen), plus serum to be tested. *Tube* 2. Red blood cells of sheep or other animal, suspended in normal saline solution, plus serum of a rabbit which had been immunized to the particular red blood cells used. Complement (a substance necessary to all immune reactions, which existed in the fresh serum of all animals), in the shape of fresh normal guinea-pig serum, was now added to Tube 1 and allowed to stand. At the end of a half hour the contents of Tube 1 were added to that of Tube 2. If the serum in Tube 1 had come from a syphilitic individual, its relation to the extract of antigen was a specific one, and complement would be absorbed thereby; so that, when the contents of Tubes 1 and 2 were joined, no hemolysis of the red blood cells in Tube 2 would take place. If the serum was not from a syphilitic, complement would not be absorbed, but would remain active to cause hemolysis in Tube 2. Hemolysis was observed in the test tube as a tingeing of the whole field with a transparent red color. The red corpuscles had been disintegrated and the hemoglobin liberated. In the absence of hemolysis the solution of red cells remained turbulent and opaque. The test, of course, involved numerous controls and a careful standardizing of the hemolytic serum and of the syphilitic extract.

The Technique of the Wassermann Reaction; Its Practical Application with Reference to Diagnosis, Prognosis, and Treatment of Nervous Disease.—Dr. E. Castelli read this paper. After describing in detail the technique of the Wassermann reaction, the author offered the following conclusions: (1) From the social standpoint, the serum diagnosis of syphilis represented one of the greatest achievements attained by medicine at the present time. The rôle played by syphilis in the life of mankind required no explanation. The highest coefficient to degeneracy and insanity was created by syphilis. (2) If we were now in a position to tell our patient that, notwithstanding his previous syphilitic infection, he could marry and create a healthful progeny, we would certainly have at our command a tremendous factor for benefiting a large proportion of our fellow beings. (3) If we could establish the fact that syphilis was curable, and did not hang like the sword of Damocles over a man's physical and mental future, again would medicine have triumphed. (4) From a legal standpoint, the fact that we might be able to aid either the prosecution or the defense with the knowledge that the criminal had a claim on the court's leniency by reason of a previous syphilitic infection, which had produced a derangement of his mental poise, might become an important factor in the administration of justice. (5) The serum diagnosis of syphilis would be a means of differential diagnosis during the preparalytic stage, when the general symptoms were very indefinite and generally masked by a well-defined neurasthenic syndrome. The differential diagnosis between general paralysis and neurasthenia during this period would represent the real prophylactic warning. The patient, during this preparalytic stage, was already dangerous to himself, his family, and to society at large, and our early recognition of his condition made possible the safeguarding of the patient. (6) While the serum diagnosis of syphilis in its present condition was not perfect, and owing to its complicated technique and to the difficulty of procuring the necessary ingredients it was limited to a few privileged students, yet it had the indisputable advantage of furnishing us with a rich amount of positive diagnostic data, and the speaker said he considered its adoption in the various hospitals and medical institutions not optional, but absolutely necessary.

Demonstration of the Wassermann Reaction Test.—By Dr. Noguchi of the Rockefeller Institute. After demonstrating the Wassermann reaction, Dr. Noguchi showed briefly a reaction evolved by him during some experimentation with the various albumin reactions in the spinal fluids of general paralysis and other disorders. This was obtained as follows: 0.1 c.c. of the spinal fluid to be tested was placed in a test tube whose diameter was 1 cm. or less. To this was added 0.5 c.c. of a 10 per cent. solution of butyric acid. The tube was now heated until the fluid was bubbling, and while still hot 0.1 c.c. of a normal (4 per cent.) solution of sodium hydrate was added. In nearly all spinal fluids an opalescence or cloud occurred, but in the spinal fluid of general paralysis the cloud soon separated into a definite flocculence which was characteristic. The flocculence usually appeared in a few moments—rarely requiring more than 20 minutes. The reaction

shown by Dr. Noguchi had the advantage of being positive in a quantity of 0.1 c.c. or less, and of being a qualitative as well as a quantitative test. What the flocculence might mean was not known, but it might consist of some globulin fraction which was found only in syphilitic or metasyphilitic disorders of the nervous system. That the reaction was not entirely quantitative, Dr. Noguchi said, was shown by the fact that many fluids from non-paralytic cases gave much richer clouds than those from paresis, but in such cases the clouds did not flocculate.

Dr. J. W. Moore of the State Pathological Institute, Ward's Island, said that they had tested thus far 80 cases by the Noguchi method. Fifty undoubted cases of paresis gave 48 positive results. The two negative cases did not seem peculiar in any way. Of three cases of cerebral syphilis, two gave positive reactions. Of the non-paralytic cases tested, five were alcoholic psychoses, two manic-depressive cases, one paranoiac state, one imbecile, and one case which was diagnosed as Korsakoff's delirium, but which proved at autopsy to be due to a fractured skull with extensive diffuse dural hematoma. Only one of the non-paralytic cases gave a positive reaction. This was a case which had originally been diagnosed as one of dementia præcox, in which, however, there were increased knee-jerks and speech defect. Five doubtful cases gave two positive results and three negative. In the majority of cases of paresis the Wassermann reaction was also carried out. Four cases of general paralysis which were negative to the Wassermann test were positive to the other. Four gave the Wassermann reaction much less definitely than they did the Noguchi reaction. In no case was the Wassermann test the more conclusive of the two. In two of the cerebral syphilis cases in which the Wassermann reaction was tried it gave a negative result.

Dr. B. Onuf said that Dr. Castelli had made the statement that in a large percentage of cases of general paresis —70 or 80—the Wassermann reaction was positive, and also in about 60 per cent. of cases of senile dementia. Could we conclude from that that senile dementia was simply a late form of general paresis? Was it an indication that syphilis produced a rather rapid exhaustion of the nervous system, while in senile dementia identical changes occurred in a longer course of time? Did Dr. Castelli mean to identify senile dementia with general paresis?

Dr. Boleslaw Lapowski, discussing the Wassermann reaction, said that on account of its technique and the material and control experiments it involved, it would always remain a laboratory test. By terming it the "Wassermann reaction" we were inadvertently doing an injury to others who laid the basis of the reaction. Wassermann simply substituted dissolved substances of bacterial extracts of organs instead of emulsions of bacteria, but the basis was the fact discovered by Bordet and Gengou, and to them at least some credit was due. The test, Dr. Lapowski said, was of undoubted value in corroborating or establishing the diagnosis of latent syphilis, but even then it did not afford absolute proof, and consequently could not always be relied upon, and, moreover, when we had to deal with primary or secondary syphilis it was not necessary.

Dr. Sachs said that, while the Wassermann test could not be made at the bedside, its technique was not difficult and could be easily acquired. For the present, of course, this test, as were many others, would be restricted to the laboratory and had to be made by persons who were specially qualified along those lines. Thus far, the reaction had been practically limited to cases of suspected tabes or general paresis, but at the Mt. Sinai Hospital an effort was now being made to employ it as a diagnostic measure in other doubtful spinal or cerebral cases when syphilis was suspected.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held November 23, 1908.

Dr. J. Riddle Goffe in the Chair.

The reports of the various committees were read and approved. During the past year 163 applications for membership had been received, all of which had been acted upon, and 155 had been admitted to full membership. There were at present 2,262 active members.

The Lessons of the Recent International Tuberculosis Congress.—Dr. Woods Hutchinson said that the first impression and lesson that one got from the recent International Congress in Washington was the extent to which the laity and public generally had come to take an interest in the work. The people had come to realize that the profession was fighting their battles rather than its own, and that it was making for the happiness and health and progress of the body politic. This congress had given to the public that which it could never have gotten in any other way. One of the most interesting and dramatic features at the congress was the great debate upon the relative importance of human and bovine infection in tuberculosis. Dr. Koch's speech had been translated into English. He carefully reaffirmed his former position that although it was possible for the bovine bacillus to become so changed as to be the infecting agent in the human being, yet as a matter of practical demonstration this had never been shown. Experiments from this point of view, however, were open to criticism. Dr. Theobald Smith had practically struck the keynote in the discussion when he stated that the question of transferring the bovine bacillus to human beings was largely an academic one. Tuberculosis of the bovine type in human beings occurred in not more than two or three per cent. of the cases. Dr. Koch acknowledged that this suggestion of Dr. Theobald Smith was rational. Therefore, the position on this question in America was as in Germany. A special meeting was held in Washington for the purpose of discussing Dr. Koch's attitude, and was attended by those who supported as well as those who opposed the stand he had taken, and it was quite dramatic to see how the question simmered down to the position assumed by the French and the German schools. Dr. Koch's position was but little shaken. Probably the next most important feature of the congress was the grouping and the character of the papers, and one of the most interesting was presented by Dr. Miller, who investigated the percentage of tuberculous cases in families with tuberculous members; from 15 to 55 per cent. of those children were found to be already tuberculous. There was another point of interest from a surgical point of view, the extremely small percentage of cases in which the glands were involved. Localized tuberculosis in children was more often found at the age when the glands were most susceptible. The prevailing impression must be revised regarding the involvement of the cervical and mesenteric glands, or other glands which might indicate the source of entry of the infection. The glandular and osseous infection occurred in the later stages of the disease. With regard to therapy, there was an almost unanimity of opinion that was not at all encouraging, that little progress had been made towards discovering any specific serum or medication in tuberculosis. The general use of tuberculin was indorsed, and it was believed to be useful, especially in those cases that had come to a standstill after the giving of the ordinary course of treatment. Another paper of interest was the one by Webb and Barbar. They selected organisms from the hanging drops, and inoculations were made subcutaneously, thus producing an immunity in animals. Their experiments were only in the earliest initial stage. There was another feature that was quite remarkable; among the sixty or seventy papers read before the section on therapy, only one mentioned the name of a

drug, the use of the calcium salts in checking hemorrhage. He believed that the rational treatment of tuberculosis had come to stay. The main impression, however, that one got at this meeting of the International Tuberculosis Congress was that the laity was coming in to help in the campaign against the disease.

The Incidence of Tubercle Bacilli in New York City Milk, with the Study of the Effect on a Series of Children.—Dr. Alfred F. Hess said that one of the most important questions which confronted those who were fighting the spread of tuberculosis to-day was what proportion of infection was human in origin, what proportion was bovine in origin. In the United States Dr. Theobald Smith stated that it was his belief that not over one per cent. of tuberculosis was of bovine origin; on the contrary, Ravenel believed that a considerable number of cases were of this origin. The British Tuberculosis Commission recently reported that a very considerable amount of disease and loss of life, especially among the young, must be attributed to the consumption of cow's milk containing tubercle bacilli. The opposite view of Dr. Koch was known to all. In view of such conflicting statements on a subject of such vital importance, physicians and laymen were at the present time undecided whether they should concentrate their energies against the dangers from the tuberculous individual, or whether they should guard against a dual source of infection. Prophylaxis suffered from this indecision. Dr. Hess said that his work was undertaken with a threefold object. First, to probe one of the elemental phases of this broad question, to ascertain how often milk supplied to a large city, such as New York, contained virulent tubercle bacilli. Secondly, to study the nature of these bacilli, to learn whether they conformed uniformly to the bovine type. Thirdly, to report upon the health of some children who were known to have consumed milk containing the virulent bacilli. He asked what importance was to be given to the fact that 16 per cent. of the general milk supply of New York City was contaminated with virulent tubercle bacilli? The very size of these figures was proof that all must possess a considerable degree of immunity to the infection. There were very few infants fed on the ordinary raw milk who did not ingest tubercle bacilli during the first year of their lives, and they probably did so repeatedly. They knew that children were especially susceptible to tuberculous infection, and yet tuberculosis was by no means the main factor in the high death rate of infancy. On the other hand, it was certain that the bovine bacillus was frequently, in childhood, the cause of tuberculosis of various organs, of the tonsils, of the cervical and the mesenteric glands. Recently Dr. Hess collected 44 cases of undoubted bovine tuberculosis of the mesenteric glands, 41 of which occurred in children. At present there seemed to be insufficient basis for a statistical estimate of the importance of bovine tuberculosis, but it should be remembered that even if they charged it with but one per cent. of the total tuberculous infections, this small percentage was sufficient to establish it as a disease worthy of active recognition. The total number of cases of tuberculosis, exclusive of duplicates, reported in Greater New York in 1907 was, according to Dr. Biggs, almost 20,000. Every one realized that this figure was far below the actual number, and yet if it was accepted, and if only one per cent. of this yearly total was considered to have been of bovine origin, 200 of the reported cases must be attributed to this cause. Dr. Hess hoped that the alarming degree of tuberculous contamination which he had found in the New York City milk, and the figures he had furnished, might prove an effective argument of those who were striving with the legislature in the cause of pure milk. If New York City was granted, instead of 47 inspectors of farms, 150 such inspectors, it was certain that 16 per cent. of the milk sold in its precincts would not be found to harbor virulent tubercle bacilli. Dr. Hess closed his paper by reporting upon certain experiments made by him with children under ten years of age whom he knew were fed on infected milk. Certain facts were given, but no conclusions were drawn.

Dr. Henry Koplik said that there was no direct proof that the children took the tubercle bacilli in the milk and that these were the cause of their tuberculosis. It was to be hoped that the work in this field would be more definite and more explicit. At present there was a great diversity of opinion, and true workers liked to know the why and wherefore. The Calmette test in children was unreliable; Baldwin of Saranac Lake had proven the fallacy of this test in children. The von Pirquet test was a safer one, was absolutely innocent, and more definite information in a certain percentage of the cases was to be had. Dr. Koplik said it was unfortunate that the pasteurizing and sterilizing of milk was, in the minds of the majority of the people, intended to prevent the one disease, tuberculosis; where, as a matter of fact, it was intended to preserve the milk and to so protect the child from acute intestinal intoxications, or infections from bacteria of all kinds, especially in summer and the spring months. He believed that too much stress was laid upon one disease, tuberculosis.

Mr. Nathan Straus said he did not come to the meeting prepared to talk. At the same time, when questions concerning the milk problem were to be discussed, he could talk from experience. He acknowledged that he knew nothing regarding theory, but he knew that pasteurized milk reduced the death rate among children.

The Relative Importance of Human and Bovine Types of Tubercle Bacilli in Human Infection.—Dr. William H. Park said that since 1901 the Department of Health had endeavored to learn what proportion of the tuberculous cases were due to bovine infection and what proportion was due to the human infection. Dr. Koch's position he thought all present knew, but he had gradually receded from his first extreme position. Dr. Park spoke of the experiences at Randall's Island hospitals, where the children drank milk taken from a tuberculous herd of cattle for over one year, and probably for several years. In this herd they found 27 of the 32 cows tuberculous; yet very few of the children drinking this infected milk became tuberculous. Those children drinking raw milk there did not develop tuberculosis to any greater extent than other children living throughout the city. On the other hand, among the tuberculous parents who nursed their children 100 cases of gland involvement, 27 per cent., had been found. Among 100 cases at North Brother's Island, 25 per cent. had tuberculous members in the family, and 47 per cent. came in direct contact with tuberculous cases. All this made him believe that the greater proportion of cases of human tuberculosis was due to human infection. The question was what proportion of the cases was due to bovine infection. Could they detect, by their bacteriological methods, the type of bacilli causing the disease? Was the tuberculous lesion caused by the bovine or the human type of bacilli? The question also arose, might not the human bacilli of the adult have been the bovine bacillus in childhood? Could this type of bacillus change into the human type? There was, according to Dr. Park's opinion, no proof of this. All agreed that the bovine bacilli in time would kill. Dr. Park presented a table showing figures obtained from German reports, from English reports, reports by Theobald Smith, and elsewhere from the literature. There were altogether some 450 cases which made up the statistics he offered. Koch claimed that no case of tuberculosis in the adult ever occurred that was due to the bovine bacillus, and that in the cases reported the presence of the bovine bacillus was accidental. In the table Dr. Park presented the human type of bacillus was present in 98 per cent. of the cases of pulmonary tuberculosis, in 95 per cent. of the cases of meningeal tuberculosis, in 95 per cent. of the cases of

tuberculosis of the bones and joints, in 75 per cent. of the cases of tuberculosis of the cervical and bronchial glands, and in 50 per cent. of the cases of tuberculosis of the mesenteric glands. This table was particularly interesting in that it showed that the human bacillus was found in the meningeal type almost as often as in the pulmonary form of tuberculosis. In cases of tuberculosis of the cervical and bronchial glands 75 per cent. were of the human and 25 per cent. of the bovine type, while both types were equally divided in tuberculosis of the mesenteric glands. Dr. Park asked that specimens of tuberculous lesions, except the pulmonary form of the disease, be sent to the laboratory at the foot of Sixteenth street for examination.

The Methods Employed to Differentiate the Different Varieties of Tubercle Bacilli.—Dr. W. H. Woglom said that the two types of tubercle bacillus were closely related, but how closely he did not know. The two fundamental tests were the quantity of the growth in various media and their virulence upon experimental animals. The bovine bacillus grew sparsely in all media; whereas the human bacillus grew luxuriantly in all media. Therefore, with certain reservations, the two types could be separated into the sparsely growing bovine type and the rapidly, luxuriantly growing human type. If they could find some material which, when added to the culture media, would inhibit the bovine and increase the human bacilli growth, it would make a wider gap between the two types. In glycerine they had such a substance and, so far as their experience went, this difference had been quite constant. It had been found that the rabbit served almost as well as the calf in differentiating between the two types. One mg. bacilli of the human type would not kill a rabbit; on the other hand, 1/100 of this amount of the bovine type would kill a rabbit within five weeks. The material was given intravenously. They had as yet found no exception to this rule. These were the two tests most useful to them. Other tests had been proposed from time to time, but had not proven of such value. The bovine bacillus was shorter and more plump than the human bacillus, but this was a fact that was disregarded by all in differentiating the two types.

Dr. R. G. Freeman gave an analysis of the cases at Randall's Island that had been fed upon tuberculous milk. He had examined the death records extending over two and a half years. Then he examined the living children. The latter were subjected to the skin and conjunctival test and most of those children reacted who were known beforehand to have tuberculosis. There were 10 per cent. who reacted but who did not give any physical signs of the disease. For two and a half years milk infected with the tubercle bacilli was consumed by children who were not supposed to be robust and healthy, and yet he said he was not able to find any records of deaths which led him to believe that any child had been infected by this milk, although they knew the herd to have been an extremely tuberculous one.

Dr. J. J. Walsh advised ridding the city of the slums if they wished to reduce the death rate from pulmonary tuberculosis. In the crowded places tuberculosis was very prevalent, and this was due to the unfavorable conditions, especially poor ventilation, overcrowding, dust, dirt, poor lighting, and spitting.

Dr. Alfred Meyer spoke of the time and money and energy that had been wasted in urging the Government of the United States to give suitable and dignified housing to the delegates to the recent Congress in Washington. Dr. Meyer was one of the committee apointed to get a suitable place for holding the Congress, and the United States Government was urged to give a place. The representatives in Congress seemed to look upon them as beggars and even charged them with hysteria, and asked them to go to New York and hold their Congress. For many months the members of this committee carried on a campaign in the different States and territories of the Union, trying to influence their servants in the national capital of the United States to give them a dignified place where they could greet the members of the profession from abroad who came here to take part in their deliberations.

Election of Officers.—*President,* Dr. H. Seymour Houghton; *First Vice-President,* Dr. John E. Weeks; *Second Vice-President,* Dr. Joseph Brettauer; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. Charles H. Richardson.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 17, 1908.

Dr. Herbert S. Carter in the Chair.

A Case of Syringomyelia.—Dr. W. N. Berkeley presented this case. The patient was a Hebrew of foreign birth, a tailor by occupation, twenty-six years old, and single. His parents were alive and well; he had two brothers and four sisters, all in excellent health. His past history was negative. Four years ago he fell from a trolley car and struck on the back of his head. Within a few months after this accident he noticed that he was growing weaker, and his hands and arms soon became so feeble that he could no longer hold the needle or flatiron. He never had any pain, whitlows, onychia, nor trophic eruptions of any kind. He never perspired unduly; he never had hot or cold flushes, nor other vasomotor disturbances. He denied venereal infection. He drank and smoked in great moderation. The physical examination of the internal organs was negative. The examination of the urine was negative. The appetite and bowels were regular. His temperature, pulse, and respiration were normal. The most noticeable feature about the patient was the atrophy of the muscles of the hands and forearms. The fingers were in the "claw-hand" position, and the muscles of the thenar and hypothenar groups, the lumbricales, and the interossei were greatly wasted. The atrophy was more marked on the right side. On the arm the biceps was fairly well preserved, but the deltoids were shrunken on both sides, and the voluntary movements of the arms and hands, while fairly well coordinated, were feeble and ineffectual. The sensory changes were characteristic. The tactile sense was preserved over the entire body, but sensitiveness to pain and temperature were quite abolished over large areas of the chest, and over most of the arms, forearms, and hands. The patient showed a large painless blister on the right hand, due to a burn made accidentally by a hot flatiron, which he took up without perceiving that it was too hot to hold. Both knee-reflexes were exaggerated, and ankle clonus was present. The pupils were unequal, but both responded to light. The examination of the bones was negative except in that there was a dorsolumbar scoliosis. There were no signs of bulbar involvement. The patient's mind was clear, his speech was as good as it ever was, and his complaint was that he could not work and had become an unwilling burden on his relatives.

Report of a Case of Brain Tumor.—Dr. Warren Coleman reported the case of a man, thirty-five years old, who was admitted to Bellevue Hospital September 30. He was an electrician by occupation. He had never had typhoid fever. He gave no venereal history. Two weeks before admission he was taken with dull, general, persistent headache. There was general abdominal pain and vomiting. There was a slight bronchitis and general malaise. There was no epistaxis. On admission his temperature was 101.4°, and his pulse 72. He was a well-nourished, lethargic man. He had a coated tongue, without tremor. There was a slight tension in pulse. There were no rose spots. On October 4 the headache continued and the patient stated that he felt as if he was losing

his mind, said his brain "leaves his head," and he talked about it very calmly. The headache continued, always frontal, and usually on both sides. In spite of the absence of venereal history it was thought that possibly the trouble might be due to syphilis, and salicylate of mercury was given, but without effect. With the exception of the headache the disease pursued a course like the later stages of typhoid. The eye grounds were not examined. On October 28 the patient presented the appearance of one seeking help to prevent the development of unconsciousness. The mental struggle was evident in his expression, and the patient was continually reaching out with his right hand. He lay on his back with his head turned to the right; there was conjugate deviation of his eyes to the right; his pupils were dilated. There was spastic paralysis of the left arm and leg. The left nasolabial fold was flattened. There was no Babinski's sign. The patient was dying on October 29, when Dr. Coleman saw him. He had had frequent attacks of vomiting, the vomitus consisting in part of dark blood. There was coma, no response to pin-pricks, stiff neck, rigid limbs, the right being more rigid than the left. A large bulla filled with clear serum developed on the calf of each leg. The history and the appearance of the patient on admission suggested the end of a mild typhoid more than anything else. The blood count on September 30 showed 30,000 whites with 84 per cent. polymorphonuclears, 15 per cent. lymphocytes, 11 per cent. large mononuclears, and 3 per cent. eosinophiles. On October 4 the Widal reaction was positive. On October 5 the serum was positive to a strain of paratyphoid bacilli. Though repeated examinations were made, these were the only days on which positive serum reactions could be obtained to any of the typhoid colon group. On October 28 Dr. Coleman recognized that the patient had a cortical irritation, and in view of the fact that they had a case of sinus thrombosis in the hospital caused by the paratyphoid bacillus, he thought that this was probably a condition of similar nature.

On post-mortem examination the spleen was seen to be small, weighing approximately 150 g. Its capsule was somewhat wrinkled. The cut section was smooth. The dura mater was normal. On sawing through the skull cap a little bloody fluid oozed from the left temporal region. The pia mater was normal. Both cerebral convolutions were markedly flattened, especially that of the right side, the right hemisphere being somewhat larger than the left. The left temporosphenoidal lobe was adherent over a large area to the left middle fossa of the skull. The left temporosphenoidal lobe was occupied by a mass of rather soft, white tumor tissue, which was extensively infiltrated with blood. The right lateral ventricle, especially the posterior horn, was distended and contained rather an abundant amount of fluid, which was clear. The choroid plexus contained a few yellowish, rather firm foci. Otherwise the right side of the brain was normal. The tumor mass, which was not sharply demarcated from the normal brain tissue, occupied the inferior portion of the temporosphenoidal lobe, and extended well into the occipital lobe, and the visual tract of the occipital lobe. The internal capsule was compressed, but was not invaded by the tumor tissue. The left lateral ventricle was somewhat compressed. The floor was somewhat softened and hemorrhagic, and there was considerable succulent yellowish edema around the anterior horn. The fluid of the lateral ventricle was clear and small in amount. The other sections of the brain, on cross section, appeared normal. The spinal cord was not examined. The ears and sinuses appeared normal. The anamomical diagnosis was a glioma of the left temporosphenoidal lobe, with hemorrhage, and acute parenchymatous nephritis of mild grade. Sections from the brain tumor showed a cellular glioma, with scanty fibril formation. There were numerous mitoses. The tumor was traversed by a number of thin-walled blood-vessels, many of which were occluded by hyaline thrombi.

The Nauheim Treatment.—Dr. David Bovaird told what he had learned of the Neuheim treatment from a visit to Nauheim last summer. He described in detail the geography of Neuheim and its surroundings, consisting of beautiful farming country extending as far as the eye could reach. There were about the place fifty attractive drives, and each drive was described in a booklet which the cab driver furnished, giving all details, including cost, etc. The Neuheim springs were all within the park. A peculiar feature about Neuheim was the variety of medicinal springs, of various depths and different temperatures. Among the peculiar properties of the various waters were, first, the varying temperatures; secondly, the high content of carbonic acid gas; and, thirdly, the varying proportions of chlorides, carbonates, phosphates, iron, arsenic, and other ingredients. The drinking waters were much used in the cure of the diseases treated at the baths. Every morning at seven o'clock the orchestra played while the patients walked about the park sipping, not drinking, from one to two glasses of water. The treatment at Nauheim, he said, could not be described except in outline, and Dr. Bovaird described the general features of a typical case. The patients rested a good part of the day. He also described the method of giving the baths. The baths were divided into half and full baths. The food each patient took was prescribed for him by the physician in attendance. From twenty-five to thirty baths were given in each case before a cure was effected. He could say but little regarding the action of these waters, nor could he give any reason for combining the waters as was done. There was but little effect observed in the blood pressure after giving one bath. Certain changes occurred in the pulse, the most prominent being a drop in the number of beats. If the pulse had before been irregular, it became quite regular, and appeared to have more force after the baths. The patients found the baths very agreeable, although at first they were followed by a certain amount of lassitude and depression. This might be due to the peculiar climate. After a few baths this lassitude and depression passed away. The Nauheim physicians insisted upon the patients having further care and treatment after the baths, and even advised them to go to other resorts for this. The resistant or Schott treatment was of a very simple character; these exercises were arranged in a series. The treatment was not limited to the field of cardiac disease; rheumatism and other arthritides, anemia, and other conditions were treated as well. He could offer no explanation to account for the effect of these baths upon the heart or circulation.

Dr. Louis F. Bishop said that he had been in Nauheim last summer in order to study the cure and to get a definite idea as to why the people with heart disease went there, why they were so much benefited, and why the treatment could not be imitated in this country. He believed the benefit derived was largely due to the change of climate, the change of diet, the *esprit de corps* encountered, etc. With regard to the cardiac cases, a large part of them were due to some cardiovascular disease marked by disturbances of tone. There was a hypertonicity of the blood-vessels with a loss of tone in the heart, and the correction of these by the resisted movements made up a large part of the treatment. This was what had made Nauheim famous, especially when this treatment was combined with the Nauheim baths. The resisted movements by acting upon the tone of the voluntary muscles helped the tone of the involuntary muscles; in this way relief was given to the heart, thus giving it a chance to improve.

Dr. Alfred Meyer said that he had made two visits to Nauheim, one when a child, another two years ago, and he was particularly interested in the *x*-ray work done there and he wondered why the attempts at outlining the heart by the *x*-ray were not made in this country. It was Beneke in 1858 who first drew attention to the value of the Nauheim baths in the treatment of the heart, and

especially of the failing heart. The value of the springs he believed to be greater than the value of the resisted movements.

Dr. Bovaird expressed much admiration for what the Germans had done in developing the work at Nauheim. In the hands of their officials the work done was truly remarkable. They did a great deal of scientific work, and in an attractive manner. There were two principal officials, one who had charge of the baths and the medical work, the other who looked after the entertainment of the visitors. Nauheim was an example of paternalism, with a pater of the right sort.

SECTION ON GENITOURINARY SURGERY.

Stated Meeting, Held February 19, 1908.

Dr. Martin W. Ware, Chairman.

Litholapaxy in the Office Under Cocaine (Two Cases).—By Dr. George K. Swinburne. The first patient was a man, 45 years old, who had been suffering from urinary disorders for a year. It was discovered that he had a stone in the bladder, and a suprapubic cystotomy was proposed, but the family objected to it, so a week later litholapaxy was done in the office. He first injected three drams of a 2 per cent. solution of cocaine into the anterior urethra, which was held for ten minutes, and just before putting the patient on the table he passed a catheter, drew off the residual urine, and injected half an ounce of a similar solution into the bladder. The patient was then placed on the operating table and six ounces of warm sterile water were injected into the bladder through a catheter, and the lithotrite gently inserted. By raising the handle and depressing the beak of the instrument in the bladder, so as to form as low a level as possible, the blades were opened and the stone fell at once into the jaws and was readily crushed and washed out through a No. 22 F. evacuating tube with the Chismore pump. The whole operation occupied about half an hour and was practically painless. The patient was sent to his home in Brooklyn to go to bed, and was told that he could go to work the following day, which he did. The second patient was a man 65 years old, who had suffered from hematuria and great bladder disturbance, which was found to be due to the presence of a mulberry calculus in the bladder. After careful preparatory treatment he was operated on January 1, 1908, in the same manner as the first patient, the operation also being done in the office. The stone was very hard and slipped many times from the grasp of the lithotrite before it could be crushed. After crushing, which occupied considerable time, an evacuator was introduced and all was washed out excepting one fragment, which was too large to come through. This was crushed and removed at a subsequent operation, a week later. After the first operation, the patient was sent home and told to go to bed. There was some reaction and fever that night, but on the following day the patient was comfortable and able to go out. There was no reaction after the second operation, the patient going home and remaining in bed for twenty-four hours. He was now perfectly comfortable; he no longer found it necessary to get up at night to urinate, and only showed from two to four drams of residual urine. The comparative ease with which the operation in these two cases was done had impressed Dr. Swinburne with the desirability of doing litholapaxy in suitable cases, with the aid of a local anesthetic when that could be done. Further, it might prove better to repeat the operation under cocaine, if all the fragments were not removed at first, rather than work over the patient to the point of exhaustion in order to get out the last fragment at one sitting.

Dr. Eugene Fuller said he had done the operation a number of times without the use of any anesthetic, local or otherwise, and he thought that the danger of using cocaine in the urethra or bladder should never be lost sight of, especially in connection with work in the office.

Dr. Frederick Bierhoff said that in cases in which litholapaxy could be done at all, he regarded it as the operation of choice. Guyon had already brought out the point emphasized by Dr. Swinburne, that it was better to do the operation in two sittings rather than to exhaust the patient too much by trying to do it in one.

Dr. James Pedersen said that in many instances he had found it difficult to obtain the necessary degree of anesthesia of the deep urethra by local means. He was of the opinion that litholapaxy could be performed oftener than it was without any anesthetic whatever. Local anesthesia was of little assistance in the operation of litholapaxy; when any anesthesia at all was required, general anesthesia was indicated. The danger of poisoning from cocaine used in the bladder was a very real one. As a substitute he recommended the use of a 2 per cent. solution of eucaine.

Dr. William G. Eckstein, in speaking of the difficulty that was at times encountered in removing the last fragment, suggested the use of the small lithotrite made in connection with the cystoscope by the manufacturer of the Nitze instrument. In that way the operation could often be satisfactorily concluded. The speaker did not approve of doing this operation in the office or dispensary.

Dr. Victor C. Pedersen said many surgeons who used cocaine had expressed the view that when morphine was given a short time before the operation, there was comparatively little danger from the cocaine, as morphine seemed to be a potent physiological antidote to cocaine.

Dr. Ware said he had always been of the opinion that litholapaxy and lithotripsy were really capital operations and should be carried out with every precaution that that term implied. After the operation perfect rest of the bladder was indicated, and he thought it was rather a precarious procedure to allow such a patient to get up and go home.

Dr. Swinburne, in closing, said he had used cocaine for years in his genitourinary work, and he could recall only one instance where dangerous symptoms resulted. In using cocaine solution in the bladder, it was his practice now to wash out the bladder after leaving the solution in for a short time. He wished to emphasize the fact that if the patient was properly protected and accustomed to urethral manipulations prior to the litholapaxy, the operation was but little more serious than cystoscopy, which was continually being done in office work.

Stone Removed from the Pelvis of the Kidney, with Primary Suture.—Dr. Joseph Wiener reported the case of a married woman, 25 years old, who was admitted to the Mount Sinai Hospital on March 13, 1907. Her family history was negative. A year ago she had an attack of cramp-like pain in the right side of the back, radiating to the right labium. Since then she had had several similar attacks, each worse than the previous one. An *x*-ray picture, which was taken in October, 1906, showed a stone in the pelvis of the right kidney. This was subsequently verified by a second radiograph, taken just before the operation, and on March 14, 1907, the right kidney was exposed through an oblique incision. The stone was removed through a one-inch incision through the cortex. The kidney was then sutured, and the abdominal wall closed, excepting for a small gauze drain down to the kidney. When the patient left the hospital, twenty days later, she had a small discharging sinus, which soon healed. Her subsequent history was uneventful.

Stones Removed, After Nephrectomy, from the Other Kidney.—Dr. Joseph Wiener reported the case of a man 48 years old, whose right kidney was removed for pyelonephrosis in 1901. For five years following the nephrectomy the man had many attacks of left lumbar pain, associated with purulent urine, and what the patient stated to have been small stones passed per urethram. At various times there had been fever and chilly sensations. For four days prior to his readmission to the hospital, on December 8, 1906, no urine had been voided, and the patient had to be catheterized, although at night he stated that he could void some urine. He complained of severe left lumbar and hypochondriac pain. No mass was palpable. Two *x*-ray pictures had been taken, with negative showings. For two days after the patient's admission no urine was excreted, in spite of hot packs and diuretics. Repeated catheterization showed an empty bladder. The patient had daily chills, with a temperature of 102° F., severe headaches, vomiting, and drowsiness. On December 11, 1906, the left kidney was exposed and opened. It was found to be distended with pus, with a large and a small stone in the pelvis. The pus showed streptococci and *Bacillus coli*. There was very little kidney tissue left. For twenty-four hours after the operation there was some improvement in the patient's condition. The dressings were saturated with urine and pus, but the bladder remained empty. Death occurred two days after the operation.

Partial Resection of the Bladder for the Removal of Carcinoma.—Dr. Eugene Fuller said that as most papillomatous growths of the bladder were carcinomatous, or became secondarily malignant, even though apparently primarily benign, it was always best, in operating on these cases, to be as radical as possible. The only form of operation which deserved to be called radical consisted in a removal not only of the growth, but also of the bladder wall containing the pedicle of the neoplasm. Many times such a resection of the bladder was not possible, as, for instance, when the pedicle included the ureteral orifice, or when the perivesical structures were also involved. The first case was that of a man, 51 years old, who presented himself in May, 1903, complaining of frequent vesical hemorrhages, which were first noticed two years before, and which had gradually become more severe. There was some urinary frequency, and, when bleeding occurred, some difficulty in starting the stream. A cystoscopic examination showed a papilloma about the size of an adult thumb, growing from the posterior vesical fundus. A suprapubic cystotomy was done, and the bladder wall containing the papilloma was invaginated into and through the suprapubic opening. In that position a large vesical resection was accomplished. By means of long threaded needles, the opposing invaginated bladder walls were sutured together, the opposite peritoneal surfaces being thus brought into tight apposition. Above the line of sutures a needle, threaded with double heavy silk ligatures was passed through the invaginated bladder walls, and the tissues on either side were tied off and strangulated. This accomplished, the papilloma was cut off, while the pedicle and the strangulated resection were dropped back into their natural vesical position, the silk ligatures being left long, so that they protruded from the suprapubic opening. On the ninth day after operation, gentle traction on the protruding ends of the silk ligature brought away the sloughing strangulated vesical resection. The patient left the hospital at the end of five weeks, urinating normally, with a bladder capacity of six ounces, which six weeks later had increased to eight ounces. Dr. H. T. Brooks pronounced the growth carcinoma. The patient remained well and active and free from hemorrhage until the middle of December, 1905, a period of two years and seven months, when there was a slight recurrence of the hematuria. Cystoscopic examination at this time showed a papilloma about the size of a raspberry, near the middle of an otherwise perfectly smooth scar which formed the site of the vesical resection. Through a perineal opening this papilloma was excised, together with its pedicle, they being seized by cutting prostatectomy forceps. The patient left the hospital well, and eighteen months afterwards (making four years after the first operation) he was still enjoying good health. Since then he has been lost sight of. The second growth was reported by Dr. Brooks to be a "villous epithelial growth with features strongly suggesting malignancy."

The second case was that of a man, 45 years old, who complained of hematuria and frequent and very painful urination, which at times was difficult, and occasionally the stream would suddenly shut off completely. The urine was foul, containing pus, bacteria, and blood. The patient was feeble, anemic, and septic. Cystoscopic examination disclosed a large villous growth. Suprapubic cystotomy showed this growth to spring from a fleshy pedicle about the circumference of an adult forefinger. The pedicle was at the posterior fundus, about two inches from the right ureteral opening. A vesical resection operation, similar to that described in the first case, was done, and the growth was removed. In this instance, however, the line of sutures was near enough to the right ureteral orifice to constrict the caliber of that canal, and for several days following the operation there was much pain and tension referable to the right kidney. With the detachment of the resected slough, however, the ureteral constriction was relieved, and the right renal symptoms disappeared. The recovery in this instance was slow and tedious, owing to the existence of general sepsis at the time of operation, which was intensified by the operation. About three months after operation the patient left the hospital relieved of his vesical symptoms, and urinating naturally and normally. He had since been lost sight of. A histological examination of the growth removed from the bladder showed it to be carcinoma.

Fragmented Filiform Removed from the Urethra.—Dr. V. C. Pedersen showed a specimen of whalebone filiform guide, about 8¼ inches of which broke off in the deep urethra while a tunneled and grooved sound was being passed. The patient was a laborer, 57 years old, who had a stricture of the anterior and posterior urethra and hypertrophy of the prostate, with secondary chronic suppurating cystitis. On February 4 a filiform was passed and seemed both to the patient and to Dr. Pedersen to have reached the bladder. A 17F sound was then threaded over it and the attempt to insert it into the bladder was made. As the sound did not pass very well and as the filiform did not work freely either within the urethra, gentle traction on the filiform was made. Resistance was encountered, which gave way rather suddenly. On this account it was concluded to abandon instrumentation. Upon withdrawing the sound and filiform, it was then found that the latter was about 8 inches short. How to recover the fragment was the next question. The three-inch endoscopic tube was inserted, size 28F, and the filiform was found about 2 1-2 inches back from the meatus, with the torn tapering end rolled upon itself. An ordinary knitting needle with a hook point was now passed down to this loop, and by its aid the loop was straightened out until the tip of the fragment presented about ¾ inch back from the meatus. It was then rather an easy matter to seize this with a pair of Kelly's "mosquito" artery forceps, and remove it. Through the endoscopic tube the bulk of the fragment could be seen as it lay straight in the urethra beyond the curled up tip, which at least suggested the fact that the accident was not due to a folding of the filiform upon itself, for in that case the other end would ordinarily have been seen also.

The Radical Treatment of Carcinoma of the Bladder.—Dr. A. A. Berg, in this paper, said that the percentage

of ultimate cures effected by the various radical operations for carcinoma of the urinary bladder was very small, and did not bear favorable comparison with that which was achieved in the radical treatment of carcinoma of other organs. These bad results were partly owing to the complicated problems we were called upon to meet in dealing with malignant neoplasms of this viscus, and partly to the fact that we had neglected to fully appreciate certain points in the pathology of this disease. The radical operative cure of a malignant tumor, according to our modern conceptions, demanded a wide removal of the primarily diseased tissue and secondarily affected lymphatics and glands. When malignant deposits had extended beyond the immediate local glandular apparatus, or had appeared in distant organs, the idea of a radical extirpation of the primary disease could no longer be entertained. It was surprising how these axiomatic principles for the radical cure of malignant tumors were constantly ignored in cases of malignant growths of the urinary bladder. Thus it had been, and still was, the common practice to entirely ignore the lymphatics and glands in the radical operation for cancer of this viscus, owing possibly to the idea that these structures were usually not affected. That supposition, however, was entirely erroneous. In the very early stages of the malignant growth, when the neoplasm was confined to the mucosa, and was not ulcerated, the lymphatics and glands usually showed no malignant changes, but as soon as the tumor invaded and infiltrated the muscular coats of the bladder, the spread to the lymphatics and glands took place, and no operation could be a radical one that did not include a wide removal of these latter structures. In 56 cases of infiltrating cancer of the bladder collected by Guyon, glandular enlargements were positively recorded in 15, and in 41 no special mention was made of this fact. If the reservoir function of the bladder could be entirely dispensed with, or satisfactorily and safely replaced or substituted in some manner, a vesical carcinoma could be dealt with much as was a carcinoma of the gall-bladder; namely, by complete excision of the affected organ; but thus far all our experience had not succeeded in showing how to safely replace or substitute this urinary function of the bladder. The use of the rectum, vagina, or partly excluded loop of intestine, *e.g.* the sigmoid flexure or small intestine, as a substitute for the bladder had been mostly abandoned because of the danger entailed thereby of an infection from these viscera ascending the ureters to the kidneys, with consequent pyelonephritis and death. Similarly, the doing away entirely with a urinary reservoir by implanting the ureters onto the skin of the abdomen or loin, or by direct drainage of the kidney-pelvis through the loin, exposed the kidneys to the same dangers of infection, and because of the attention and care that had to be expended upon the toilet of the urinary fistulæ, it placed additional worry, annoyance, and discomfort upon the patient. It was, therefore, very desirable in the radical operations for vesical cancer to preserve enough of the bladder to act as a urinary reservoir, provided this was consistent with the requirements of a radical extirpation of the disease. In cases where the carcinoma was primary in the bladder, and limited to one part thereof, a wide removal of the neoplasm (partial cystectomy), together with all the lymphatics and glands, would afford as sure a protection from recurrence as would a complete extirpation of the organ. Furthermore, the immediate operative mortality after partial cystectomy was not half as high as that after entire removal of the bladder, and the objections raised by Watson to ureteral implantation into the intestine, vagina, or skin did not apply to ureteral reimplantation into a remaining healthy portion of the bladder. Dr. Berg was, therefore, forced to the conclusion that when we had to deal with growths limited to a third of the bladder, and especially when their site was on the fundus and lateral walls, partial cystectomy, with reimplantation of the ureter into the remaining portion of the bladder, was by far the operation of choice. When the cancer was diffusely spread over the greater part of the bladder, thus forbidding us to save a sufficient portion thereof to form a reservoir for the urine, or when there was a bad cystitis that did not yield immediately to therapeutic measures, and which necessarily increased materially the dangers of ascending ureteral infection after reimplantation of the ureters, then complete extirpation was advisable, provided the patient was otherwise sound. The preliminary operation of lumbar nephrostomy would certainly seem to be indicated when complete excision was done.

Dr. Howard Lilienthal said he was quite in accord with the views expressed by Dr. Berg, and in dealing with this condition of carcinoma of the bladder, he thought that no one would deny the necessity of early and very radical operation. The bladder was an organ the muscles of which ran in every conceivable direction. It was an organ that was constantly in motion, either being emptied rapidly or being gradually filled. When a neoplasm of the bladder got below the mucosa and invaded the muscular structure in the slightest degree, the extent of the diseased tissue would be apt to be very much greater than would appear on direct examination with the unaided eye. Therefore, even with an apparently small vesical cancer, an extremely wide resection would be the proper thing. Partial cystectomy, in order to be successful, should be performed in what we were accustomed to call selected cases. As to the other cases, in which the disease had progressed so far that a partial cystectomy was out of the question, under those conditions it was also a question whether any operative procedure of a radical nature should be undertaken. The outlook then was extremely hopeless, and only simple operations for the relief of the patient should be undertaken. Dr. Lilienthal thought there was no doubt that the use of urotropin and other formalin liberating drugs had greatly improved the outlook for all bladder manipulations, and especially for operative procedures on that viscus, and the statistics quoted by Dr. Berg might possibly be changed if a similar number of cases were gathered since the introduction of urotropin and a realization of its value. As to the Watson operation of simultaneous double bilateral lumbar nephrostomy in these cases, to which the reader of the paper referred, Dr. Watson advised it only in suitable cases in persons who were so situated that they were not obliged to work and who could be properly cared for afterwards. The procedure was certainly of greater value than was a colostomy in cancer of the rectum, and the latter was certainly of enormous value in carcinoma of the rectum. It was undoubtedly true that ureteral implantation into the functionating gut would invariably be followed by septic nephritis and death, usually within a year. This fact had been demonstrated experimentally and also in practice. In suitable cases of carcinoma and also of extrophy of the bladder he had on former occasions already advised the possible expediency of doing an ileocolostomy with exclusion of the cecum and ascending colon, and then implanting both ureters into this nonfunctionating section of gut, possibly utilizing the appendix as a urethra.

Dr. F. Tilden Brown said that the radical operation for carcinoma of the bladder was one regarding which surgeons naturally did not feel very enthusiastic, and, from a personal standpoint, believed that if such a patient was made moderately comfortable, he would be better off than to risk the danger and discomforts of a successful radical operation. The speaker thought that the danger of infecting the kidneys by lumbar implantation of the ureters, or even by nephrostomy, was no greater than by implantation into the viscera.

Dr. Fuller said that in bad cases of carcinoma of the bladder he strongly questioned the wisdom of a radical operation. Much could be done to relieve these patients

by palliative measures. The bladder could be opened above the pubes, and much of the growth removed with the curette, especially when it involved the urethral outlet and gave rise to pain or suppression; or, in suitable cases, the involved bladder wall could be invaginated through a suprapubic opening and removed in the manner he had described in his two cases of tumor of the bladder. Nephrostomy did not appeal to him, excepting for the purpose of prolonging life.

Dr. Joseph Wiener said he thought the consensus of opinion among surgeons was that complete excision of the bladder did not give as good results as a partial resection. The speaker called attention to the comparative frequent occurrence of malignant changes in the hypertrophied prostate, and he suggested the advisability of removing the prostate in all cases of carcinoma of the neck of the bladder in the vicinity of the prostate, even if its involvement at the time was not apparent. The added danger of this procedure to the patient was almost *nil*.

Dr. Edward L. Keyes, Jr., said he agreed with Dr. Fuller that when the bladder wall was the seat of a comparatively small growth, its radical removal was indicated, but in cases where one-third or more of the bladder had to be removed, the chances of a successful operation were very slight. These tumors were often of very slow growth, and he recalled cases where the patients were comparatively comfortable for a period of five years and longer. The speaker said that while he considered Dr. Wiener's suggestion to take out the prostate in connection with tumors of the neck of the bladder a most excellent one from a pathological standpoint, still this would be by no means a small addition to the operation, because it would imply removal of the capsule of the prostate, as well as its glandular tissue.

Dr. Berg, in closing, said he thought that patients with cancer of the bladder had been done an injustice; too many of them had been allowed to die of their malady without an attempt having been made to save them. The state of affairs was analogous to that which formerly existed in connection with cancer of the stomach, which for a long time was a disease that surgeons were afraid to touch. Commenting on Dr. Lilienthal's plan of implanting the ureters into a section of the excluded ascending colon, Dr. Berg said that a German writer had suggested making a side-to-side anastomosis of the two loops of the sigmoid at their roots, excluding unilaterally the afferant loop and implanting the ureters into this section of the bowel. This method would be much less hazardous than the one suggested by Dr. Lilienthal. The speaker agreed with Dr. Keyes that the removal of the prostate in these cases, in order to be efficient, must also include the removal of its capsule. It was unnecessary, he thought, to do this in tumors of the papillomatous and squamous type, unless they secondarily extended into the prostate, as these types of tumors were primary in the bladder; it should only be resorted to in connection with tumors of the adenomatous and fibroid or scirrhus type. The suggestion of Dr. Fuller was only feasible when the cancer involved the peritoneal surface of the bladder; it was impossible to do it with extraperitoneal tumors.

An Indirect Vision (Prismatic) Double-Catheter Telescope for Composite Cystoscope.—Dr. F. Tilden Brown demonstrated this instrument.

New Phosphorus Medication in the Treatment of Rickets.—Paul Sittler has used various of the newer forms of phosphorus compounds in rickets, and has found a combination of the glycerophosphate of lime and the nucleate of soda of the greatest value. The amelioration of symptoms is rapid. A child under one year takes a powder of .05 gram of the glycerophosphate and 0.1 gram of nucleate in sweetened water or milk twice a day. With older children the dose is taken oftener. The author obtains better results when hygiene and fresh air and hydrotherapeutics are added to the medication.—*Revue Mensuelle des Maladies de l'Enfance.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners, Territory of Arizona. *October, 5 and 6, 1908.*

ANATOMY.

1. Give a description of the general lymphatic system.
2. Give the histology of compact bone.
3. Give the structure of the spinal cord.
4. Name the muscles of the back, grouping them in their different layers.
5. Give the origin, insertion, action, blood and nerve supply of the following muscles; occipitofrontalis, pectoralis major, deltoid, adductor longus, rectus abdominis, and sternomastoid.
6. Name the lobes and fissure of the brain.
7. Describe the peritoneum.
8. Name the anatomical structures derived from the epiblast, mesoblast, hypoblast.
9. Give the gross and minute anatomy of the kidney.
10. Describe the brachial plexus and give its distribution.

MATERIA MEDICA.

1. Explain the distinction between the physiological action and the therapeutic use of drugs; between rational and empirical therapeutics.
2. What ratios do hypodermic and rectal dosage bear to that by the mouth? Give rule for children's dosage.
3. What are alkaloids? Give the four official alkaloids of cinchona bark.
4. Give a safe and efficient dose for an adult of morphine sulphate; strychnine sulphate, cocaine hydrobromide; hyoscine hydrobromate; tr. digitalis; tr. aconite.
5. Give the active principles of digitalis; give indications and contraindications for the use of the drug in diseases of the heart.
6. Name five potassium salts commonly used in medicine. State dose.
7. Give source and action of ergot.
8. Name some of the chief alkaloids of opium and state the therapeutic differences in the use of opium and morphine.
9. What hypnotic should be avoided if patient has a weak heart?
10. What anesthetic do you use, and why do you prefer it?

PHYSIOLOGY.

1. Upon what theory is physiology founded? What is the structural basis of all organisms?
2. Life is in its ultimate analysis the metabolism of plasm; define plasm and metabolism. Give chemical constituents of plasm.
3. Lymph: where elaborated; how conveyed; composition and function.
4. Give source and function of adrenalin, thyroidin, and opsonin.
5. Describe the local peculiarities of the circulation of the blood in the brain, lungs, liver, and erectile organs.
6. Give mechanism of respiratory movements; ratio of respiration to pulse; effects of atmospheric pressure on respiration; influence of respiratory movements on heart and circulation of the blood and lymph.
7. Give the source and action of the various secretions concerned in the process of digestion.
8. Where are the following centers: (*a*) Parturition, (*b*) auditory, (*c*) respiratory, (*d*) visual, (*e*) micturition?
9. Define: (*a*) Amnion, (*b*) corpus luteum, (*c*) leucin, (*d*) erythrocyte, (*e*) neuron, (*f*) hemolysin.
10. Distinguish between cerebral and spinal paralysis in (*a*) muscle-tonus, (*b*) nutrition of muscles, (*c*) electrical reactions of muscles.

CHEMISTRY.

1. Define decomposition. Name three physical decomposing agents.
2. Sulphur: (*a*) occurrence in nature, (*b*) physical and chemical properties, (*c*) what compound of sulphur is liberated in decomposing organic matter?
3. Give chemical formula for (*a*) hydrochloric acid, (*b*) sulphuric acid, (*c*) Epsom salts, (*d*) Rochelle salts, (*e*) Glauber salts.
4. What is an alkaloid? Name five important ones and give derivation of same.
5. What are ptomains? Give usual symptoms present in ptomain poisoning.
6. Name the general properties of carbohydrates and mention the occurrences in nature.
7. Describe in detail (*a*) a chemical test for blood; (*b*) for pus in the urine. (*c*) What urinary test is considered

most important from a diagnostic and prognostic standpoint in pulmonary tuberculosis? (*d*) How may the amount of total solids passed in the urine in 24 hours be approximated? (*e*) How many grains of total solids should a man weighing 160 pounds pass in 24 hours? (*f*) Give normal sp. gr. of human urine. (*g*) Give test for albumin in urine; (*h*) for sugar in urine. (*i*) What is the normal amount of urea passed by man in 24 hours, and give a method of estimating the amount excreted.

8. (*a*) Name a test by which arsenic may be detected with certainty. (*b*) Give antidote for arsenic poisoning.

9. Name some drugs which combined in a prescription would be chemically incompatible. Give chemical formulæ.

10. Give chemistry of pancreatic ferment in digestion.

PATHOLOGY.

1. In what diseases does hypertrophy of the heart most commonly result? Why?

2. What are the commonest underlying conditions in angina pectoris?

3. What are the microscopic characteristics of the exudate in croupous pneumonia? In catarrhal pneumonia?

4. What pathological conditions are productive of icterus?

5. Differentiate, pathologically, between a typhoid ulcer and a tuberculous ulcer of the intestine.

6. Give the usual methods of metastatic extension of carcinoma and of sarcoma.

7. In what locations in the body is the typhoid bacillus found in typhoid fever?

8. Name the parasite of malaria and describe its development in the blood.

9. Describe briefly lesions in the cord in tabes dorsalis.

10. What is pathological leucocytosis?

PRACTICE.

1. Give differential diagnosis between measles, scarlet fever, and smallpox.

2. Give treatment of acute gastrointestinal catarrh in children.

3. Give predisposing cause and treatment of pulmonary hemorrhage.

4. Describe the etiology and pathology of typhoid fever.

5. Give diagnosis and treatment of pneumonia.

6. What is the prognosis as to the cure of epilepsy? Treatment of epilepsy?

7. Give treatment of acute bronchitis.

8. What are the complications and sequelæ of scarlet fever?

9. Give varieties of erysipelas, with treatment.

10. Give treatment of asthma.

SURGERY.

1. What is the point of election for ligation of the subclavian artery? Describe fully the technique.

2. Give differential diagnosis of osteosarcoma and tuberculous knee-joint.

3. Differential diagnosis of renal and cystic calculi. Give treatment of each.

4. How does the Halstead differ from the Bassini operation for inguinal hernia?

5. Symptoms, diagnosis, and treatment of prostatic hypertrophy.

6. Etiology, diagnosis, and treatment of fistula in ano.

7. Diagnosis and treatment of embolism of the mesenteric vessels.

8. Diagnosis and treatment of ulcerative perforation of the intestine.

9. Differential diagnosis and treatment of hydrothorax and pyothorax.

10. Describe minutely the operation for enucleation of the eye.

OBSTETRICS.

1. Describe the changes that take place in the mucous lining of the uterus preparing it for the reception of the fertilized ovum. If it becomes attached, what further changes take place? If it passes without becoming attached, what further changes?

2. Describe the conditions most likely to result in laceration of the cervix and perineum and what remedies would you use and what treatment would you employ to reduce the danger as much as possible?

3. Describe fully how you would conduct a face presentation.

4. Describe how you would conduct a breech presentation to decrease the danger to both mother and child as much as possible.

5. Classify, give symptoms, and treatment of extrauterine pregnancy.

6. Give classifications, symptoms, and treatment of placenta prævia.

7. Give technique of obstetric asepsis and antisepsis during pregnancy, parturition, and the puerperium.

8. Mention four important causes of active uterine contractions of normal labor.

9. Give the cause and treatment of puerperal sepsis.

10. Give the three important diameters of the fetal head at term; the diameters of the normal female pelvis.

GYNECOLOGY.

1. What are the most common causes of pelvic cellulitis?

2. State how chronic purulent salpingitis may cause sterility.

3. Give differential diagnosis between acute nonpuerperal ovaritis and appendicitis.

4. Describe urethral caruncle and give treatment.

5. When is ventral fixation contraindicated?

6. What is vaginismus? Give its causes and treatment.

7. Give treatment in detail of retroversion of less than one year's standing.

8. Explain how fibroid tumors may cause ascites.

9. When would you perform trachelorrhaphy and when amputation of cervix in cervical lacerations? Give technique of trachelorrhaphy.

10. What is the cause of chronic inflammation of Skene's glands? Give treatment.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS, TERRITORY OF ARIZONA.

October, 5 and 6, 1908.

ANATOMY.

4. MUSCLES OF THE BACK. *First layer:* Trapezius, and Latissimus dorsi.

Second layer: Levator anguli scapulæ, Rhomboideus major and Rhomboideus minor.

Third layer: Serratus posticus superior, Serratus posticus inferior, Splenius capitis et colli.

Fourth layer: Erector spinæ, Iliocostalis, Longissimus dorsi, Spinalis dorsi, Cervicalis ascendens, Transversalis cervicis, Trachelomastoid, Complexus, Biventer cervicis, and Spinalis colli.

Fifth layer: Semispinalis dorsi, Semispinalis colli, Multifidus spinæ, Rotatores spinæ, Supraspinales, Interspinales, Extensor coccygis, Intertransversalis, Rectus capitis posticus major, Rectus capitis posticus minor, Obliquus capitis superior, and Obliquus capitis inferior.

6. *Lobes of the brain:* Frontal, parietal, occipital, temporal, central, limbic, and olfactory.

Fissures of the brain: Longitudinal, transverse, Sylvian, of Rolando, calcarine, parietal, and parieto-occipital.

8. From *the epiblast* are derived: The skin, and its appendages (hair, nails), and glands (including the mammary glands); the nervous system (brain, spinal cord, ganglia and nerves); the epithelial parts of the organs of special sense.

From *the mesoblast* are derived: The skeleton; connective tissues; muscles and bones; heart, blood-vessels, lymphatics, and spleen; the urinary and generative organs.

From *the hypoblast* are derived: The epithelial lining of the alimentary canal and its glands; the epithelial lining of the respiratory tract, Eustachian tube, thyroid and thymus.

MATERIA MEDICA.

1. The *physiological action* of a drug is the influence which the drug exerts upon the various bodily organs or tissues in a state of health. The therapeutic use signifies the use of drugs in accordance with "rational" or "empirical" usage as defined below.

Rational therapeutics is the use of remedies based on a combined knowledge of their physiological action and of the pathological condition present in the patient.

Empirical therapeutics is the use of remedies based on no other "reason" but that some one has found them useful or beneficial in conditions similar to the one under treatment.

2. If the dose by *mouth*, is one grain, the *hypodermic* dose would be about one-half grain, and the dose by *rectum* about one and a half grains.

Rule for children's dosage: Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

3. *Alkaloids* are organic nitrogenized substances, alkaline in reaction, and capable of combining with acids to form salts in the same way that ammonia does.

The *four official alkaloids of cinchona bark,* are: Quinine, quinidine, cinchonine, and cinchonidine.

4. Morphine sulphate, dose, gr. ¼; strychnine sulphate, dose, gr. 1/64; cocaine hydrobromide, not used, the dose of cocaine hydrochloride is gr. ¼; hyoscine hydrobromate, dose, gr. 1/128; tr. digitalis, dose ɱxv; tr. aconite, dose ɱviij.

5. Digitalis. *Active principles:* Digitalin, digitalein, digitin, digitoxin, and digitonin.

Digitalis is indicated in diseases of the heart, (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in non-valvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high.

6. *Five potassium salts:* Potassium bromide, dose, gr. xv; potassium iodide, dose, gr. vijss; potassium acetate, dose, gr. xxx; potassium citrate, dose, gr. xv; potassium chlorate, dose, gr. iv.

7. Ergot. *Source:* The sclerotium of the claviceps purpurea.

Physiological action: Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue.

8. *The chief alkaloids of opium,* are: Morphine, codeine, thebaine, narceine, narcotine, papaverine, and pseudomorphine.

Therapeutic differences in the use of opium and morphine: Opium is more slowly absorbed, acts more slowly, the effect lasts longer, and its immediate local effect on the intestines is more marked. Morphine is less irritating, less constipating, less diaphoretic, less stimulating to the heart and nervous system, and affects the secretions less than opium. Morphine is more liable to cause skin eruption and itching, it is more certain and rapid as an anodyne and hypnotic, and is also more quickly eliminated.

9. If a patient has a weak heart, *chloral* should not be used as a hypnotic.

PHYSIOLOGY.

1. Physiology is not founded upon any theory; it is rather based upon a knowledge of anatomy, histology, chemistry and physics.

Perhaps the examiner wants "Virchow's cellular theory."

Cells are the structural basis of all organisms.

2. *Plasm* (or *protoplasm*) is the physiological basis of life, being the substance of which the cells are made.

Metabolism is the name given to the entire series of changes which occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive, called *anabolism;* and (2) destructive, called *katabolism.*

The *chemical constituents of protoplasm,* are: Water, and solids; the chief of the latter are proteids (which contain carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus); lecithin; cholesterin; and chlorides and phosphates of calcium, sodium, and potassium.

4. *Adrenalin* is obtained from the medulla of the suprarenal gland. It is supposed to maintain the tonicity of the muscles, also to maintain the blood pressure, and to stimulate the muscle fibers of the heart and arteries.

Thyroidin is found in the thyroid gland. It is supposed to have some favorable influence on general metabolism, and to antagonize certain toxic substances.

Opsonin has its origin in the blood serum. It is said to increase the phagocytic action of the leucocytes.

7. The various secretions concerned in the process of digestion, are the saliva, gastric juice, pancreatic juice, bile, and succus entericus.

The *source* of the saliva is the salivary glands; of the gastric juice, the glands of the stomach; of the pancreatic juice, the pancreas; of the bile, the liver; and of the succus entericus, the glands of the small intestine.

The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The functions of the gastric juice are: (1) To change proteids into proteoses and peptones, and (2) to curdle the casein of milk.

The functions of the pancreatic juice are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The functions of the succus entericus are: The secretion of enterokinase, secretin, and crepsin, which assist the pancreatic juice in digestion.

8. The *center* for (*a*) *parturition* is in the lumbar enlargement of the spinal cord; (*b*) *auditory,* is in the first and second convolutions of the temporal lobes of the brain; (*c*) *respiratory,* is in the floor of the fourth ventricle; (*d*) *visual,* is in the occipital lobes of the brain; (*e*) *micturition,* is in the lumbar enlargement of the spinal cord.

9. (*a*) *Amnion,* is the innermost of the fetal membranes, it secretes and contains the liquor amnii.

(*b*) *Corpus luteum* is the scar or yellow body left on the ovary at the site where a Graafian follicle has discharged its ovum.

(*c*) *Leucin* is amidocaproic acid; it is found in the pancreas, spleen, liver, kidneys, thymus, lymphatic and salivary glands; it is due to the decomposition of proteins by acids or alkaloids, and during putrefaction.

(*d*) *Erythrocyte* is a red blood-corpuscle.

(*e*) *Neuron* is a nerve cell with all its processes.

(*f*) *Hemolysin* is "a substance produced in the body of one species of animal by the introduction of red blood corpuscles derived from the body of another species; it is capable of dissolving the red blood corpuscles of the animal species from which the blood was obtained."—*Gould.*

10.

	Cerebral Paralysis.	*Spinal Paralysis.*
(*a*) Muscle tonus.	Spastic; may be contractures.	Flaccid.
(*b*) Nutrition of muscle	Normal, or slight atrophy.	Marked atrophy.
(*c*) Electrical reaction	Normal.	Little or no response to faradic current; partial or complete reaction of degeneration to galvanic current.

CHEMISTRY.

1. *Decomposition* is the splitting up of a compound into simpler compounds or into its constituent elements.

Three physical decomposing agents: Heat, light, and electricity.

2. Sulphur. (*a*) *Occurrence in nature:* It is found free, also in combination in the sulphides and sulphates, and in proteids, especially the keratins.

(*b*) *Physical and chemical properties:* Yellow crystalline solid, slight odor and taste which are characteristic, insoluble in water, soluble in carbon disulphide, it is dimorphous; on being heated, it first fuses to a thin yellow liquid, on further heating it becomes thick and brown, at a still higher temperature it again becomes thin and lighter in color, and at a higher temperature again it boils, at the same time giving off a brownish-yellow vapor. Suphur has a valence of two or six, atomic weight of 32, molecular weight of 64; it readily combines with other elements; heated in air or oxygen, sulphur dioxide is produced; if burnt in hydrogen, hydrogen sulphide is produced. The compounds of sulphur are similar in constitution and (to some extent) in chemical properties to the compounds of oxygen.

(*c*) In decomposing organic matter, sulphuretted hydrogen H_2S is liberated.

3. (*a*) Hydrochloric acid, HCl; (*b*) sulphuric acid, H_2SO_4; (*c*) Epsom salts, $MgSO_4$; (*d*) Rochelle salts, $NaKC_4H_4O_6$; (*e*) Glauber salts, Na_2SO_4.

4. An *alkaloid* is a basic nitrogenous substance of alkaline reaction and capable of acting with an acid to form salts in the same way that ammonia does.

Five important alkaloids: (1) Strychnine, from strychnos nux vomica; (2) Atropine, from atropa belladonna; (3) Coniine, from Conium maculatum; (4) Nicotine, from tobacco; (5) Cocaine, from coca erythroxylon.

5. *Ptomains* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction.

Ptomain poisoning. Symptoms: Chilliness, headache, vertigo, muscular twitchings, hallucinations, imperfect vision, weak and rapid pulse, nausea, vomiting, diarrhea, cyanosis, early dyspnea, often subnormal temperature, and

occasionally cutaneous eruptions. The prognosis is guardedly favorable.

7. (*a*) *Chemical test for blood in the urine:* To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

(*b*) *For pus in the urine:* Acidify the urine with acetic acid, then filter it, and treat the filter with a few drops of freshly prepared tincture of guaiacum; a deep blue color denotes the presence of pus.

(*c*) Ehrlich's diazo reaction.

(*d*) and (*e*) The average amount of solids in the urine is about 850 to 950 grains in twenty-four hours. It can be estimated as follows: Take the specific gravity of the twenty-four hours' output; multiply the two last figures of this specific gravity by the number of ounces of urine passed in the twenty-four hours; multiply this product by 1.1; this represents the total urinary solids in grains.

(*f*) The normal specific gravity of the urine is about 1015 to 1025.

(*g*) *Test for albumin:* "The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered.

"The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of nitric acid."

(*h*) *Test for sugar:* First remove any albumin that may be present, then "render the liquid strongly alkaline by addition of sodium carbonate. Divide about 6 c.c of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color."

(*i*) The normal amount of urea passed by a man in twenty-four hours is about five hundred and twenty grains.

A comparatively easy test for *Urea* is that of Fowler, based upon the loss of the specific gravity of the urine after the decomposition of the urea by hypochlorite. "To apply this method the specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ (Squibb's). One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7791 gram of urea in 100 c.c. of urine. The specific gravity determinations must all be made at the same temperature; and that of the mixture only when the evolution of gas has ceased entirely."—(Witthaus' *Manual of Chemistry.*)

8. (*a*) *Test for arsenic:* Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

(*b*) The chemical antidote for arsenic poisoning is freshly prepared ferric hydroxide. The ferric hydroxide changes the arsenic into ferrous arsenate, which is nonpoisonous.

9. Lead acetate, Pb ($C_2H_3O_2$), and Potassium iodide, KI, are chemically incompatible in a prescription.

10. The pancreatic juice contains three ferments: (1) *Trypsin,* which changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; it only acts in an alkaline or faintly acid medium. (2) *Amylopsin,* which converts starches into maltose. (3) *Steapsin,* which emulsifies and saponifies fats.

PATHOLOGY.

1. Hypertrophy of the heart most commonly results from the following diseases: Arteriosclerosis, chronic interstitial nephritis, exophthalmic goiter, valvular disease (particularly aortic), pulmonary emphysema, adherent pericardium.

2. The commonest underlying conditions in angina pectoris, are: Arteriosclerosis (either general, or of the aorta); obstruction of the coronary arteries, from atheroma, embolism or thrombosis; degeneration of the myocardium.

4. *Pathological conditions productive of icterus,* are: Catarrh of the duodenum and common bile duct, pancreatic disease, gallstones, cirrhosis of the liver, obstruction of the bile ducts, septicemia, acute yellow atrophy of the liver, tumors of liver, pancreas, stomach, or kidney.

5. *In the typhoid ulcer:* (1) The main axis of the ulcer lies parallel with that of the intestine; (2) it lies opposite to the mesenteric attachment; (3) it has smooth floor and undermined edges; (4) it commonly leads to perforation.

In tuberculous ulcer: (1) The long axis of the ulcer lies at right angles to that of the intestine; (2) it is not necessarily situated opposite the mesenteric attachment; (3) its floor is not smooth nor are its edges undermined, but rather funnel-shaped and irregular; (4) it is not apt to perforate, but it does not tend to heal, rather to spread.

6. The usual method of metastatic extension of *carcinoma,* is by the lymphatics, occasionally by the blood-vessels; of *sarcoma,* by the blood-vessels.

7. In typhoid fever, the typhoid bacillus may be found in: The intestinal lesions, intestinal contents, spleen, liver, kidneys, urine, blood of the macular spots in the skin, lungs, parotid glands.

9. In *locomotor ataxia,* the posterior columns of the spinal cord are gray and shrunken and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbrosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent.

SURGERY.

4. *The Halstead differs from the Bassini operation for inguinal hernia,* in that in the Halstead operation: (1) A new and closely fitting internal ring is made; (2) the internal oblique and transversalis muscles are incised as well as the external oblique; (3) the spermatic cord is left between the skin and the aponeurosis of the external oblique; and (4) most of the veins of the spermatic cord are excised.

5. *Symptoms of hypertrophy of the prostate gland:* Slowness in starting urination; difficult micturition; frequency of micturition, particularly at night; the presence of residual urine; dull, aching pain in the perineum and above the pubes; enlargement of the lateral lobes of the prostate; there may be cystitis and retention of urine.

Treatment consists in: Catheterization, under proper precautions; prostatectomy may be required; formerly less radical measures were occasionally employed, such as castration, vasectomy, and Bottini's operation.

7. *Embolism of the mesenteric vessels* is *diagnosed* by the sudden onset of intense pain, which is sometimes persistent and sometimes has paroxysms of extra intensity, rapid pulse, subnormal temperature, abdominal rigidity, exhaustion, nausea, vomiting, and in about half the cases bloody diarrhea; meteorism may be present, and a mass may be palpated over the affected region.

Treatment: Exploratory laparotomy, and if the affected area is small, resection of the part of the intestine involved is indicated. If a large portion of the intestine is gangrenous, little or nothing can be done.

10. *Enucleation of the eyeball* is performed as follows: "A general anesthetic is generally given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the conjunctiva, we may begin with a tenotomy of the internal rectus and then divide the conjuctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward, and thus the optic nerve is put on the stretch. A pair of enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn, slightly opened, and the nerve is divided close to the sclera. The eyeball

is held between the thumb and index finger of the left hand, and the oblique muscles, and other unsevered attachments are divided. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is usually closed with a single suture, which is passed through its edge at intervals and tied like the string of a pouch. The eye is bandaged and the patient kept in bed for a day."—(May, *Diseases of the Eye.*)

GYNECOLOGY.

1. *The most common causes of pelvic cellulitis,* are: Traumatism during labor or the puerperium, abortions, sepsis, gonorrhea, an ill-fitting pessary, spread of inflammation from any part of the genital tract.

2. *Chronic purulent salpingitis may cause sterility,* by: Destroying the cilia in the tube, and so hindering the transmission of the ovum; causing adhesions, thickening, stenosis, kinking, or atresia of the tube, and thus hindering the transmission of the ovum; pathological secretions may also destroy the ovum.

3. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *inflammation of the right ovary* the pain is not localized, but may be bilateral, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

4. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

5. *Ventral fixation is contraindicated* when there is any possibility of a future pregnancy.

6. *Voginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, caruncule myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

8. Fibroid tumors cause ascites by pressure on the large vessels which thus induces an effusion of liquid through the walls of these vessels.

9. *Trachelorrhaphy* should be done: When the lesion is slight, and there is not much loss of tissue or erosion; or in uncomplicated cases.

Amputation should be done: When the lesion is greater, or stellate, or where there is much loss of tissue, or when complications are present.

10. Generally gonorrhea, or maybe tuberculosis.

Treatment: The tubules should be slit open and cauterized with pure carbolic acid, or excised.

Louisiana.—The Louisiana State Board of Medical Examiners recognizes at present certificates of examination issued by the following State boards: Colorado, Connecticut, Delaware, District of Columbia, Illinois, Indiana, Iowa, Kansas, Kentucky, Maine, Maryland, Michigan, Minnesota, Missouri, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Dakota, Ohio, South Carolina, Texas, Utah, Vermont, Virginia, Wisconsin.

Texas.—The regular semiannual examination of the Texas State Board of Medical Examiners will be held in Cleburne, June 22, 23, and 24, 1909. All applicants should be present at 9 A.M. Tuesday, June 22. The order of examination as determined by a published schedule cannot be varied from in any respect, and every applicant who desires to be examined must commence the examination on the morning of Tuesday, June 22. No person will be examined on June 22 except those who have made proper application on the blank forms issued by the State Board of Medical Examiners and have paid the fee on or before June 10. The fees paid will be returned to those unable to appear for examination. The application and fee must be sent to the Secretary, Dr. M. E. Daniel, at Honey Grove. The applicant must present his diploma for inspection at the examination. The filing of an application or the taking of the examination does not entitle applicants to practise, the only legal authority being a certificate from the State Board of Medical Examiners recorded in the district clerk's office of the county of residence or in some county in the State.

TUBERCULOSIS AMONG THE JEWS.*

BY MAURICE FISHBERG, M.D.,

NEW YORK,

PHYSICIAN TO THE UNITED HEBREW CHARITIES.

AMONG the many peculiarities observed among, or attributed to, the Jews, the most noteworthy is their alleged immunity to the noxious effects of contagious diseases, especially tuberculosis. Physicians practising their profession among Jews have repeatedly spoken of the rarity of Jewish consumptives; vital statistics compiled in Registrars' Offices of various countries and cities have shown that the number of Jews who die from tuberculosis is proportionately smaller than that of the non-Jewish population around them. About fifty years ago physicians stated that a Jewish consumptive was very rare; to-day it is only stated that, while there is no lack of tuberculous Jews and the Jewish Sanatoria for the treatment of tuberculosis are crowded with patients and have, as a rule, long lists of patients waiting for their turn to gain admission to the institutions, still, demographic statistics, wherever available, show that tuberculosis is proportionately less often a cause of death among Jews than among non-Jews in the same cities and countries.

In a report on the vital statistics of the Jews in the United States the Census Bureau has given proof of the incidence of consumption among the Jews in this country.[1] From the returns of an investigation among 10,618 Jewish families, including 60,630 persons, living in the United States December 31, 1889, it is seen that the death rate from consumption per 1,000 total deaths was among Jews, 36.57, and among Jewesses, 34.02, as against 129.22 among men, and 146.97 among women in Massachusetts in 1888. This would lead one to conclude that the general population of Massachusetts is liable to die from tuberculosis about four times as much as the Jews in the United States. But considering that the Census Bureau, while collecting these Jewish statistics, has dealt with a select class of people whose addresses have been obtained by its agents, it must be conceded that comparisons with the general population of any State may lead to rather odd results. Indeed, among the Jews included in the above investigation, 18,115 were reported as having some definite occupation, and of these 14,527 were wholesale or retail dealers, bankers, bookkeepers, clerks, etc., while only 84 were reported as being laborers, and 383 as engaged in agricultural pursuits. Such a group of persons should be compared only with another group which in the main follows the same class of occupations before attempting to draw conclusions as to the liability to tuberculosis of either group.

In 1901 I reinvestigated this problem in New York City. Not having any denominational statistics published by the Census Office or the Board of Health it is impossible to determine the exact death rates of the Jews in any city in the United States. But owing to their voluntary segregation in certain parts of a city, especially in New York, the mortality of the Jews can often be ascertained more or less near the true coefficient. My results showed that in the fourth ward, inhabited mostly by Irish and some Italians and Greeks, and very few Jews, there was the highest rate of tuberculosis mortality, 565 per 100,000 population; the first and sixth wards, inhabited by Irish and Italians respectively, also showed a mortality of between 400 and 500 per 100,000 population. In the wards inhabited mainly by Jews, I found that the thirteenth showed a tuberculosis mortality of 110; the tenth ward, 172; the eleventh ward, 155, and the seventh ward, 213 per 100,000 population. This showed that the Jews in New York City have only one-quarter of the tuberculosis mortality observed among the Italians and Irish who live in the same neighborhood.[2] Moreover, we are not dealing here with a select class of Jews, following certain occupations which are not conducive to morbidity, as I pointed out was the case with the statistics of the Jews compiled by the Census Office. The Jews living in the seventh, tenth, eleventh, and thirteenth wards, which are well known as the lower East Side of the city, are not all merchants. Most of them are artisans, working for long hours daily in tailoring shops, often of the sweatshop variety. Their dwellings are of the worst types of tenements, and an idea of the overcrowding can be gained when I mention that at the time this investigation was made, there were in the seventh ward 360, in the tenth ward 643, in the eleventh ward 407, and in the thirteenth ward 539 persons to the acre of land. If it is recalled that a very large proportion of the Jews living there were immigrants, *i. e.* adults between the ages of 15 and 45, when tuberculosis is most apt to occur, it is the more surprising that the mortality was found to be so low.

Nor is New York City unique in this regard. In Eastern Europe where 7,500,000, out of a total number of 12,000,000 Jews in the world, live in the three countries, Russia, Austria-Hungary, and Roumania, the same has been observed. Statistics collected in the just mentioned countries show that when compared with the Christians among whom they live, the mortality from tuberculosis is lower among the Jews. In Vienna it was elicited that during 1901-1903 the following were the proportions per 10,000 population:[3]

	——Tuberculosis——	
	Pulmonary.	All forms.
Catholics	38.8	49.6
Protestants	24.6	32.8
Jews	13.1	17.8

Roughly speaking, the Catholics in Vienna have a mortality from tuberculosis about three times, and the Protestants about two times that observed

*Paper presented to the International Congress on Tuberculosis, Washington, D. C., September 30, 1908.

among the Jews. In the Province of Galicia, where the poverty among the Jews is known to be appalling, they have a higher mortality from this disease than in Vienna, but still not as high as that observed among the Christians in that region. Thus in Lemberg, a city with 159,619 population, 44,258 of which were Jews during the census of 1900, the average annual number of deaths due to tuberculosis during the six years 1897-1902 were 734.3 Christians, and 135.6 Jews; in Cracow there were 25,670 Jews among a total population of 91,653, and the average annual number of deaths due to tuberculosis during 1896-1900 was, among Christians, 436, and among Jews, 52.6.[4] The tuberculosis mortality per 10,000 population was consequently as follows:

	Lemberg.	Cracow.
Jews	30.64	20.49
Christians	63.51	66.41

In other words, the tuberculosis mortality is proportionately among the Jews only one-half that observed among the Christians in Lemberg, and only one-third in Cracow.

In Budapest, Hungary, the census of 1906 shows that among a total population of 791,748, there were 186,047 Jews, or 23.5 per cent. During 1905 there occurred 3,195 deaths due to pulmonary tuberculosis, of which 408 were Jews, *i. e.* 12.8 per cent. Per 10,000 population there succumbed 21.93 Jews and 46.01 Christians to this disease; again one-half the rate among the Jews when compared with others.

In Roumania, where the mortality from tuberculosis is very high among the general population, although most of the people are engaged in agricultural pursuits, the Jews are also less often victims of this disease. Proca shows that in Bukarest the mortality was 38.7 per 10,000 Roumanians, and only 25.6 per 10,000 Jews.[5]

Not having any available vital, and demographic statistics about conditions in the Orient, where a large number of Jews live, I am unable to state definitely as to the morbidity and mortality from tuberculosis in those regions. Drs. Tostivint and Remlinger have, however, spoken of it in a paper on the subject published in 1900.[6] They show that in Tunis during 1894-1900 the tuberculosis mortality was among the Mussulman Arabs, 11.3; among the Europeans, 5.13, and among the Jews only 0.75 per 1,000 population. Any one who has seen the unsanitary surroundings and the poverty in the Jewish district of Tunis will be surprised at this favorable showing made by them in regard to their tuberculosis mortality.

In western countries many similar reports are available. The most recent inquiry made in London showed that the tuberculosis mortality of the Jews in the city is about one-half that observed among the general population. During 1897-1901 the number of deaths due to tuberculosis constituted 5.2 per cent., and during 1901-1906, 5.6 per cent. of the total number of Jewish deaths, while according to the Registrar General's returns, the number of persons who die from tuberculosis make up in London 9.2 per cent. of the total mortality. Per 10,000 population the mortality, was among the Jews, 13.3, and among the general population, 17.9.[7] It must be mentioned in this connection that the bulk of the Jewish population in London lives in the well-known Whitechapel district, and the majority is engaged at indoor occupations, especially tailoring and bootmaking. Still, when compared with the general population of London, or England and Wales, their mortality from tuberculosis is much lower. Similar conditions have been reported from Australasia, especially New South Wales, where the tuberculosis morbidity and mortality of the Jews is stated to be lower than that of the Christian population.

While discussing the statistics of the United States Census Office I pointed out that they are not conclusive, because an unusual proportion of merchants and other professional men are included, among whom tuberculosis is less frequent than among artisans. This objection does not hold when we speak of the Jews in Eastern Europe, or in London, New York, Chicago, St. Louis, Baltimore, etc. It is well known that the city dweller is more liable to contract tuberculosis than the inhabitant of the open country, especially the agriculturists are a favored class. The Jew all over the world is a city dweller *par excellence*. In Prussia over 50 per cent. of the population lives in the country, while only one-seventh the number of Jews live in rural communities. In Russia, while only constituting 4 per cent. of the total population, they make up 15.6 per cent. of the total urban population. The same is true of Austria, Hungary, and Roumania. Of the 2,000,000 Jews in the United States I have calculated that over 60 per cent. live in the nineteen cities which during the last census were found to have had over 200,000 population, while only 16 per cent. of the general population of the country were found in those cities. The Jews are essentially urban dwellers, and are more inclined to live in the great cities than in the small towns. This is natural, considering their occupations; they can only find an outlet for their activities in the large modern commercial and industrial centers. This again is important in its bearing on the liability to contract tuberculosis. It is well known that Jews prefer to work at tailoring, but few appreciate, when speaking of pulmonary diseases, the extent to which they are thus working at these dangerous trades. According to the Russian census of 1907, 782,454, or one-seventh of the total number of Jews who were gainfully employed, were dependent on the garment industry for subsistence. In this class were included tailors, shoemakers, hatters, capmakers, milliners, glovemakers, etc. In Austria also it was found during the census of 1900 that 81 per 1,000 Jews were engaged at the garment industry, as against only 40 of the Catholics. The same is true of the Jews in Hungary and Roumania. While we have no denominational statistics about conditions in the United States, still the figures compiled by Rubinow from the Reports of the Commissioner General of Immigration are showing that the same obtains here. Among the 330,573 Jews who were admitted to the United States during 1901-1906 there were 78,502 tailors, and 13,123 shoemakers,[8] *i. e.* 28 per cent. were garment workers. Here many of the Jewish immigrants who were not tailors in Europe learn the simpler kinds of machine operating, so that an estimate that 35 per cent. of all the immigrant Jews in the United States are garment workers will be about correct.

We all know the sweatshop worker. In the first place he is as a rule of poor physique even before he engages in tailoring. Men with well-developed muscles find more remunerative occupations. His chest is flat, presenting all the stigmata of the so-called *habitus phthisicus*. This chest, while to a great extent due to the malnutrition and anemia which is very prevalent, still it owes its miserable appearance mostly to defective muscular development. Flabby muscles cannot keep the ribs at a respectable elevation, but permit them to drop down at an acute angle in relation to the spinal column. The result is that the so-called "Jewish" or tailor's

chest is not only flat, but also of inferior capacity. In healthy individuals the horizontal circumference of the chest is over 50 per cent. of the height, but in the majority of tailors in New York City I have found by actual measurement that the girth is hardly one-half the height of the body.* The cramped attitude of the tailor's body while he is at work, as well as the lack of muscular movement, because sewing by no means involves free exercise of most of the muscles, in conjunction with the defective ventilation of the usual sweatshop, all conspire to reduce the vitality of the tailor and render his lungs predisposed to infection by the tubercle bacillus. As a matter of fact, statistics collected all over Europe show conclusively that tailors are more liable to tuberculosis than workers at other trades, excepting stone cutting, printing, and the like.

It is remarkable that in spite of this large contingent of Jewish tailors in Eastern Europe, England, and America, their mortality from tuberculosis is lower than that of any other class of artisans. The causes of this lesser liability to die from tuberculosis has been discussed by many medical authors. Some are inclined to attribute it to a special inherent vitality of the Jewish "race," which is also alleged to manifest itself in a low mortality from all other contagious diseases. Some have even maintained that the "Semitic" blood which flows in his veins renders the Jew immune to the virus of infection, and gives him an advantage in the struggle for existence when compared with the "Aryans" among whom he lives. But this argument is fallacious for various valid reasons: The Jews are by no means as pure a race as has been thought by some who depend more on sentiment than on scientific observation in their judgment of the subject. When we recall that we have about 30 per cent. of blond Jews, that there are tall and short Jews, dolichocephalic, mesocephalic, and brachycephalic Jews, we must acknowledge that we do not deal with the pure ethnic group. I need not enter here into details beyond saying that anthropologists of to-day deny the purity of the Jewish race as much as they deny the purity of the so-called Latin, Anglo-Saxon, Slavonic, and other "races." Be that as it may, we know that, on the whole, tuberculosis displays no racial preferences. Within certain limits, depending on social conditions, the white, black, yellow, and red divisions of mankind are attacked by this disease in the same manner, and the variations observed in the frequency, type, and course of the disease in different groups of people are alike traceable to the same causes, irrespective of racial affinities. We know that the variations displayed by the various social groups of white humanity, such as the differences in the incidence of the disease between city and country dwellers, rich and poor, those engaged in indoor or outdoor occupations, persons active in a dusty atmosphere as compared with such as are working in clean, airy shops, and the like, are just as great, often greater than the differences observed in the white, black, red, or yellow races. When we find that the morbidity and mortality from tuberculosis of the black and yellow races in the United States are excessive and appalling we cannot say that this is due exclusively to the differences in the anatomy and physiology of these and the whites. There are many social groups of whites who have just as high, even a higher morbidity and mortality, as can be seen from demographic statistics published in many countries, where causes of death are given according to the occupations of the inhabitants. Stone cutters, furriers, upholsterers, printers, and others who are engaged in an atmosphere laden with organic and inorganic particles of dust have also an excessive mortality from tuberculosis. On the other hand, the Indian living in our Western plains unaffected by modern conditions of civilized life, which in his case often consists mainly in the abuse of alcoholic beverages; the negro in his home in Africa, or even here during slavery, are only very rarely affected by tuberculosis. The same is true of the native tribes in Australasia, among whom tuberculosis was very rare, some even say it was unknown, before the advent of the white man, who while introducing a civilized mode of life brought along the white plague which is to-day decimating the native population. Similarly in Polynesia tuberculosis has been spreading like a wild fire among the natives, and it is stated by competent observers that the majority of deaths are due to this disease.[9] One hundred years ago a physician traveling among these races could justly say that tuberculosis is a very rare disease in Australasia, Polynesia, or in the Western region of the United States, and try to explain it as due to the superiority of the climate of those regions, or to the great power of resistance displayed by these races.

Another potent reason against the theory that the lower mortality of the Jews from this disease is due to an inherent racial resistance to the disease is the fact that intermarriage with non-Jews does not at all increase the number of consumptives among them. One example will suffice. In Berlin the number of mixed marriages between Jews and Christians is very large, reaching 44 per cent. of the pure Jewish marriages in 1905. We know that certain racial immunities, like those of the negro against malaria and yellow fever are impaired in the mulatto. By analogy we should expect that the number of Jewish consumptives should be higher in Berlin than in Austrian-Galicia, where practically no intermarriages are taking place between Jews and Christians. As a matter of fact, however, conditions are as follows. There were in 1905, according to the census returns, 98,893 Jews among a total population of 2,040,148 in the city of Berlin. During the same year there occurred in that city 4,302 deaths as a result of pulmonary tuberculosis, of which only 97 were Jews,[10] showing a mortality per 10,000 population of 21.66 Christians, and only 9.81 Jews. In Cracow, where no intermarriages take place, the tuberculosis mortality was 30.64—three-fold that observed among the Jews in Berlin. The fact that intermarriage does not increase the mortality from tuberculosis is, I believe, sufficient proof that there is no ethnic immunity to be elicited.

Some have maintained that the lesser mortality from tuberculosis is due to the elimination of most of the Jews who were predisposed in former times, thus leaving a race which is refractory to the effects of the tubercle bacillus. By breeding in-and-in, this resistance was fixed within the race. Reibmayr, who elaborated this theory, maintains that the Jews may abandon all their habits and customs, and as long as they abstain from intermarriage with non-Jews, their immunities to contagious diseases, including tuberculosis, will not be lost.[11] But, as we have seen, intermarriage does not render them vulnerable to the disease, but, on the contrary, the number of Jewish consumptives is much smaller in Berlin, and also among the native Jews of France, Italy, England, Australia, etc., than among the Jews in Eastern Europe, who do not at all intermarry with non-Jews. As I will soon show, these differ-

*See M. Fishberg, "Materials for the Anthropology of the Eastern European Jews," *Memoirs Amer. Anthrop. Ass'n.*, Vol 1, pp. 1-146. The girth of the chest is discussed in detail on pp. 50-56.

ences are due to social conditions and not racial causes.

Some authors have maintained that the ritual dietary laws practised by Jews are responsible for the lesser number of deaths from tuberculosis among them. As is well known, Jews, before pronouncing meat as fit for human consumption (*kosher*), subject every carcass to a thorough examination by an expert. Special attention is paid to the condition of the viscera, particularly the lungs, pleura, liver, and spleen. Those animals whose lungs present any adhesions to the thoracic walls or adhesions between the lobes of the lungs, or in which small nodules are discovered scattered over the surface of the lung are pronounced *terefa*, or unfit for human consumption. It has been stated that bovine tuberculosis is thus prevented from gaining a foothold among the children of Israel. In the light of our present knowledge of the origin and spread of tuberculosis, some of the foremost authorities (Calmette, Behring, and others) being of the opinion that tuberculosis is more often acquired by ingestion than by inhalation, the Jewish dietary laws should be an excellent preventive when strictly adhered to. But as a matter of fact, all the evidence is against this view. In Eastern Europe, where the Jews follow the dietary laws, strictly adhering both to the letter and spirit of the sacred ordinance, there is more consumption among them than among their coreligionists in Western countries who disregard the dietary laws in part or completely. In Germany, France, England, Italy, etc., where the majority of the native Jews are constantly seen eating in Christian restaurants, and many are not particular to procure *kosher* meat at home, there is less consumption among them than in Eastern Europe, the East End of London, or the East Side of New York City, where the poor, as they generally are, pay exorbitant prices for meat which is, or is alleged to be, *kosher*.

The incidence of tuberculosis among Jews depends more on their economic and social environment than on racial or ritual affinities. In Berlin, where they are as a class economically prosperous, there is but little tuberculosis among them. The death rate of pulmonary tuberculosis during 1905 was 9.81 per 10,000 Jews. In Vienna, where a large proportion are on a high plane economically, but where many poor Jews are found, the death rate is higher than in Berlin, reaching 13.1 for pulmonary and 17.9 for all forms of tuberculosis. In Budapest and Bukarest, where there are more poor Jews than in Vienna, the rates are higher, 21.93 and 25.6 respectively. In Galicia the poverty of the Jews is appalling; in fact, I do not know a poorer lot of humanity than is met with in the small towns of Austrian-Galicia. It is there where we have found the highest rate of mortality among Jews, reaching 30.64 per 10,000. The influence of economic conditions on the incidence of tuberculosis among Jews is well illustrated by conditions in New York City. In a recent report of the Charity Organization Society[12] I find an analytical table of the cases of tuberculosis registered in New York City. Altogether there were in Manhattan and the Bronx registered with the Board of Health 10.29 cases of tuberculosis per 1,000 population. In the Fourth, Sixth, Eighth and Tenth Assembly districts, which are almost wholly inhabited by Jews, the majority of whom are poor artisans engaged in the garment industry, the number of registered cases was 11.9, 12.0, 13.5, and 11.7 respectively per 1,000 population, while in the Thirty-first Assembly district, in Harlem, where the majority of the population consists also of Jews, but such as are on a higher economic plane, most of them merchants, manufacturers, professional men, and the like, the number of cases is proportionately the lowest of any assembly district in the city, being only 3.6 per 1,000 population. The Jews in the lower East Side are more orthodox, more strictly adhering to their faith and traditions, and still have proportionately a higher rate of morbidity from tuberculosis than their coreligionists in Harlem who, as is characteristic of Jews all over, with their prosperity have more or less discarded many of their religious practices, the first of which consists in consuming meat not prepared according to the dietary laws.

The social and economic aspect of tuberculosis has been studied quite carefully during recent years. Demographic statistics have shown that there are more deaths from tuberculosis in cities than in rural districts and that it is essentially a disease of people who live indoors. The concentration of population in cities is a comparatively recent phenomenon. Only about 100 years ago the urban population of any European country was only a small percentage of the total population. To-day there is a constant migration of the country dweller to the large industrial centers, where the opportunities for advancement are better than in the villages. But that the average country dweller is more or less incapable of resisting the deleterious effects of overcrowding, with its concomitant facilities for the spread of contagious diseases, is evident from the fact that very few of the inhabitants of the modern large cities in Europe can trace back their ancestry for more than three generations. It appears that the country dweller, after immigrating to the city, is the most vulnerable; he has the most chances to contract contagious diseases, particularly consumption. To begin with the extreme type of country dweller, those who live always in the open air, as the nomadic Kirghiz Tartars in the Siberian plains, or the aboriginal inhabitants of Australasia, Polynesia, or North and South America, we find that tuberculosis was quite unknown before the advent of the white man, who brought to these tribes not only civilization, often in the shape of whiskey, but also the tubercle bacillus. Never having met with these bacilli, these tribes were very vulnerable, like virgin soil. This is not only the case with tuberculosis. We know that the same is true of measles, scarlet fever, smallpox, etc. Whenever they are imported into a country where these diseases were unknown before they attack almost everybody. Similarly the rural population of our modern civilized states, owing to their open-air life not having undergone as rigid a process of selection in which most of those predisposed to tuberculosis have succumbed, are more often infected when they migrate to the city and begin to live in overcrowded houses, lacking fresh air and sunshine, and enter the modern factory and mill, where they often meet with fellow-workers who suffer from tuberculosis. It is this class of rural dwellers, not adapted to indoor city life, that is lacking among the Jews, who have for 2,000 years lived exclusively in cities, and during Medieval ages were confined in the worst parts of cities, the Ghettoes. Indeed, only rarely was the Ghetto enlarged to meet the demands of a growing population, but the Jews were compelled to accommodate themselves the best way they could in a small area. Under such conditions most of the Jews who were predisposed to tuberculosis succumbed, leaving no progeny. The same process is to-day going on with most other inhabitants of large cities. The Jews have only the advantage of having passed through a process of infection during past cen-

turies. Hence their lower mortality to-day from tuberculosis.

An excellent illustration of this process is going on before our eyes in New York City. The large number of immigrants who have settled in the East Side of the city consists mainly of Italians and Jews. The former come mostly from southern Italy, Sicily, Calabria, Basilicata, etc., where the mortality from tuberculosis is the lowest in that country, and lower than in many northern and western European countries. During 1904 the mortality from tuberculosis in Italy was 16.4 per 10,000 population, while in Calabria it was only 9.6; in Basilicata, 10.6, and in Sicily, 11.5; while in northern Italian provinces, where a large proportion of the population lives in modern cities, the tuberculosis mortality was much higher, 21.6 in Liguria, 21.1 in Lombardy, etc.,[13] and in the cities of Rome, Turin, Genoa, etc., the rates are even over 30 per 10,000 population. It is thus seen that in his native home the southern Italian does not display an excessive vulnerability to tuberculosis. But coming to the United States, as was pointed out by Dr. Stella, three-quarters of them settle in large cities, though in southern Italy nine-tenths of these immigrants lived in rural districts.[14] In New York City their mortality from tuberculosis is 276.3 per 100,000 population,[15] nearly three times as high a rate as in their native land, and even this does not at all give us the real rate, because many Italians contracting tuberculosis in New York City return home for a cure or to die. Every steamer going from New York or Boston to Mediterranean ports has in its steerage many tuberculous Italians who are returning to their native land.

The exact opposite is the case with the Jewish immigrants in New York City. Although their overcrowding is not so great as that of the Italians, and their standard of life is much superior on the average, still they more often engage in indoor occupations, where the opportunities for infection are very great. But in spite of the unfavorable surroundings in which they find themselves, their mortality from tuberculosis is lower than that of people of any other faith. According to Gilfoy, it was 172.4 per 100,000 Russian Jews in 1906. The main reason is, as was already indicated, the fact that the Jew does not make any material change in his milieu by changing his abode from eastern Europe to America. He lived there in a city, and here again settles in a city; he worked there at some indoor occupation, and does the same here; he lived there in an overcrowded dwelling, and moves here into a "double-decker" tenement. He has paid the price for urbanization already for several hundred years, while the Italian, Syrian, Irish, Slavonic, and Hungarian peasant coming to the United States meets with the urban conditions for the first time and must pay an exorbitant price for it in the shape of victims to the white plague.

The effects of the thorough urbanization of the Jews are manifesting themselves in many other ways. It has been observed by many physicians that even when infected by the tubercle bacilli, the prognosis is more favorable in the Jew than in other people. The course of the disease is slower. I have seen very few cases of tuberculosis of the fulminant or galloping type among several thousand cases of consumption in Jews. Acute miliary tuberculosis is very rare indeed among them. The cases in which the victim is stricken with high fever, rapid extension of the disease with cavity formation within a few weeks or months are also rare. But cases of the extreme chronic type, running on for years and still permitting the victim to make himself useful at some easy occupation, are common; more so than among other people of the same social status. Of course, to a certain extent this is also due to the infrequency of alcoholics among them, but this alone does not explain the condition. It appears that thoroughly urbanized humanity does not offer a good soil for the growth and development of the tubercle bacilli, while the inhabitant of the open plain, and less so the peasant or farmer in modern European and American villages, offers a virgin soil for these parasites. This is the only reasonable way we can explain the high rates of morbidity and mortality from tuberculosis of the rural dwellers who emigrate to cities. Being more predisposed to infection they also more often supply cases of the acute fulminant or galloping type, as well as acute miliary tuberculosis.

There are indications that this advantage of the Jews is not permanent. It appears that in eastern Europe tuberculosis has been on the increase during recent years, and the same has been reported from London. In New York City the number of applicants to the United Hebrew Charities who suffer from tuberculosis has exceeded 1,000 during 1907, while six years ago only one-half that number applied. The total number of applications for relief has not increased materially during these years. It seems that, adapted as they are to indoor life, they still cannot resists infection when their economic conditions become very unfavorable.

The Elimination of Uric Acid in Children in Normal and Pathological Conditions.—E. Modigliani gives us the results of his estimations of the elimination of uric acid in well and sick children, fed on a diet of milk and bread, and kept in bed during the time of estimation. The diet is kept up for four days before estimations begin and then estimates are made for four days. The results obtained are that the elimination varies with body weight in well children, the limits being from 0.61 to 0.168 gr. in children from two to six years of age. In sick children it varies between 0.062 and 0.300. The amount is in relation to the body weight, the age, and the amount of leucocytosis.—*Rivista di Clinica Pediatrica.*

ITALIAN IMMIGRATION AND INSANITY.*

By ALBERT WARREN FERRIS, A.M., M.D.,

NEW YORK,

PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY.

The first meeting of the Italian parliament was convened in Turin in 1861 and Victor Emanuel was proclaimed King of Italy; but Rome and Venice were still under the control of the enemy, and Cavour died in that year. You may reckon the existence of United Italy from that date, if you choose; but "Italy free" was not an accomplished fact until Jules Favre, foreign minister of France, withdrew the French troops from Italian soil and the King, entering Rome, was left in sole control on September 20, 1870.

An amalgamation of many different peoples cannot be accomplished in one generation; scarcely in two generations. Florence, with all her beauty, could not accomplish within the span of our own lives the unification of the Italian peoples. Rome, with all her grandeur, could not compel rapid homogeneity of race in the land which music calls her own.

In the days of Hannibal, Carthage was a regal city, set upon a fertile soil, with a population of 700,000 boasting the prestige of local naval supremacy, controlling Sardinia, Sicily, Malta, Corsica, and the north coast of Africa, profiting from the returns of rich argosies engaged in trade with Spain, Britain, and the Baltic countries, with enormous income from a trade with the interior of Africa, and enjoying a certain wealth that seemed to assure her ambitious citizens a continuous prosperity. Yet she cut down her forests and suffered the devastations of war, and the former powerful rival of Rome dwindled into insignificance. To-day the site of Carthage is marked by the habitation of a few hundred struggling Arabs.

Not so Italy. The storm of the French Revolution broke in 1792 and Napoleon, four years later, entered Italy and "let loose the dogs of war." She has been partitioned repeatedly by hostile forces. Taxes and tithes have been wrung from her by rapacious conquerors. Greed and avarice have combined to drain her very lifeblood. Yet she is emerging rapidly from the gloom of oppression, and in another generation is destined to resume the occupation of recording a brilliant history, such as was written for centuries before.

One-tenth of the territory of the country is barren rock. One-third consists of mountains. The destruction of her forests has rendered her soil dry and comparatively unproductive. Yet terraces have been formed by patient labor, and earth has been gathered and conserved, gardens have been constructed, and the unconquerable spirit of the Italian people has asserted itself until the sheer force of their industry, perseverance and shrewdness compels the admiration of the world.

Metternich once said, "Italy is nothing but a geographical expression." By this he meant that it is a name given to a territory in which live several groups of distinct peoples, with almost tribal differences. The student or traveler of to-day receives the same impression. Thus it becomes necessary, in describing Italy and the Italians, to consider separately North Italy and South Italy, as distinct countries with distinctive inhabitants.

Some of our Italian immigrants come to us from provinces of North Italy—from Genova of Liguria, Bologna of Emilia, Udine of Venetia, and Pesaro of Marches. By far the greater number comes from the southern provinces, notably Napoli, Caserta, and Avellino of Campania; Chieti of Abruzzi; Campobasso of Molise, and Reggio di Calabria; while many Sicilians sail hither from Messina, Catania, and Palermo.

Not only are there differences in manners and in character, but there are marked physical, really ethnical differences. In the North there is more activity in industrial pursuits and the Northerners are more generally progressive. A keen interest is evinced in political education and in social questions. There is a greater advance in the accumulation of wealth, in the extension of trade and in education. An examination of recruits for the army revealed a percentage of 14.98 illiterates among the Piedmontese, and of 18.42 among the Lombards. The Piedmontese and Tuscans are excellent landlords; they use chemical fertilizers to enrich the soil and they pursue successful dairy farming. The men are all tall and strong. The Northerners show the persisting influence of former Austrian rule.

In the South, on the other hand, are found the results of the corruption and cruelty of the Spanish and Bourbon rulers of the olden times. The South is wholly agricultural and is poor. Many of the men are undersized and apparently ill-nourished. The social and political questions of the day are viewed with apathy. There is less advance in trade or education than in North Italy. The proportion of illiterate recruits from the province of Napoli was 51.57 per cent., from Sicily of 55.04 per cent. There has been in the past greater tendency to crime. Nine times as many murders have been reported in Sicily as in Venetia or Lombardy. Taxes fall rather heavily on the agriculturist and less money has been spent for purposes of education, of railways and of public works.

Brigandage, however, originally a political movement, later a powerful alliance of criminals for robbery or murder, no longer exists. For many years it survived as an expression of poverty and of hatred of the landlords, and until a decade ago was maintained in some localities simply for revenge and robbery in the form of the Mafia or the Camorra. The present system known as the Mafia levies toll on farmers' wine-growers and orange growers, threatens those who resist, and in rare instances influences judicial decisions and public contracts. Camorra, flourishing only in Naples, was an organization of thieves and dishonest people of the lowest class. Formerly its members levied tolls on trade and professions. At great expense, the government has eradicated it.

In the Southerners there is an Albanian and Greek intermixture, and in Sicily and Sardinia the Arabic blood is strong. This fact accounts for the remarkable differences in physique, temperament and characteristics of northerners, southerners and islanders.

Italy is said to average as cold as England; but the warmer weather in the South is an alleged reason for the decrease of steadiness and for the increase of laziness and passionateness one notices in traveling from central to southern Italy.

In the time of the Bourbons and up to about 1850, Southern nobles have been described as ignorant, overbearing, lazy and corrupt. They absented themselves at Rome and Palermo; they were spendthrifts, and excited an evil influence in politics; they were hated by the peasantry with a few shining exceptions. In the cities the youths of the wealthy class of those days secured little education,

*Read before the 64th Annual Meeting of the American Medico-Psychological Association held in Cincinnati, O., May 12-15, 1908.

passed their time in driving, hunting, traveling, and spending money, and showed a rooted aversion to work. Professional men were very poorly remunerated. A large number of government officeholders received mere subsistence.

Why should not the peasants of that time have been unhappy and resentful? Their soil was nearly exhausted, they had little or no farm machinery. They raised wheat, corn, wines, olive oil, oranges, and lemons. They had few cattle in the South, and little pasture. For greater safety, they dwelt in villages frequently on hilltops and walked miles to their work. They were half starved, ill-clad. They knew the meaning of misery. In the interior of Sicily at that time the greatest poverty was found, and the people were far from provident. The petty accumulations of months were often spent on a single feast day. The irregular day laborer was the most miserable. He dwelt in a rude hut and suffered from absentee landlords, yet he did not resort to drink.

The lapse of over half a century has made an astounding difference. The conditions I have described have absolutely disappeared; but they undoubtedly left their impress and were responsible for certain characteristics of the Italian people. The most remarkable fact in connection with this matter is that the Italians were not crushed by such circumstances. They emerged patient, courageous, industrious, and hopeful. In fact, Southern Italy has contributed a large percentage of the professional men, art critics, painters, philosophers, and patriots of late years.

Two prominent industries have been the sulphur mines and the marble quarries. In Sicily, men and boys, all peasants, labor in the sulphur mines, with little return because of the primitive methods employed and the falling price of sulphur. The miner (*picconiere*) works six to seven hours a day for five days in the week, at forty cents to sixty-five cents per day. The *carusi*, or carriers, boys of seven to eighteen years old, stagger out of the headings with 70-pound loads from seven to eight hours a day, each having been leased by his parents to the miners for $10 to $60, which sum is worked out slowly under frequently brutal task-masters. The miners are ignorant, quarrelsome, deficient in moral sense, and prone to gambling.

The quarrymen, on the contrary, who labor in the mountains in the province of Massa in Northern Tuscany, are stalwart specimens of manhood, careless and extravagant, somewhat turbulent and restless, and fond of adventure.

In the North and certain other parts of Italy among the newer industries are the manufacture of silk, linen, and cotton; ship building, sugar beet raising; and the manufacture of steel goods, locomotives and electrical machinery. Among the people engaged in trades and regular occupation thrift and frugality are noticeable.

For many long years the taxes constituted a heavy burden; and they so continued under the old policy of the Bourbons. The State, until about two decades ago, took about 30 per cent. of one's income. There was an income tax and a family tax; a tax on horses, carriages, servants, and dogs. While saddle horses went free, the peasants' donkeys were taxed. The poor were the greatest sufferers, for how could an agriculturist, earning sixteen cents to twenty-nine cents a day (or in the South, eight cents to ten cents a day and his lodging) afford to pay a tax? All this is changed to-day, and now the taxes are levied in accordance with the English law; they fall heaviest on the owners and landlords.

The peasant's foods must needs be simple. He has a bread made of Indian corn (*polenta*) or of wheat. He has no meat. He has beans, celery, radishes, fruit, a little salt fish, bacon, frogs, and snails. The majority of laborers live on *polenta* and macaroni only. Butter is rare in the South. So many suffer from inadequate food that the government a year ago proposed to provide extra food for the school children in the village of Vercelli in Piedmont, as an experiment, in the hope that the race might thereby be improved in stature.

Several families occupy one room, dress in rags, and yet are cheerful. In the South one sees castles surrounded by hovels, with donkeys, cattle, pigs, and human beings in close proximity. There is no poor law, yet there are many splendid private charities for the infirm, insane or infants, especially in the North.

There is a great deal of sickness among the peasants. Dr. Cavalire Antonio Stella, of New York, is authority for the statement that while prevalent among Italians in America, tuberculosis is almost unknown in Italy except where imported by returning emigrants. Malaria is the worst scourge. It was reported a few years ago that 80 per cent. of the Southerners are exposed to it, and that 20,000 died annually in Basilicata, Calabria, Maremma, and Sardinia. The reclaiming of the Pontine Marshes is resulting in great improvement in the death rate of Southern Italy. The peasants are driven by malaria into the town; but they prefer town life. They have strong attachment for the house or home, and for their native village. They take little interest in sanitary conveniences, bathing once or twice a week, when well-to-do; otherwise only in the months of July and August. In the cities the poor live in crowded quarters in large tenements, without ventilation. In Naples many live in damp cellars, several families together, fostering disease, filth, and vice.

Italians at home are prolific, the birth rate being nearly the highest in Europe, and parents are very fond of their children. Burly and apparent rough laborers are gentle and tender with the babies. But in this country, in the second generation, owing to the work the women do in the shops, or stooping over sewing machines, and also owing to venereal disease, absolute sterility or one-child-sterility is common.

Women are respected. There is little sexual immorality among the Italians. Family ties are properly regarded. A married woman or engaged woman will not be seen in the company of any but her own man. In the South travelers tell us the women are much like Mohammedan women. They are uneducated except as regards the kitchen, the linen closet, their children, and the work of the fields. The high sense of honor among Italian men in respect to women is probably better preserved for the reason that there are practically no drunkards among the Italians, while there are no abstainers.

Religion is a primitive affair among the Italian peasantry. In South Italy there is a simple belief in miracles and mysteries, and a surprising amount of superstition. Fifty years ago the clergy were uneducated, and belonged largely to the lower classes of society. The average priest of that time mastered only reading and writing, and did not lead an austere or pure life. But a tremendous change occurred, and the enlightenment of Italy as shown to-day came largely through a new, educated and devoted clergy.

The army is a great feature of Italian life. When on a peace footing Italy maintains a standing army

of 330,000 men, and about 3,250,000 in time of war, recruiting by conscription from the able bodied men from twenty to forty years of age. A few are in exempt classes. The discipline of army life has a very salutary effect in removing provincial differences and in cultivating order and self-control. Besides this, the recruits are instructed by their officers and profit much thereby.

An educational system is being elaborated by some zealous and able men, but is not yet entirely efficient. Parents find a way to evade the compulsory education law. However, the proportion of illiterates fell from 78 per cent. in 1867, to 67 per cent. in 1881, and to 36 per cent. in 1896, in the South. In Venetia and Lombardy only 6 per cent. of the children of school age are absentees, but in the South the figure is much larger. The proportion of the population attending schools in 1895 was 8.2 per cent., while the proportion in England at the same time was 17.5 per cent. The illiterary of Italian immigrants into the United States is 46 per cent., while that of German immigrants is less than 3 per cent.

We have thus examined hastily and generally the many factors that combine to influence or modify the physical and mental development of the Italian people who come to our shores, and have fairly weighed their temperamental and acquired mental traits. Now, let us consider them as immigrants.

It is stated that 600,000 Italians emigrate annually into European countries, to Tunis, Egypt, South America, and the United States.

The statistics of the Department of Labor of the State of New York obtained from the authorities at Washington show that the total number of immigrants into the United States from Italy during 1907 was 264,208, of which number, 1,809 were debarred, leaving 262,399 in the country, of which total probably 100 were returned after landing. Of these people 45,545 came from North Italy, including 4,145 illiterates and 3,418 who had been in this country before. South Italy sent us 218,663, of whom 107,132 were illiterates and 13,546 had been in the United States previously. Every year 160,000 return to Italy. This year (1908) 200,000 did so.

The Rev. Antonio Mangano tells us what reasons operate to send the Italians from home to-day. Mr. Mangano was educated at Brown and Columbia Universities, and is a Baptist clergyman in charge of a missionary chapel in Brooklyn. His articles on Italians in the publication, *"Charities and The Commons,"* are of much interest. He says that Italians leave home because of poverty, wretchedness and want; high rent; the indifference of absent landlords, and the severity of agents; class distinctions; occasional failure of crops; comparatively heavy taxation; systematized repression; temptation of steamship agents; glowing tales told by returned emigrants; and the very laudable desire to rise in the world, to educate their children, and to become respected property holders.

From the reports in the *"Bulletin"* of the National Department of Labor at Washington, by Emily Foote Meade, who made an exhaustive study of "The Italian on the Land" in this country, we must conclude that Italians have good instincts that are easily awakened, latent tendencies that only need opportunity, strength and resistence of fiber, imitativeness and adaptability, and that they become desirable and useful citizens.

Into what occupation does the Italian immigrant drift, or what work does he choose, in this country? How much stress and strain are his portion in the first years of life in this new land? The occupations in which we usually see Italian peasants employed are the following: In the cities they become day laborers, sellers of fruit, nuts and candy; dealers in coal, ice, and wood; furnacemen, caretakers of unoccupied houses, watchmen over new buildings; street cleaners; while others become shoemakers; plasterers; importers of fruit, florists, caterers, public officials, bankers, merchants of wine and oil, and most efficient policemen. The women become factory hands and dressmakers. Of the garment workers in New York city 95 per cent. are Italian men and women.

In the country, men become successful gardeners and farmers, berry pickers; brick makers, glass polishers and general factory workers; mill hands, builders, and contractors.

Mr. Severn, New York State representative of the Italian-Swiss Agricultural Colony of California, states that next to Chinese labor, fruit growers find nothing equal to Italian labor. He corroborates the statement made by Elliott Lord in "The Italian in America," wherein a number of Italian fruit garden colonies scattered through New England, as well as through the South and West, are described. Lord shows that Italian colonists increase surrounding land values very materially wherever they settle.

About 1892 an Italian named John Carini went to South Glastonbury, Conn., in the employ of the New Haven and Hartford Railroad Company as an axeman to cut railroad ties. It is reported that at the end of two years he had saved enough money to purchase a farm and send to Italy for his family. The entire family worked upon the farm until it produced enough income to enable him to buy additional land, and to-day he owns 1,500 acres, almost all of which is under high cultivation. He raises peaches, apples, plums, pears, grapes, small fruits, and vegetables.

J. H. Hale of South Glastonbury is authority for the statement that the Italian cultivates successfully land which others find too difficult to use on account of rocks and stumps. The perseverance and the courage of the Italian in matters of agriculture are indomitable.

With the willingness to work at anything and with work to be had, there is no very severe pressure, no great confusion or difficulty experienced except in the coldest part of the winter. We should, therefore, not expect to see much mental alienation among the Italians in this country; and the fact is, there is little.

Of alcoholic intemperance I can not make a definite statement illustrated with figures; but all reports are to the effect that there are remarkably few cases. As to epilepsy, its incidence among Italians in this country is practically negligible. Of 2,450 epileptic patients received into Craig Colony for Epileptics, at Sonyea, N. Y., up to April 10, 1908, but 7 were born in Italy, and but 16 were born in America of Italian parentage.

Many of the figures quoted hereafter regarding the Italian insane were complied by Dr. Thomas W. Salmon, formerly a physician in one of the New York State Hospitals for the Insane, and now an assistant surgeon in the U. S. Marine Hospital Service, at Boston, Mass. Of 100 immigrants certified for insanity at Ellis Island, New York City, where all the immigrants are inspected by U. S. Government and New York State alienists, 12 were Italians, 12 were Austro-Hungarians, 12 were Greeks, 17 were Russians, or Finns, 13 were English and 19 were Irish. Of 100 deported from public institutions 10 were Italians, 5 were Germans, 21 were Austro-Hungarians, 29 were Russians, or Finns, 5

were English, 19 were Irish. The percentage totals of all arrivals that year were as follows:

Italians	28.8
Germans	3.5
Austro-Hungarians	25.4
Greeks	2.
Russians, or Finns	19.6
English	3.7
Irish	2.6

This makes a very favorable exhibit for the Italians.

For the fiscal year of the New York State Hospitals for the Insane ending September 30, 1905, Dr. Salmon gives some very instructive figures, quoting from material collated by Dr. William L. Russell, Medical Inspector of the New York State Commission in Lunacy. The percentage of the whole number of foreign-born patients in these hospitals was as follows:

Italy	3.9
Germany	25.9
Austria-Hungary	6.3
Russia and Poland	8.8
England and Wales	5.9
Ireland	36.

The percentage of the whole number of foreign-born in the State of New York at the same time was:

Italy	9.6
Germany	25.3
Austria-Hungary	6.9
Russia and Poland	12.4
England and Wales	7.5
Ireland	22.4

The ratio of insane to population was therefore as follows:

Italy	1 to 431
Germany	1 to 173
Austria-Hungary	1 to 199
Russia and Poland	1 to 249
England and Wales	1 to 209
Ireland	1 to 111

Before the "New Immigration" from Italy began, the proportions of the foreign-born insane in the State Hospitals was much as shown by Dr. Russell's statistics of Willard State Hospital, namely:

Italy	3.
Germany	26.
Austria-Hungary	4.
Russia and Finland	6.
England	8.5
Ireland	43.

The changed conditions are illustrated by Dr. Russell's figures regarding foreign-born admissions to Manhattan State Hospital in New York City, in 1905, namely:

Italy	6.5
Germany	18.
Austria-Hungary	14.
Russia and Finland	13.
England	3.
Ireland	24.5

With the vast numbers of Italians entering into the country since the "new immigation" began in 1900, the ratio of insane Italians to the whole population in the United States is only 1 to 439; Austro-Hungary presenting 1 to 292 and Russia and Finland 1 to 380.

Dr. Salmon remarks: "In spite of the most effective inspection which can be devised, there must every year be admitted many immigrants already insane, and many thousands who are destined, under the unusual stress of the first ten years in the United States, to become insane." This statement, one must say on reflection, does not apply to the Italian immigrants.

There are dangers to be feared in the case of Italy. Her illiterates are a drawback, though they learn rapidly and the second generation furnishes a satisfactory if not an admirable class of citizens. The idiots and imbeciles, the mentally defective and the constitutionally inferior we receive from Italy constitute indeed a menace.

It is probably a fact that practically all the able-bodied peasants of certain localities are now in this country, but the statement is untrue that an effort is being made to aid the diseased and inferior who had been left behind in these localities, to come over also and share the advantages of this foster country.

Naval Surgeon Colonel A. Montano of the Italian navy, in the official bulletin of Italian immigrants published at Rome in 1907, makes the following report:

Number of cases of mental diseases found among Italian immigrants who came to North America or returned from North America to Italy during 1906:

Number of Cases Counted on the Ships.

	Bound for the United States		Bound for Italy		Total
	Men	Women	Men	Women	
Alcoholism	..	..	2		2
Mental Alienation	..	..	23*a*	3	26
Dementia	..	..	9	3	12
Sensorial Phrenosis	..	..	1	..	1
Melancholia	..	..	8	9	17
Acute Mania	..	..	2	..	2
Persecution Mania	..	..	5	..	5
Religious Mania	..	..	1	..	1
Paranoia	..	1	4	..	5
Sudden Alienation	1*b*	..		..	1
Total	1	1	55	15	72

a—One committed suicide on board. *b*—Jumped overboard and was drowned.

On almost every vessel that carries Italian immigrants into or out of the United States a representative of the Italian navy sails, charged with the duty of examining his fellow-countrymen in the matter of all diseases that affect their physicial or mental condition, and of reporting to his Government at the time the ship reaches port. It is the desire of the Italian Government that sick, and especially insane, Italians shall not be sent out of their country.

Investigation reveals the fact that the Italian insane in New York State are recruited almost exclusively from the rosy, round, well-nourished vegetarian country people, who, after immigration into our country, settle in our large cities in close quarters, engage daily in long hours of in-door labor, and live upon a diet consisting largely of meat of bad quality. A year of such life works havoc with them.

Italy is caring for her poor and diseased at home. Italy is preparing to enforce her compulsory education laws, to make effective her humanitarian schemes, to uplift her people at home.

The problem will be easy and immediately solved if we assist to suburban or, better, to farming localities the peasants from the country regions of sunny Italy.

It is our duty and our opportunity to join hands with the active, scientific and wise Italian organizations in New York City—the great entrance gate of this country; to enforce with no faltering hand the rules that must govern all immigration, and to co-operate with the Italian Government in making, as it now does, a careful selection of immigrants at the Italian ports of embarkation. Thus our country will receive a valuable class of desirable new citizens, unusually free from insanity or a tendency thereto.

THE OPIATE HABIT.

By WILLIAM F. WAUGH, A.M., M.D.,

CHICAGO, ILL.

The potent and seductive drug extracted from the poppy is and has ever been one of the most important weapons in the arsenal of medicine. In every country where it is known we find also that many acknowledge the sway of the spirit inhabiting it, and the most powerful of human intellects have bowed beneath its imperious domination. When De Quincey published his "Confessions" they came like a shock upon England. "Opium eating" was one of those unaccountable vagaries of the Oriental, which could scarcely be comprehended, much less assimilated, by the West. Since De Quincey wrote his opium-inspired dreams the use of this drug in some form has become only too familiar. We have been told that an incredibly large percentage of physicians puncture their skins with the hypodermic needle, while in every large city where a Chinese colony is planted there are numerous victims of "the pipe."

Draw a broad line of demarcation between these two. The physician resorts to the needle to enable him to keep at his duties and continue on his rounds, when otherwise exhausted nature would compel a rest. The man who "hits the pipe" is simply a jaded *roué* in search of new vices. The end for both is the same. Once under the domination of the opium fiend every day sees a new strand added to the bonds. The manner in which opium insinuates itself into the life of its victim is diabolical—appalling. The metabolism of the body is conducted under its influence. The organic functions lag and refuse to commence the vital activities until put in operation by a dose. The mental faculties are similarly enslaved—the mind is torpid until the potent thebaic stimulus sets it in operation, and this lasts only until the effect of the drug is exhausted. The moral realm is invaded—the man *thinks* opium, he believes only in opium, he enshrines it as his God. Very often his whole life is absorbed into this one ruling, all-pervasive influence—everything else sinks into nothingness, and he lives only to renew his daily supply of the drug.

In others, however, even in many cases, there is a persistent moral revolt against the enslavement. The victim protests against it, he struggles Titanically to free himself, but in vain. The relentless, never for a moment intermitting, steady pressure drives him back to his prison. He may resolve never so courageously—while under the influence of the drug—and he may do without his accustomed portion for a varying length of time, but the pressure constantly increases, resolution weakens as the stimulus dies out, the reasons for stopping the drug grow shadowy, and the specious arguments in favor of taking it grow more forcible, until he succumbs and the struggle is "postponed." The most appalling feature of this drug is the manner in which it can convince its slaves that the only right and proper thing is to return to their chains. It becomes actually a duty to take a dose.

Nevertheless, there are brave souls that to the last protest against their enslavement, and finally put an end to life rather than remain in such degrading subjection. A venerable physician, after 30 years' opium taking, applied for aid in throwing off the habit. When told it was impossible, his physical condition being such as to prohibit any attempt to discontinue the drug, he departed with tears streaming down his face, saying that if he could not live free he would not live at all. The next week a notice appeared telling of his sudden death.

Every attempt to elucidate the pathology of the opium disease by autopsy has failed. No material lesion has ever been established as essential to or characteristic of this drug's action. It is only by a study of the vital phenomena presented during life that the problem can be solved. But by this method the mystery quickly ceases to be such. The solution is unexpectedly easy. We have simply to note the effects of a single dose of opiate and follow from that point.

When an average dose of any opiate has been taken the victim experiences a sense of ease, of comfortable well-being, denominated euphoria. Under this influence the sense of physical and mental fatigue is lost, and unremitting exertion of body and mind becomes possible as long as the effects of this dose continue, or while it is sustained by subsequent doses. As with the so-called stimulant doses of alcohol, self-consciousness is depressed, the fancy is loose from restraint, and a delightful sense of freedom, of superior powers ensues, endowing the victim with unwonted brilliancy of thought and speech. The brakes are off—the velocity is exhilarating. As these effects subside the patient sinks into a corresponding state of dullness; he is sluggish, inanimate; thought lags, mental depression supervenes, and every exertion requires an effort. Another dose—"the hair of the dog is good for his bite"—and, presto! the miracle is wrought and the former state of happy, buoyant animation is resumed.

Sooner or later the victim finds that the period of brightness is less marked and more evanescent, the gloom deepens. Larger doses are requisite, and still larger and more frequent. Besides, he gets to crave the sense of euphoria, and hopes that by taking more opiate he may experience more of the delights. Vain hope! The more of the drug he takes, the more rapidly its pleasures evaporate; and he finds himself in a state where it is necessary to him, not to excite pleasure but to sustain the energies—to live, in fact.

Here the histories diverge. Some settle down to a certain dose and adhere to it for years; others devote their lives to the effort of absorbing all the opiate they can crowd into their systems. The life of the former runs on uneventfully. They live, perform a certain limited series of mental and physical evolutions, but their progress ceases, their career culminates. They gradually retire from the activities of the community and grow yearly more contracted in their operations and their sympathies. Ambition is dead, incentive has perished—they just live and no more. The man collects his little rents, sees to his little kitchen garden, eats a trifle, wears his old clothes and sits alone at home, reading a bit, meditating long, ruminating most of the time; producing nothing; a quiet, inoffensive, retiring hermit, of no use to himself or to anybody else, neither hated nor loved by any mortal man. Only the druggist knows the truth.

The other keeps up his activity, works at high pressure, pushing feverishly along in his chosen vocation, sometimes doing brilliant work—and making frightful mistakes at others—always crowding the drug and rapidly exhausting its euphoric power, until he reaches a point where it gives absolutely no relief. Then he grows desperate. "D—— it, I'll see if I can't get enough to do the work!" and he takes a huge dose—and the community is shocked to hear of the sudden death of the popular young doctor. "Accidental overdose," says the

coroner; "suicide" is the whisper that goes about.

Both wrong: The end is inevitable when we consider the physical action of the drug. When a dose of opiate has been taken a large part of the toxic excretive disappears from the urine. A search in the blood fails to detect it. What has become of it, since evidently it has not been excreted from the body? It has been thrown back into the cells by which it was first separated and thrown off into the blood for excretion. Somewhere in the cellular structures of the body this toxic matter is locked up, away from the circulation and therefore latent, inactive.

The inhibitory effects of the opiate subside, the cells give off their stored toxins, reinforced by the new supply produced by the metabolism of the inhibition period. This enters the circulation and becomes thereby active, and the result is the general depression above described. These toxins weigh heavily upon the mental and physical powers, poisoning the wellsprings of life. Wherever there is a *locus resistentiæ minoris*, the effect is manifested by a return of the customary local malady, a neuralgia, catarrh, or other recurrent affection.

Repeat the opiate and relief quickly follows; the subsequent depression being more marked after each repetition, as the abstracted toxins increase in bulk. Inevitably the patient becomes rooted in the conviction that for all the ails that torment him when he seeks to discontinue the opiate, it alone will prove effective—since it alone will throw back the toxins into their cellular storehouses. Hence, the obdurate pessimism with which he regards every suggestion to obtain relief from other remedies.

Here, again, is where the histories diverge. There is a saturation point at which the cells reach the limit of their capacity to store toxins. Some meet this condition by reducing to the minimum their vital expenditure and consequent manufacture of toxins. They reduce their ingestion of foods to the lowest possible limit, and only he who has studied this attentively can realize how very little food is required to sustain an inactive life. His activity is likewise reduced to the minimum, and thus the toxin formation is restricted to the point where the modified elimination, under moderate daily doses of opiate exactly balances it, and the individual goes on for years in this torpid, reptilian existence.

The other leads a life of superactivity, constantly increasing the daily opiate, until the cells become so engorged with toxins that even the opium barrier is insufficient to hold back the flood, which forces its way into the blood despite the most frantic efforts to hold it back. We then see that frightful final stage, where the patient is unable to live with or without opium. He presents a typical picture of autotoxemia. The body exhales a cadaveric odor mingled with that of the poppy—even when pure morphine has been the only opiate taken. The digestive functions being inhibited, the feces and food lie in the alimentary canal until they decompose. The breath becomes fetid and all the symptoms of fecal toxemia are manifested in an aggravated form. The respiratory centers are affected, the patient feels a frightful load on his chest, he gasps for breath, and suffers the agonies of suffocation. His body is racked by convulsions. Sleep is broken by horrid dreams and terrifying nightmares, from which the patient awakes choking. In agony he implores his attendants to keep him awake when he is dying for sleep. His lost opportunities, misspent life, sacrifices of prospects, friends, career, usefulness, all come to fill his waking moments with remorse—all sacrificed—to what? An unnatural craving for a useless drug; all lost for lack of the manly power to bear a little suffering; "little" that is, in comparison to what he is now undergoing. Every man who has witnessed the last days of one of these unfortunates acquires a horror of the drug, and becomes hardened to a certain extent against the lamentations of the withdrawal period, knowing that the suffering then experienced is trifling compared with what the patient is escaping. And this is literally true, without seeking in the least to belittle the ordeal through which the patient passes on his way to freedom.

Few, however, live to reach this point. As before stated, a huge dose of opiate is taken, not by accident or with suicidal intent, but in the desperate endeavor to dam up the flood of toxins pouring into the blood, and obtain a temporary respite.

Why is it that an opium habitué makes up his mind to seek freedom from his master? What is it that at one time rather than another induces him to make the effort? On the reply to this question depends our own decision—whether we will undertake the cure or not. If the patient cannot give a reasonable explanation of his resolution, are we justified in taking his case? Is he really in earnest, or does he merely imagine he wants to be cured?

One man applied for relief because he had just "experienced religion" at a revival, and his conscience would not permit him to continue the degrading habit. (It is regrettable that the "conscience" did not hold out to the payment of his fees.) Another came because he was convinced that the spirit of his dead wife would look down with approval on him. This man endured his sufferings with a fortitude rarely equaled, went home in good condition, and when he visited his physician a year later, while on his wedding trip with a second wife, was still free from the habit. More than one mother has broken the dominion of the opium fiend, because her children were approaching the age when the truth could not be kept from them—and she could not consent to live without the respect of her children.

But the vast majority give no special reason for their resolution to quit the drug. The following episode may throw some light on the question: Some years ago the writer selected 500 letters he had received from habitués, asking about the means of cure, but who had not applied in person. A circular letter was sent to these, asking what had been their subsequent history. The result was remarkable—all but about a dozen of the letters were returned, marked "Dead"! Was the impulse to seek a cure due to an inward premonition of an impending break-up?

In a number of instances where a cure was sought and secured, the symptoms were such that patient and physician were firmly convinced that death would soon have followed if the drug had not been discontinued. The problem presenting was not so much the cure of the opiate habit as saving the patient's life.

If the view here taken of the pathology of the opium disease be correct, the treatment follows as a matter of course. The indication is unmistakably elimination. We must rid our patient of his stored toxins, must disembarrass his system of the excess, and reduce his manufacture of new toxins to that point at which he will need no opiate inhibition to make him comfortable. If elimination is thus established he will find the need for opiate lessening with each discharge of excretory material, and it will be merely a matter of time when he will need none. Empty the impacted colon, loosen the masses of

toxins stored in the liver, keep the renal action up to its highest level of efficacy, incite the skin to aid in throwing off the toxic products whenever there is evidence of their active presence in the blood. Meanwhile, give a non-nitrogenous diet, and keep the patient at rest as absolutely as circumstances permit. The means to be employed to secure these ends need not be detailed here—besides, they vary with each case, and the physician who treats such maladies must be qualified to fit his treatment to the varying indications that present.

With this application of therapeutics to the pathological condition, such a degree of success follows as fully vindicates the correctness of this theoretic conception of the malady. The "ordeal" is wanting; the "withdrawal symptoms" fail to put in their appearance. There remain, however, certain results of the habit's continuance that require consideration. It is not all of therapeutics to remove the cause of a disease—its results may remain. Plucking a dagger from a wound does not heal it.

First we have a remarkable hyperesthesia to cope with. The nerves, relieved of the benumbing effect of the opiate, take on exuberant action, and this excessive sensibility must be moderated or the patient will suffer needlessly. I hesitate to suggest a remedy, for fear it will be seized upon and efforts made to utilize it as a "cure for the morphine habit." Besides, different cases respond differently to remedies and each requires to be treated on its own merits, with the remedies indicated in that particular case. Part of this hyperesthesia is toxemic and subsides after a grain of calomel in broken doses, followed by a saline laxative; or after a diaphoretic hypodermic of pilocarpine. As one learns to study closely these cases he finds that one or another of a large and increasing group of remedies is especially indicated now and again. Thus, one finds special indications for physostigmine, picrotoxin, emetine, solanine, nuclein, cicutine, apomorphine, strychnine, rarely thebaine, and, above all, gelseminine. If there be one drug more frequently, almost generally, indicated in this malady, it is this priceless educt from the yellow jasmine. No other remedy so completely assuages the craving for opiates, soothes the hyperesthetic nerves, calms the restlessness, and induces quiet, natural, restful sleep. So great is the relief that patients anxiously ask if there is danger of a gelseminine habit. Up to the present no instance has presented itself. In the worst cases ever treated by the writer during the twenty years he has been studying this malady, the patients use the gelseminine for a time, a week or a month, very rarely longer, and invariably in decreasing frequency until it is no longer desired.

Another and a more serious, because more persistent, difficulty is the influence of habit. This requires a combination of physical, mental, and moral treatment impossible to preconize. The environment, whatever it may have been, must be altered as radically as possible. The patient who resides in the lowlands should betake himself to the mountains, and *vice versa*. A pessimistic family circle, immovably convinced that the cure is illusionary and relapse certain, will render every precaution nugatory. Change of occupation should involve the disuse of all opiates. The physician must learn to practise without them, or give up practice.

A further proof of the correctness of the toxin theory is found in the fact that every attempt at work, everything involving an expenditure of vital force and an increase in toxin-formation, indulged in during the months immediately following the cure, serves to bring back a craving for opium. The patient has had the *habit* of working only under the influence of morphine and feels powerless without it; he persists, however, resulting in an increased metabolism and toxin formation, and at once the need for morphine is felt. What is the remedy?

How can one possibly expect, after ten years of opiate habit, to quit the drug and in a few weeks be able to live and work without it? Nature does not work miracles—neither do we. Voltaire's definition of a physician as "an unfortunate gentleman who is expected to work miracles every day," must surely have applied to one who treated opium users. The habits of years are not discontinued readily, nor without inconvenience resulting. Time must be allowed for the altered conditions to be established, for the patient to learn to live without drugs, for the various organs to accustom themselves to functionate independently of drug control. It is not too much to exact a year's absolute rest, of real playtime, after the cessation of the habit.

During this period the metabolism is apt to fall into arrears, and toxins tend to accumulate. One of the most significant symptoms of this period is a subnormal temperature. Another, usually accompanying it, is respiratory oppression. These demand instant action, in emptying the bowels, unloading the liver, and stimulating all the vital functions by the use of that priceless vitalizer, strychnine. Calomel, emetine, pilocarpine, strychnine, juglandin, and salines should be always at the patient's disposal, and he himself should be carefully instructed in their application, so that he may be independent of the chance practitioner, who may be of the sort who look on "suffering as an indication for morphine!"

With a year of rest, properly so-called, there is no reason for any cured patient relapsing. But—people are not always reasonable—and who can guarantee a man against the curiosity that leads him to "try one dose to see if it has any attraction for me"!

EARLY DIAGNOSIS OF GASTRIC CARCINOMA.*

By ANTHONY BASSLER, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE ST. MARK'S CLINIC.

Surgery offers the one cure for stomach cancer, and success in this depends absolutely upon a diagnosis being made early in the case. For when the malignant growth is large enough to be easily diagnosed, involvement of the organism is usually so great in extent, that surgical interference merely hastens the fatal ending. Bringing consideration down to the clinical details of the subject, it is truly unfortunate that no absolutely positive symptoms or methods of examination have been found for early cancer of the stomach. Nevertheless, as the result of a close observation of this subject, running over several years, I am convinced that a number of these cases can be diagnosed in the early stages of the disease, and in time for hope of cure in the surgical way. It may be said at the onset that this is but rarely done to-day, and further, that little can be expected along the lines of simple clinical observations of these cases.

Three main facts appear as the *sine qua non* of an early diagnosis: (1) A very close study of the laboratory findings and symptomatic details in all cases

*Paper read before the Queens-Nassau Medical Society Oct. 10, 1908, and the Richmond County Medical Society Oct. 14, 1908.

of gastric disease that do not accurately or most plausibly belong to the benign affections; (2) full experience in observing and examining cases of gastric disorders by one who is always on the alert for cancer, and who has a courageous, willing, and intelligent patient to deal with, and (3) the assistance of an understanding surgeon, whose depth of mind, as well as whose technique of hand, is broadened by ripe experience.

Cancer is a disease which begins as a small nidus in the glandularis. In its incipiency it is a small accumulaton of cells, microscopic in size, causing no symptoms, either subjective or objective, and thus cannot be diagnosed. Insiduously the cells rapidly multiply, accumulate in mass, and infiltrate surrounding tissues. Clinical changes now ensue which are mostly objective, and but rarely observed by the patient. The diagnosis of such early disease can be made only from the laboratory findings of the gastric contents, to which it may be said that the subjective and other objective symptoms are but rarely present, or if so, are of no value in the specific way. Of course, a case must be seen early, and it must be remembered that in these cases we deal only with small clinical facts, in a stomach at best but little known to us. Therefore it is that mistakes—mostly of omission—are liable to occur. The one significant keynote to lead us right in the work is the constant and progressive presence of abnormal findings in the gastric contents. What are they?

Hemorrhage.—This is usually minute is but rarely seen as such, and is almost always occult. The expression method of extracting stomach contents must not be resorted to—it is too liable to be performed with trauma—but just a simple aspiration, enough to overcome the force of gravity and to raise the meal through the tube. The bottle I have described serves well for this. (Extracting Test Meals, *New York Medical Journal,* June, 1908.) If retching occurs during the process the presence of blood is of no value in the suggestive way, and should be discounted. We should not be anxious to empty the stomach at these times—10 or 20 c.c. will do for these examinations. When a patient strains continually and under all conditions, and our suspicions of malignancy have been aroused in the case, a few meals extracted under nitrous oxide anesthesia may be wise. When blood is constantly present in meals extracted twice a week, we should be on our guard—It is more liable to be cancer than ulcer. This symptom is found in about 20 per cent. of the early cases, and its absence does not necessarly exclude cancer, since in about half of the cases of this disease hemorrhage is not observed in the vomitus even late; but still in many of these, blood in small quantities is present in the stomach from an early date. Examining the feces for blood in these early cases is of no value—the blood is too small in amount and is digested and absorbed, and thus not liable to give the reaction. We should be careful not to permit the taking of flesh food for twenty-four hours preceding the test meals. Washing the stomach before the meal is taken, or the night before, is inadvisable. Lavage of the empty stomach and examining the water for blood is not so good as the test meal method—we want the longer presence of the meal in the stomach, the gastric motility, the secretion, and the normal increase of the blood to the stomach during digestion to encourage the bleeding from the free surface.

Pus Cells and Bacteria.—These come next in significance. Pus cells are not products of a normal stomach, and when they are found (excluding that which may be swallowed in sputum, from the oral cavity, or in the stomach of a phlegmonous gastritis) they are indicative of ulceration. In my experience, they are often found in the stomach in early cancer, proving, I believe, that ulceration is common in early malignant growths. They are not very numerous and rather difficult to discern among the amylum of test meals. Lavage, or extraction after 10 minutes of normal saliva instillations and centrifuging the return, gives the best results in the way of examination. The cells are sometimes found in dense conglomeration suggestive of a slough from an ulcered surface. When these cells are regularly found, and particularly when red blood cells are also present, we should be on our guard. With them the bacterial flora of the stomach contents is also increased. The cocci seen are either the staphylococci, streptococci, or diplococci. A common type of organism, which may be markedly predominant, is a streptobacillus. Loops from the test meals suffice well for the bacterial examinations. The presence of what may be considered as increased numbers of microorganisms can only be judged in a relative way. They are found in test meals from nonmalignant and normal stomachs, and their nature, whether suppurative or not, is difficult to determine. But when one type of them largely predominates, and is present constantly with blood and pus cells, they are of much significance. The Boas-Oppler bacilli are found late in cancer.

The presence of minute particles of tumor tissue may be found and would be conclusive. These are very uncommon in early cases. The same may be said of loose tumor cells which are always doubtful in their nature—they resemble the free nuclei of digested normally free cells too closely.

Hydrochloric Acid.—In the beginning of cancer in an otherwise healthy stomach the acid is slightly increased. This is due to irritation of the growth or its toxins, and is significant only when it is on the increase up to a certain point and then takes on a steady fall. In some cases of cancer, and in ulcus carcinomatosum, it may be present to the very end. Then again, stomachs (normal and pathological) vary so in their hydrochloric acid contents, and this secretion is influenced by so many conditions, that its mere presence or absence at one time is of no value in this connection. The practical point in the way of diagnosis is its steady progress, either upward and then downward, or just downward (according as the case is early or later). Its rise upward is much more rapid than its subsequent fall. When it begins to decline it starts slowly, acquiring speed as it comes downward, and runs an average fall of about 4° in a week. In a suspicious case giving this excursion or a downfall of total hydrochloric acid, we should be on our guard, lest a tumor be palpable in the epigastrium a month or two afterward.

On the gastric enzymes so much reliance cannot be placed. The tests for them are not so accurate as those for acid, and they are liable to vary more than the HCl—depending upon the part of the stomach that is affected, and this may be anywhere. As the hydrochloric acid runs low, the organic acids begin to appear. Tests for their beginning should be made, as well as for other evidences of fermentation and delayed motility. There is liable to be retardation in motility before actual dynamic obstruction exists. In other cases little delay is observed, although fermentation is liable to be increased above the normal.

The Solomon test for gastric carcinoma is sometimes positive in an early case. Its absence is not

significant in the negative way since it may not be present even in an advanced case. But it is a measure along with the others which may be helpful. The method consists of washing out the stomach the evening before, and then on the following morning introducing 400 c.c. of normal salt solution. This solution is removed after a short stay in the stomach, and tested for the presence of albumin and for the proportion of nitrogen. Marked turbidity with Esbasch's reagent (picric acid), or the presence of more than 30 mg. of nitrogen indicates the presence of carcinoma.

Upon the history of heredity and subjective stomach symptoms, little dependence can be placed in the matter of diagnosis. "Family cancer," even more than "family tuberculosis," is only of historical significance. Subjective symptoms, one and all, are of no value in the way of early diagnosis, since many, if not most, cases begin and progress markedly without as with them. When they are present, they are the same as those found in the benign and simple stomach conditions, and may even be of less intense form. Marked anorexia, eructations, aversion to meats, pain, pressure, distress, vomiting, hematemesis, tumor and so on are all late symptoms. Of some value, however, is loss of weight. This begins rather early in the case in a slow way, and hastens later on. To record this best, it is advisable for the patient to weigh himself stripped each morning after his bladder and rectum have been emptied and before he has partaken of food or drink. Careful observations should be made and a record kept in ounces of the changes in weight. A loss of a pound or more in a week is suspicious, and conclusive when the laboratory picture continues strongly suspicious. But when making these observations nothing should be said about dieting, excepting that the patient should continue eating and drinking as before. If we curtail a normal person's diet, he is liable to lose in weight; and if we enlarge it, or add a fluid or semisolid diet—a common practice in treating digestive disorders—he may gain even in the face of a cancer being present in the stomach. Above all, we should be watchful for the patient who has dieted himself before coming to us.

To tell a patient, in a soft, guarded way, that he has a tuberculosis which can be cured, usually insures his hearty cooperation to bring this result about. Likewise, in a suspicious case of carcinoma, to inform him that a serious stomach disorder is imminent (we need not mention cancer), and that it is impossible to find out what it is unless he carries out our orders and reports regularly for observation and examination, usually makes him attentive in the way of carrying out our wishes. Office visits are better in these observations than placing the patient in a hospital.

In patients who present themselves for treatment of gastric troubles, view with suspicion every one over 40 years of age who does not show improvement after a course of treatment, whatever the diagnosis may be. Penzoldt rightfully advises that, in these cases, the diagnosis of cancer must either be made or refuted. At those ages also we should be on our guard with every case that gives a history of a "good stomach" before the present illness. In the diagnosis of early cancer laxity in thoroughness and expectant measures may be handmaids of disaster leading to a disagreeable surprise. It should never be forgotten that it is the usual thing that when a tumor manifests its presence, the case is past the hope of cure. In favorable cases it takes from one to four weeks of steady observation to make a diagnosis of early malignant disease of the stomach. In these, the careful examination of six or more test meals is unusually necessary. Then, with a reasonable certainty that cancer of the stomach exists (and that it is not in the cardia), the case should be turned over to a surgeon for exploratory incision, and if the diagnosis has been confirmed, total extirpation of the diseased area, adhesions, and metastases should be performed. It may be incidentally remarked that unless the abdomen is very fat, exploratory incision can be satisfactorily performed under one-tenth of one per cent. solution of cocaine. Under this, when the peritoneal cavity is entered, some care should be exercised not to impinge roughly on the parietal peritoneum (it is sensitive), nor should there be any tugging on the mesenteries when examining the stomach or intestines (patients are liable to vomit). In most instances, with a little extra care and patience, the examination can be made most satisfactorily under this form of local anesthesia, the posterior wall of the stomach can be explored, and, if need be, the entire hand can be put into the peritoneal cavity so as to reach some distance beyond the incision of entrance. Patients will submit to an exploratory incision under cocaine, but often refuse operation when a general anesthetic is to be used. Usually about an ounce of cocaine solution is employed at these times, representing only one-half a grain of cocaine, a safe quantity for an adult. Ether or chloroform can be quickly substituted when operative intervention is indicated.

There is no always nor no never in medicine. This is well exemplified in the early diagnosis of this disease. The surgeon has a right to believe that many of these cases can be diagnosed earlier than he usually sees them. But he must also remember that a few cannot. And the internist likewise must be respectful of his full duty to these patients, and not fail to gain or not lose sight of the valuable moment in which substantial help might have been offered.

SYSTEM AND THE DOCTOR.

By LEONARD K. HIRSHBERG, A.B., M.D.,

BALTIMORE.

The successful lawyer is usually methodical; the financier and business man always; the doctor, perhaps, never. Doctors may come and doctors may go, but there is very little interruption to the ever-present confusion. Reform may rake the ships of state, finance, and law, fore and aft, but the noble old sloop of medicine remains untouched. Jupiter may have brought order out of chaos, but Æsculapius omitted to obtain his fair share.

Only the other day the remark was made to me by a well known financier: "In my broad experience with men of the medical profession, I have reached the conclusion that in a business sense physicians are a hopelessly irresponsible, unmathematical, careless class of society. However 'long' they may be on medical skill and knowledge, on practical affairs and the methodical care and management of important matters, they are most 'short.'"

If there are extenuating circumstances for a few fairly educated physicians to feel themselves exempt from the proper systematization of their affairs, the university trained doctor cannot honestly allow himself any such excuse. There is really no reason for his lackadaisical bookkeeping and worse office arrangement.

When the doctors of the nineteenth and preceding centuries died, many of them with lucrative

practices of $20,000 a year cash income, they frequently left forty and fifty thousand dollars worth of uncollectable debts. The chaotic condition of their accounts, the negligent method of their collections, the careless entries of charges entailed frequent poverty upon their widows and heirs. Such a condition now is by no means exceptional, it is rather the rule. The exceptions are the other way about. Even to-day, a period perhaps in the future to be called The Age of System, the few doctors who are practical and precise in their methods, although steadily on the increase, are by no means in the numbers naturally to be expected.

When we consider there is no group of men, whether mechanics, business, or professional men, so quick to adopt innovations, new remedies, new instruments, new surgical procedures, new books, new journals, and new scientific discoveries of any proved value, does it not seem strange that in matters affecting their worldly welfare, their daily bread, and their wives and children, physicians should be so negligent, so short-sighted, so derelict in their duty as to ignore the benefits coincident with and derived from system.

Since my sophomore year in the Johns Hopkins University (Medical Department), I have been in the habit of using a most valuable series of card devices for various purposes, as I shall try to indicate. Dr. William Osler, great in medicine, science, and the humanities, was, if that were possible, greatest in the marvelous manner in which he disposed of his work. His system was as complete in detail as it was perfect in its comprehension. He gave clinics, delivered lectures, made addresses, attended banquets, wrote monographs, journeyed miles in consultations, saw students, examined patients, read all the medical and general periodicals, received his royalties, and gave ready references to anything without ever taxing his memory or losing one jot of his genial demeanor and ever-ready wit. It all worked like clock-work, yet no one could ever accuse Dr. Osler of automatism.

As a student, I first learned of this when he suggested that we employ a card index system in obtaining the past diseases, present complaints, and results of physical examination of every patient with whom we came in contact. The beauty and value of such a plan was evident and began immediately. For every patient seen, examined, and treated in the dispensary, in his home, and in the hospital, I made out a separate card. Upon it went his name, age, occupation, nativity, condition, date, complaint, personal history, family history, illness, examination, diagnosis, and treatment. Frequently three and four cards had to be pinned together for one patient, especially when he was seen frequently or interesting developments occurred.

By the time I graduated, I had nearly two thousand records of patients I had seen, complete and detailed. Every common disease was many times represented, and many, many rare ones. Eighty odd typhoid patients, almost as many pneumonia, and such rare diseases as Addison's and hemachromatosis were among them. This is a vaster and more valuable experience than physicians have in fifteen years of a profitable private practise.

In addition to this card index system for patients (which has been continued in both my private and hospital practice since graduation) I began simultaneously a system of cross references to all the worthy contributions in the current American, German, French, English, and Italian medical literature. Every week I would take a couple of hours from my practical work and retire into the libraries and take references on cards. If the subject was bacteriology, I would index it under that subject, with the author's name and the name of the periodical (such as *Medizinische Wochenschrift*, No. 26, Vol. XXI, 1900) as two cross references.

Now when we consider that textbooks of medicine, like all scientific volumes, are so quickly out-of-date, it can be readily seen how valuable my card index of references is to me in writing memoirs, contributing original work, or delivering a lecture or a clinic to my medical students. But it proved its value to me, long before I graduated, for in each of my sophomore, junior, and senior years it helped me to publish original contributions to medical science. This was greatly facilitated by the accumulated references to current medical problems in five countries.

Since my return from Europe in 1902, the two volumes on "Bacteriology" and "Action of Light" were aided very definitely by these references which I continue to collect on my cards. Every journal and book read has its annotations on these cards. Every lecture heard has its gist filed away under its appropriate title, easily referred to.

System in my home and in office has extended and ramified in such a manner that my wife predicts that the individual coals in the bin will only remain to be tagged, filed away, and indexed.

A doctor's rapidly growing library can be correctly cared for only by a system of card indices. This fact, though well understood by librarians, is usually lost sight of in the doctor's office. At the beginning of private practice, I started the system of sectional bookcases and the card index for my library. It works admirably in both instances. No more flexible method of growth and expansion could be adopted. As the volumes increase, so do the cards and the sections. They grow in a natural, logical manner. Nothing could be simpler.

Where the physician has, hitherto, erred most grievously, however, where the results of his complacent negligence have entailed most serious consequences, is in the keeping of his accounts, in the capital, investment, debits, and credits. It is just here, most of all, that the systematic adoption of some carefully regulated method is a tower of strength and a delectable mountain of glory.

It has been my custom since the first pay patient to employ about the plainest, clearest kind of ledger cards. At the top is a space for the name and address. Below are series of columns with the twelve months, named one below the other, and thirty-one perpendicular columns for the days of the month. Above the months, the year may be inserted or two, three, or four years without destroying the card. A very simple code is indicated above the columns by the appropriate abbreviations—V, visit; N, night call; S, operation; O, obstetrics; P, office treatment; C, consultation, etc. Beneath the spaces are lines upon which brief notes of treatment, diagnosis, charges, or other family names may be entered. Totals are carried out in the last perpendicular column under the word, Total. The appropriate symbol in any space indicates the kind of visit, treatment, month, and day. When a circle surrounds a symbol, it means that treatment has been paid for, and a line drawn through the total indicates complete payment for that month. Upon the reverse side are six columns, headed date, credits, date, charges, balance, memoranda, which allow additional but self-explanatory entries to be made.

Although most physicians claim to lose (and from their haphazard and antique book methods, I am sure they do lose) from 20 to 35 per cent. of their bills, I believe I allow a liberal percentage if I say I lose 5 per cent. of my charges. Besides the ease of manipulation, the accessibility of the cards, the flexibility of the system, and the limited space required, there is the added advantage of simplicity. For were anything to happen to me, my affairs would be as plainly and methodically accessible to the veriest school boy, as they are to me. Not one of my patients could escape his just debts because of any lack of system or confusion in my affairs.

What is more, I have a sixth, but more limited card index to my insurance papers, will, bankbooks, real and personal property, debts, uniform expenditures, and what I designate a day card. On this day card is printed the year, month, and days. If the card happens to be December 4, 1905, it would read:

EXPENDITURES.

November electric light bill	$ 3.30
November telephone bill, C. & P. phone	3.55
Millinery bill	12.00
Stamps	.10
Car fares	.60
Lunch	.40
Drug bill	4.25
Theater, etc., in the evening	3.40
Total	$27.60

INCOME.

Cash	$12.00
Bill paid by United Railways	45.00
Total	$57.00

At the end of every month the day cards of that particular month are totaled and the actual income and expenses compared. References to items can be made at any time.

The best feature, however, in systematizing the modern doctor's office is to employ a stenographer and purchase a standard typewriter. All bills should be sent out monthly and typewritten. It makes them legible, keeps them clean and dainty, and the dignity it gives the physician more than pays for itself. The stenographer is able to look after the accounts, study the patients, and urge the delinquents.

Another idea which has proved of value in adding substantially to the completion of my scientific records, is to send a personal letter every year to patients who have not called on me for more than twelve months. Asking them in this way what has been the subsequent course of their illness, my history cards are kept up to date, and, at the same time, I am able to discover in a delicate way, those patients who have drifted into other hands. The ledger cards of these patients are removed from the file and destroyed.

Metal cases for any of these indices may be obtained but the best way to protect them from injury, especially fire, is to purchase a fireproof iron safe, into which have been fitted compartments of just the size for the various system of cards. This completes the link in a systematic chain of medical necessities.

1937 Madison Avenue.

Cow's Milk and Rickets.—A writer in *The Hospital* says that about 9 per cent. of the milk consumed in Great Britain is obtained from cows in calf; and to this he attributes the prevalence of rickets. As the embryonic calf grows, it requires more calcium for its bones, which is obtained at the expense of the milk. Children fed on this milk are not getting the necessary elements which go to form healthy bones. This milk-drain must also have a bad effect on the calf.

PANSINUSITIS DEXTRA WITH PARALYSIS OF THE RIGHT VOCAL CORD.

By IRVING WILSON VOORHEES, M.S., M.D.,

NEW YORK.

J. O., Austrian, aged 32, was seen by me in the Department of Laryngology, Vanderbilt Clinic, July 5, 1908. As the patient spoke very little English a good history was not obtained; suffice it to say that for eight years he had complained of pain in head, discharge from the right nasal cavity, front and rear, and pain and cough in the right chest, This pain and cough had remained about the same and had not kept him from work. He came to the clinic on account of headaches, insomnia, and complete loss of voice, which had peristed for the past three months in spite of all treatment.

Patient is of slender build, round shouldered, and flat as to the chest. He seems to have lost some flesh and is rather sallow as if septic. T., 99°; P., 82; R., 20. The frontal sinus is somewhat but not markedly tender on percussion and palpation, as is also the antrum of Highmore. Anterior rhinoscopy shows a deviation of the septum high up and to the left. The middle turbinate is enlarged and looks cystic. There is some pus between the septum and middle turbinate, and in the middle meatus. Rhinoscopy on the left side reveals a practically normal condition. Posterior rhinoscopy shows hypertrophy of right middle and inferior turbinates with yellowish pus in the nasopharynx which appears chronically inflamed. The tonsils are of the embedded type and contain caseous masses in the crypts. The tongue is coated with whitish fur, and the teeth are not in good condition. Mucous membranes normal save as already noted. Cervical lymph nodes slightly enlarged. Both membranæ tympani appear normal. Laryngoscopy shows some hypertrophy at base of tongue and chronic congestion of mucous membranes. The right vocal cord appears smaller than the left and is in a position of cadaveric rigidity. During efforts at phonation the left cord swings far inward and crosses the median line. A hoarse whisper is all that the patient is able to produce.

Examination of the chest by a number of physicians elicited a variety of opinions as to the presence or absence of aortic aneurysm. As a matter of interest, the writer examined the chest and found an area of dullness and bronchovesicular breathing about two inches in diameter over the second right intercostal space. There was no thrill or cough upon palpation and percussion. Heart sounds normal. Pulse at the wrists about the same on each side in force, frequency, rhythm, and fullness. If there was any difference at all the left pulse was stronger than the right. Tracheal tugging was absent. The eyes were normal. The chest symptoms were probably due to an enlarged lymph node pressing on the right recurrent laryngeal nerve. It was impossible to rule out aneurysm, but the weight of evidence was against this diagnosis.

Under cocaine anesthesia I explored the right nasal cavity on July 11. The middle turbinate proved to be nothing but a sac of pus. All bone was destroyed save for a thin lamella adjacent to the septum, evidently the last remains of a rarifying osteitis. After complete extirpation of the middle turbinate I found to my surprise that with little difficulty one could pass a bent probe into the frontal sinus. This was followed by a copious discharge of pus. The antrum, ethmoid, and sphenoid regions were all likewise explored with some discharge of pus from each. At a second sitting it was found

that a Eustachian catheter could be passed into the frontal sinus and moved about in various directions, consequently saline irrigations at 110° F. were begun and continued daily for three weeks. Curettage of all the sinuses was carried out as thoroughly as possible during the second and third sittings. No great amount of granulation tissue was removed, but there was considerable necrotic membrane with pus. After the fifth irrigation protargol, 25 per cent., was instilled into each sinus following each daily washing, and the outlets of cavities were packed with gauze in order that the protargol might be retained. After four weeks the discharge had practically ceased and the patient expressed a feeling of great relief. After nearly four months there has been no repetition of the intranasal disturbance. The laryngeal condition remains the same.

This case is of interest chiefly because it was amenable to intranasal treatment. It is seldom that one finds a case of such long duration which yields to any other measure save radical external operation. Whether the intrathoracic condition was related in any way to the intranasal condition it is quite impossible to prove.

THE PREVENTION OF HEMORRHAGE DURING OPERATIONS UPON THE NOSE AND THROAT.

By HENRY HUBBARD PELTON, A.M., M.D.,

NEW YORK.

ADJUNCT ASSISTANT ATTENDING PHYSICIAN TO BELLEVUE HOSPITAL; CHIEF OF THE MEDICAL CLINIC, PRESBYTERIAN HOSPITAL, OUT-PATIENT DEPARTMENT.

Having occasion not long since to excise a patient's enlarged tonsils and adenoids the idea suggested itself to the writer that the always annoying and sometimes dangerous hemorrhage which may result from such operations might be mitigated to some extent by the previous administration to the patient of one of the calcium salts. It is well recognized that the internal administration of calcium chloride and, more especially, of calcium lactate, has a distinct influence in increasing the coagulability of the blood.

The patient, a boy of seven years, was accordingly given eight grains of calcium lactate three times daily, after meals, for two days previous to the operation. At the time of operation the bleeding was comparatively slight and ceased very quickly.

To a second patient, an adult, whose elongated uvula was to be amputated, twenty grains of calcium lactate were given three times in the twenty-four hours before the operation. On returning for the operation the patient remarked that he had scratched his finger rather deeply that morning and that, to his surprise, the blood "quickly became brown and dried," while, as a rule, he was accustomed to bleed rather freely after such injuries. The uvula was amputated and the hemorrhage was quite inconsiderable.

While the instances reported are far too few to lead to any definite conclusions it would seem that the administration of calcium lactate as a routine preliminary to operations upon the nose or pharynx might be a measure worthy of trial. It certainly is a harmless one and if it causes a diminution of the bleeding at the time of operation not only will the blood be conserved to the patient but the operator will be benefited in that the field will be less obscured by the accumulating blood and the procedure will be easier and more quickly performed. A lessening of the tendency to postoperative hemorrhage is an additional advantage which will accrue.

The ordinary adult dosage of calcium lactate is twenty grains thrice daily. The doses for children should be regulated in accordance with the age of the patient.

It is said that the administration of the salt for a period longer than two or three days brings about a condition of lessened coagulability; on this account it is unwise to prescribe it for a longer period than twenty-four to forty-eight hours at a time, which is quite long enough to produce the full effect of the agent.

345 West Eighty-fifth Street.

The Overcoat.—The season of overcoats is approaching, and probably in no other department sartorial is there exhibited so much indifference to hygienic considerations. The greatest fallacy of all, perhaps, in regard to the choice of an overcoat is that the terms "weight" and "warmth" are synonymous. As a matter of fact they are nearly always diametrically opposed. Heavy materials are often good conductors of heat and are calculated therefore to allow the heat of the body to escape, while light materials are bad conductors and so preserve the heat and energies of the body. Moreover, the heavy overcoat is a tax on the resources of the organism and destroys the economy which a good insulating cloth is intended to secure. Further, heavy material encourages an uncleanly and unhealthy state of the body chiefly by imprisoning the exhalation of the skin. That cloth is best, therefore, which gives the minimum of weight and the maximum of warmth whilst being porous enough to admit of ventilation. It is not generally realized that in protecting the body from the dissipation of its own heat—*i.e.*, from cold—clothing really serves as an economizer of fuel—that is, food. Could we accustom ourselves to wearing no clothing at all under cold climatic conditions we should have to consume much more food than we do in order to compensate for the rapid loss of heat which would happen if the body were not wrapped in nonconducting materials. This point needs to be borne in mind by those who advocate the banishment of the overcoat. It is, of course, possible to dispense with an overcoat, provided that the clothes worn are particularly warm. The overcoat, however, offers the decided advantage that it can be superimposed over a comparatively light suit of clothes, and thus while preventing the escape of heat, provides also an air space between the ordinary clothes and itself—an air space which is open to ventilation. There seems to be little doubt that a well-chosen overcoat surrounding a warm but light suit of clothes is for the reason just given much more comfortable than a heavy suit of ordinary clothes. There is another important point about the qualities of an overcoat, and that is in regard to the color of the material. The choice of a somber hue—black, dark gray, dark brown, or dark blue—is totally opposed to scientific indications. The polar bear is not provided with black fur; if he were he would not be able to defy the cold with that impunity which he does. Light colored material, as a matter of fact, does not so easily give up its heat as does dark material, and this would appear to teach that our notions as to the suitability of color of garments for winter wear are illogical. Fashion and custom bind us hard, and are seldom on all fours with reasonable ideas. If he would follow the dictates of science and common sense, the purchaser of winter clothing would choose, if he were able to do so, garments of a light rather than of a dark hue. And why should every one be clothed in a funereal type of material just when winter sets in, when every effort is necessary to compensate for the dreariness and darkness of its days?—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 26, 1908.

THE INFLUENCE OF EXERCISE AND HABIT UPON REFLEX AND AUTOMATIC PHENOMENA.

IT is a matter of common knowledge that any unusual circumstances interfering with the normal processes of the organism are followed by various reflex and automatic phenomena aimed at the protection of the organism or the compensation of a disturbed function. The usual opinion, however, is that these reflex and automatic phenomena cease as soon as the physical stimuli that have called them forth have disappeared. Writing in the *Deutsche medizinische Wochenschrift* for November 12, 1908, Dr. Treupel claims that such is not the fact: the processes called forth by the unusual circumstances continue for some time after all seeming significance of them is gone, and Dr. Treupel considers that this is due to the influence of exercise and of habit upon the nervous mechanisms of such phenomena. Thus, a fit of coughing is the logical outcome of an inflammation of the pharynx with accumulation of secretion which is gotten rid of by the cough; long after the inflammation and increased secretion have subsided attacks of coughing continue to trouble the patient. The hoarseness or even the total aphonia accompanying inflammation of the vocal cords continues after the parts have assumed their normal anatomical relations. Examples of this sort may be multiplied indefinitely, one of the commonest being the constant winking that may be noticed in persons who had gone through an attack of conjunctivitis.

Of course, while we say that no physical causes remain that may explain the continuation of these processes, yet, as Treupel correctly states, the cells of the nervous system may be assumed to retain some effects of the unusual stimuli that called the protective or compensating processes into action and it is these changes in them which lead to the continuation of these processes. Our crude histological methods, however, are not able to demonstrate such changes in the cells of the nervous system. Treupel's observations are of great interest when we apply them to many clinical phenomena. Certainly the loss of some special function that is often met with in hysterical or highly nervous individuals, after disease or accident affecting this function, is thus explained; the therapy of these conditions, too, may sometimes be greatly influenced by having the patient carry out this or that action in a normal manner by dint of mental or even physical compulsion; once the success of this is demonstrated to the patient the inhibiting factors are easily overpowered by subsequent exercise.

Reeducation of the nervous mechanism of action is really at the bottom of many such therapeutic processes, just as the loss of function is often due to temporary interference with the proper functioning of this mechanism. The very successful treatment of the ataxia of tabes dorsalis introduced by Frenkel depends upon such reëducation, while a number of examples may be cited where habit changes the response of the nervous mechanism from the usual or normal to what is really very unusual or abnormal, but is not so interpreted by us simply because of our familiarity with such phenomena. As an instance of this, one need only compare the effects of alcohol or of tobacco upon the man who indulges in these stimulants for the first time and upon one who has the habit of using them. A more striking example, simply because it is more rare, is quoted by Treupel: A patient in whom the taking of the smallest portion of an egg as food was always followed by most intense phenomena of reaction was given small doses of egg albumin in the shape of pills, the dosage being gradually and constantly increased; within a short time he could take in the shape of these pills as much albumin as is contained in an egg without any discomfort, and then easily passed on to enjoying eggs in their usual mode of preparation. Whatever changes took place in his organism they certainly must be accounted for by the influence of habit due to gradual and constant accommodation of the nervous system to the stimuli that formerly called forth an intense reaction.

Treupel's observations thus point out the real significance of many functional disturbances and at the same time furnish therapeutic hints for the management of these affections. The difficulty consists in finding the ultimate cause which has set such disturbances into action, the cause in nervous individuals being often extremely insignificant in itself. Careful attention to the minute details of the anamnesis of such patients often gives the clue to the proper procedure in freeing them from their affection.

THE ABSENCE OF CONTRAINDICATIONS TO NURSING.

TEXTBOOKS of obstetrics and of pediatrics usually name a number of conditions in the presence of which maternal nursing should not be attempted. Among these are enumerated tuberculosis, serious complications in pregnancy, in labor, or the puerperium, previous ill-success in nursing, grave chronic disease of whatever nature, and extreme nervousness. Writing in the *Münchener medizinische Wochenschrift* for November 24, 1908, Walcher, the director of a large school for midwives in Stuttgart, tells his experience in disregarding all these supposed contraindications and insisting that every mother delivered in the establishment under his charge should nurse her own child. In his opinion there are no anatomical conditions that could be looked upon as preventing nursing, outside, of course, of accidental defects in the mammary glands; there certainly are no physiological or moral reasons for the neglect of a function so important for the welfare of the in-

dividual child and of the whole race. The only stimulus necessary for sufficient production of milk is persistence in allowing the child to nurse, the quantity of milk produced being proportionate to the demands made upon the glands. The other important factors influencing the secretion are the will of the mother, the degree of her love for the child, and the realization of the great injury done to the latter in robbing it of its natural food; this with the provision for abundant diet for the mother is all that is necessary to insure the success of nursing.

Walcher has confirmed these theoretical considerations by the practical results obtained by him in his clinic, where before his advent only twenty-three per cent. of women nursed their children entirely. His first order was to increase the food allowance of the puerperal women from the very first day after the birth of the child, and then use every possible means of impressing upon the patients as well as upon the attendants that every woman who has been able to give birth to a child should also be capable of nourishing it entirely with her milk. The final result has been that bottle-feeding is restricted in his clinic to the unfortunate babies whose mothers died in labor or the puerperium; all other babies, averaging about eight hundred a year, have been given breast milk alone while in the hospital. This has been accompanied by an average gain in weight that was much more marked for the stay of thirteen days in the hospital than the figures for former years. The effect upon the mothers has also been very favorable, even tuberculous patients being benefited by the increase of appetite coincident with nursing and the psychic influence of the consciousness that they were able to fulfill the functions of a nursing mother as well as healthy women.

Walcher concludes his paper by calling attention to the economic causes that often prevent mothers from nursing their children and compels them to leave the babies in charge of some old woman relative whose methods of feeding are the cause of a frightful mortality. Little better are the results obtained in various homes for taking care of the babies of working mothers, overcrowding being added to the other factors detrimental to the well-being of the children. According to Walcher the factories employing women should provide special conveniences so that mothers among them could attend to their children at certain stated intervals, for the mortality among the babies of the poor can be fought successfully only when the truth is recognized that "the only true home of a nursing child is the mother's breast."

THE ENIGMA OF MALIGNANT DISEASE.

The study of malignant disease has been very eagerly taken up by numerous observers in recent years, the advances in biochemistry and in our knowledge of the tumors of animals having given an impetus to such work. The realization of the frightful prevalence of the disease and of the helplessness of the medical profession has led lay persons and associations to organize various committees and scientific institutes for the prosecution of the fight against cancer. Yet in spite of all this activity it must be confessed that we are as little advanced as before so far as our knowledge of the etiology of cancer is concerned; that our therapeutic successes have not been much increased, either, is shown with painful clearness in Zangemeister's review of the recent methods of treatment, in the *Deutsche medizinische Wochenschrift* for November 19, 1908. Of the many attempts to effect the cure of cancer by various physical methods, among them the use of heat, cold, electrical energy, light, and rays of every kind, the use of radium alone seemed to have been attended with some success in the treatment of superficial cancerous growths. But of course such success offers hardly any advantages over the use of the knife and introduces new elements of unknown danger from the powerful agent used.

Of the chemical methods of treatment the use of ferments has had a brief though an extensive popularity. Trypsin especially raised the hopes of many, yet the results have been a disappointment, the necrotic changes produced in cancer tissues by local injections of the remedy proving to be of no use in curing the organism of deep-seated disease. The experimental workers have attempted to produce specific cytolytic sera for the treatment of cancer: but the favorable results obtained in animals have not been repeated in human beings and the analogy of tumors of mice and rats to the cancer of human beings has been seriously questioned by some acute observers. The latest avenue of attack has been opened by the finding of various ferments in cancer tissue that may be supposed to have detrimental effects upon the organism either in overcoming local resistance to the growth of tumor cells or causing a general cachexia. A multitude of antiferments have therefore been tried as of possible use in stopping the progress of malignant disease, but the results have not been satisfactory, however enthusiastic some of the early reports have been. Zangemeister concludes that up to the present no therapeutic measure has been found that could compare in effectiveness with the operative treatment that has been in vogue for so many years. This simply means that the many new measures proposed by the enthusiastic workers in cancer research have only a local destructive effect; the progress of surgical technique, however, has been such that the use of the knife is the safest way of attaining such effects if the site of malignant disease is at all accessible. The only effect of the widespread agitation of the cancer question has been the accentuation of the advisability of early operation, and there is little enough hope in that.

Sporotrichosis.

In recent times the attention of clinicians has been drawn to the diseases caused by infection with various yeasts; in addition to the saccharomycoses and blastomycoses, the picture of which has been fairly well worked out, there has been added another similar affection caused by the organism first described by Beurmann and called after him the *Sporotrichium beurmannii*. The importance of knowing the possible *rôle* of this organism in the causation of disease is illustrated by two cases reported by Spillman and Gruyer in the *Annales de Dermatologie et de Syphiligraphie*, Vol. IX, No. 10.

The first patient presented a typical picture of multiple cold abcesses situated on the fingers and arms. The clinical picture of the affection and the fact that the patient suffered from a chronic cough, while his history gave a number of cases of tuberculosis in his immediate family, led to the diagnosis of a tuberculous affection of the skin. However, a bacteriological examination of the pus of the abcesses showed the presence of *Sporotrichium beurmannii*. The second patient, a veterinary physician, presented a lesion the size of a quarter dollar on his left cheek, that had the appearance of an actinomycotic ulcer, the profession of the patient and the involvement of the regional lympatic nodes lending strength to this diagnosis. But here also bacteriological examination revealed the presence of the above organism. These cases show the necessity of keeping in mind the possibility of an infection with this organism in all cases that clinically resemble one or another of the commoner chronic affections of the skin of parasitic origin: in every such case a bacteriological examination should be made without fail, not only because of the scientific interest attached to this rare affection, but also because correct diagnosis may be followed immediately by proper treatment, which consists in the administration of potassium iodide. It may be expected that further cases of infection with this yeast will soon be published, attention having been drawn to the occurrence of such a condition: with the increase of material the biology of the causative organism too may be cleared up; so far it is only known that it leads a saprophytic existence upon certain plants and animals and from them it is transmitted to the human being.

News of the Week.

Street Car Accidents.—The Public Service Commission of New York reports that during the month of November, 1908, there was a considerable drop in the number of street car accidents as compared with the previous month and with November, 1907. The total number of accidents was 3,992, which is 45 less than in November of last year, and 676 less than in October of this. Thirty-six persons were killed, and 169 others were seriously injured. For November of last year the number of persons killed was 45 and the number of those otherwise seriously injured was 198. The number of persons injured while getting on and off the cars, though slightly larger than last year, was only about one-half that for June and July, the difference being due largely to the use of closed instead of open cars.

Death Rate in New York.—The figures for the week ending December 12, show that New York is the healthiest city in the country. The number of deaths was 1,249 as against 1,667 for the same week of last year, an actual decrease of 418 deaths for one week. The rates were estimated as 14.73 for this year, and 20.29 for 1907. The report shows that the deaths from measles and scarlatina were only half as many as in the corresponding week of last year; influenza caused 6 deaths as against 42 for 1907; lobar pneumonia 96 as against 201; and pulmonary tuberculosis 153 as against 188. The only increase was in deaths from diphtheria, 42 occurring last week and 34 a year ago. In the tenement houses there was a total decrease of 222 deaths.

Death Rate in New York State.—According to the report of the New York State Department of Health, the death rate in this State for the year 1907 was higher than the average, and was surpassed only by the rates of Rhode Island and of California. The average rate for all the States was 16.1; New York's rate was 17.1. In comparing the rate with those of foreign countries, it is shown that Norway has a rate of only 14.5. Hungary's rate is 26.2, the highest. In New York, the smallest death rate of the year was in the Adirondacks and the northern section. The statistics also show that the marriage rate of New York, particularly of New York County, is unusually high.

The Health of the Canal Zone.—The report of the Department of Sanitation of the Isthmian Canal Commission, for the month of October, 1908, shows upon the whole good health conditions, though the sick rate has not fallen as in previous years. The sick rates for the past three years, comparing September and October, are as follows: 1906, September, 37.7, October, 33.6; 1907, September, 27.7, October, 26.9; 1908, September, 25.09, October, 26.6. The death rate of the force makes a very good showing, the total rate from all causes being 12.93, though of this only 7.7 was due to disease. Comparing again the past three years as to deaths due to disease, the following rates are given: October, 1906, 42.4; 1907, 23.6; 1908, 7.7; that is, the death rate from disease in the force during the past October was only about one-sixth what it was in 1906. The month showed an increase in the number of cases of malaria over the preceding month and over the same month of last year. There has been no case of yellow fever since May, 1906, though it exists at several points to the north and south of the Canal Zone. No case of bubonic plague has appeared since August, 1905, though that disease also has broken out not far away: and there has been no case of smallpox during the year.

Pullman Cars to be Investigated.—Dr. Harvey W. Wiley of the Department of Agriculture is authority for the statement that the Pullman cars are down for the next investigation. The interest aroused in Washington by the Tuberculosis Exhibition has revived the movement for safe and sanitary cars. Dr. Wiley thinks that thousands of cases of contagious diseases in which the source of infection cannot be traced are due to the microorganisms absorbed during railway travel, and considers the modern upholstered sleeping car as congenial a home and breeding place for microbes as is a laboratory.

The Raybrook Sanatorium.—The annual report of the State Hospital for the Treatment of Incipient Cases of Tuberculosis at Raybrook, New York, for the past year shows that 477 patients were treated, and that 163 cases are now under its care, eighty of whom are males. During the year only three patients died in the sanatorium, and 301 were discharged, most of them benefited and many of them as cured. The care of these patients costs the State $9.47 a week per capita, the total for the year for all purposes being $109,017. Of this, $37,250 was spent for provisions, and $18,301 for salaries, wages, and labor.

Optometry Regulations.—Regulations governing the practice of optometry were recently given out by the New York State Board of Examiners in Optometry, to become effective on January 1, 1909, after which date, under the new State law, no one may examine eyes for glasses without a certificate from this board. Investigation is now being made as to the qualifications of a large number of those who have applied for these certificates. Dispensing opticians who merely fill prescriptions or

sell glasses to customers on the latter's selection are not required to have certificates.

The Crusade Against Cocaine.—The new cocaine law was declared valid recently by the Illinois Supreme Court in the first case which has gone to it for decision since the act was passed by the last Legislature. The case at issue was a fine of $500 imposed upon two druggists, who were convicted in the lower court of having sold a catarrh powder containing cocaine. The court has decided that cocaine cannot be sold in patent medicines, in fact, in no form unless upon a physician's prescription. In the court of General Sessions, New York, Judge Crain recently sentenced a man, who had previously been convicted of selling cocaine, to serve five months in the penitentiary and to pay a fine of $100.

Fined for Violating Ordinance.—Two Chicago physicians were recently fined ten dollars and costs for failing to report cases of epidemic diseases to the Commissioner of Health.

Dr. Francis G. Benedict of the Carnegie Nutrition Laboratory of Boston will deliver the first of a series of special lectures arranged for the benefit of the students of the University of Wisconsin. Dr. Benedict will speak on "The Influence of Mental and Muscular Work on the Assimilation of Food."

Dr. Joseph Springer has been appointed coroner's physician, vice Dr. Otto W. Lewke, resigned.

Mrs. Mary E. Farrell of Midland Park, N. J., celebrated her 105th birthday on December 19. Mrs. Farrell was born in New Jersey, her parents being Hollanders, and has had ten children, six of whom are living.

Death of a Centenarian.—James Clancy, said to have been the oldest Civil War veteran, died at the National Soldiers' Home in Milwaukee, on December 19, aged 100 years. He enlisted with the Fourth Michigan Guards in 1862.

The Scientific Temperance Federation.—The second annual meeting of this association was held in Boston on December 8. The report of the year's work summarized the outlook for the anti-alcohol movement from the scientific standpoint, reviewed the special investigations reported during the year, and the work accomplished by the federation in disseminating this and other information. The officers elected for the coming year are: *President,* Rev. C. A. Vincent; *Vice-President,* Mrs. A. J. Gordon; *Recording Secretary,* E. L. Transeau; *Corresponding Secretary,* Cora Frances Stoddard; *Treasurer,* Robert H. Magwood.

The Milwaukee (Wis.) Medical Society, at its annual meeting on December 11, elected the following officers for the ensuing year: *President,* Dr. W. H. Washburn; *Vice-President,* Dr. L. F. Germain; *Treasurer,* Dr. Joseph Kahn; *Secretary,* Dr. A. W. Gray.

The Watertown District (S. D.) Medical Association held its annual meeting on December 10. The following officers were elected: *President,* Dr. H. W. Sherman of Doland; *Vice-President,* Dr. S. B. Dickinson; *Secretary and Treasurer,* Dr. J. B. Vaughn of Castlewood.

The Marshall County (Ia.) Medical Society, at its annual meeting on December 8, elected the following officers: *President,* Dr. Theodore Engle, State Center; *Vice-President,* Dr. H. H. Nichols; *Secretary and Treasurer,* Dr. F. P. Lierle; *Censor,* for a term of three years, Dr. E. W. Jay.

The Muskegon-Oceana (Mich.) Medical Society held its annual meeting, on December 4, at which officers for the ensuing year were elected as follows: *President,* Dr. J. F. Denslow; *Vice-President,* Dr. J. D. Buskirk; *Secretary,* Dr. Vernon A. Chapman; *Treasurer,* Dr. Jacob Oosting; *Trustee,* Dr. George S. Williams.

The Minnesota Valley Medical Association, at its twenty-ninth annual meeting on December 8, elected the following officers: *President,* Dr. F. N. Hunt of Blue Earth; *First Vice-President,* Dr. A. Strickler of Sleepy Ele; *Second Vice-President,* Dr. Lida Osborn of Mankato; *Secretary,* Dr. A. G. Liedloff of Mankato; *Treasurer,* Dr. G. F. Merritt of St. Peter.

The Grafton County (N. H.) Medical Society held its annual meeting on December 8. The election of officers resulted as follows: *President,* Dr. G. W. Hazelton of Haverhill; *Vice-President,* Dr. W. S. Woodman of West Lebanon; *Secretary,* Dr. G. A. Weaver of Warren; *Delegate to the State Medical Society,* Dr. W. D. Smith of Hanover.

The Mitchell District (Ia.) Medical Society, at its annual meeting on December 9, elected the following officers: *President,* E. N. Wagar, Bijou Hills; *Vice-President,* Bert Menser, Bridgewater; *Secretary,* W. R. Ball, Mitchell; *Treasurer,* B. A. Bobb, Mitchell; *Press Censor,* E. W. Jones, Mt. Vernon.

The Southern California Medical Society closed its fortieth semi-annual meeting at Santa Ana, on December 3, with the election of officers, which resulted as follows: *President,* Dr. F. R. Burnham, San Diego; *First Vice-President,* Dr. C. D. Ball, Santa Ana; *Second Vice-President,* Dr. J. M. Holden, Long Beach; *Secretary-Treasurer,* Dr. J. M. King, Los Angeles.

The Lake County (Ohio) Medical Society recently elected the following officers for the ensuing year: Dr. A. P. Brady, *President;* Dr. H. W. Grauel, *Vice-President;* Dr. M. H. Carmedy, *Secretary;* Dr. C. W. Hawley, *Treasurer;* Dr. H. C. Spence, *Delegate;* Dr. T. M. Moore, *Member of the Auxiliary Committee;* and Dr. J. W. Lowe, *Censor for three years.*

The Columbiana County (Ohio) Medical Society, at its meeting on December 8, elected the following officers: *President,* Dr. William N. Bailey, East Liverpool; *Vice-President,* Dr. P. C. Hartford, East Palestine; *Secretary,* Dr. Alex Cruikshank, Salem; *Treasurer,* Dr. J. B. Talmadge, Columbiana.

The Champaign County (Ohio) Medical Society held its annual meeting at Urbana on December 10. The following officers were elected: *President,* Dr. Robert Henderson; *Vice-President,* Dr. E. W. Ludlow; *Secretary,* Dr. Houser; *Treasurer,* Dr. S. M. Mosgrove; *Delegate to the State Convention,* Dr. David O'Brine.

Philadelphia Academy of Natural Sciences.—At the annual meeting held December 15, the following officers were elected for the ensuing year: *President,* Dr. Samuel G. Dixon; *Vice-Presidents,* Drs. Arthur Erwin Brown and E. G. Conklin; *Recording Secretary,* Dr. Edw. J. Nolan; *Corresponding Secretary,* Dr. J. Percy Moore; *Treasurer,* George Vaux, Jr.; *Librarian,* Dr. Edw. J. Nolan; *Curators,* Drs. A. E. Brown, S. G. Dixon, H. A. Pilsbury, and Witmer Stone; *Councilors,* Drs. Henry Tucker, Charles B. Penrose, Charles Morris, and Spencer Trotter.

Philadelphia County Medical Society.—At a public meeting held December 15, a series of com-

munications was presented dealing with "The Public Health and the Medical Profession." Dr. Joseph McFarland read a paper entitled "Vaccination as a Protection to the Public," and remarks on the same subject were made by Professor Edwin J. Jouston. Dr. George W. Wagoner, president of the Medical Society of the State of Pennsylvania, read a paper entitled "Medical Legislation as a Benefit to the Public," and remarks upon the same subject were made by Samuel Scoville, Esq. Dr. D. J. McCarthy read a paper entitled "Science and the Public Health," and remarks on the same subject were made by Dr. Henry H. Donaldson.

Obituary Notes.—Dr. Robert Henry Davis, recently of Brooklyn, died on December 14, after a brief illness, aged 81 years. Dr. Davis was a first cousin and intimate friend of Jefferson Davis, and served throughout the war in the Confederate Army. At the close of the war he settled in Texas, where he practised until his retirement.

Dr. Elias Buell Heady of Milford, Conn., died at his home on December 16, aged 62 years. Dr. Heady was graduated from the Yale Medical School in 1872, and was a member of the American Medical Association.

Dr. Abraham Morrell Cory, one of the oldest physicians of New Jersey, died at his home in New Providence on December 16, aged 81 years. Dr. Cory was graduated from the Medical and Surgical College of Philadelphia in 1857, and served as a surgeon in the Civil War. He was well known as a writer and also as an inventor, one of his inventions being a universal solar clock by which the time at any given portion of the earth's surface could be instantly determined.

Dr. Michael A. Kadien of New York died suddenly on December 15, of myocarditis, after a short illness. Dr. Kadien was born in 1859, and was graduated from the Bellevue Medical College in 1901.

Dr. Henry Clay Winger of Harrisburg, Penn., died at his home on December 6, at the age of 72 years. He was a graduate of the medical department of the University of Pennsylvania and a veteran of the Civil War. During his early life he served as a scout with Kit Carson.

Dr. J. Warren Roop of Harrisburg, Penn., died on December 8, aged 66 years. Dr. Roop was graduated from the medical department of the University of Pennsylvania in the class of 1868, and was at one time president of the Dauphin County Medical Society.

Dr. John Davis of Pottstown, Penn., died at his home on December 11, at the age of 76 years. Dr. Davis was graduated from the Eclectic Medical College of Philadelphia in the class of 1862.

Dr. Edwin Bidwell of Deep River, Conn., died at his home on December 11, as the result of a general breaking down due to old age. Dr. Bidwell was born in 1819 and was graduated from the Yale Medical School in 1847. He had practised in Deep River since 1860.

Dr. William Mackie, one of the foremost surgeons of the Northwest, died suddenly on December 9, at the home of his son in Milwaukee, Wis. Dr. Mackie was born in Scotland in 1855, and was graduated from the University of Aberdeen in 1881. Two years later he settled in Milwaukee, and had for years served as chief of staff at the Milwaukee Hospital, in which position he followed Dr. Nicholas Senn. Dr. Mackie was a member of several medical societies and a frequent contributor to medical literature.

Dr. Augustus Le Plongeon of Brooklyn, well known for his explorations in South America, died suddenly of heart disease on December 13. Dr. Le Plongeon was born in the Isle of Jersey in 1826, and received his medical education in France, going later to South America, where he practised for a number of years. Becoming interested in the ancient history of the South Americans he made a number of tours through Peru, Yucatan and Mexico, and two of his books are considered the authoritative works on Peru. During the last ten years he had lived in Brooklyn, devoting his time entirely to writing.

Dr. William Martin Ogden of Pasadena, Cal., died on December 3, after a long illness, aged 67 years. Dr. Ogden was graduated from the Harvard Medical College in 1865, and afterward the University of Edinburgh. He was a member of the Massachusetts Medical Society, at one time vice-president of the Boston Microscopical Society. He was also for many years one of the faculty of the Boston Dental College, where he filled the chair of general and dental surgery. Because of ill-health he was compelled some years ago to relinquish his practice, and had since lived in California.

Dr. John E. Russell of Mt. Vernon, Ohio, died on December 8, of disease of the kidneys, aged 48 years. Dr. Russell was a graduate of the Starling Medical College of Columbus, Ohio, and had practised in Mt. Vernon for over twenty-five years. He was a member of the Board of Trustees of the Hospital for the Criminally Insane at Lima.

Dr. E. A. Stewart of Dayton, Ohio, died at his home on December 10, of pneumonia. Dr. Stewart was born in 1867, and at one time was engaged in journalistic work. He abandoned this, however, to take up the study of medicine and was graduated from the Ohio Medical College at Cincinnati in 1897. He was one of the charter members of the Dayton Academy of Medicine, and also belonged to the Montgomery County Medical Society.

Dr. Samuel Gluck of New York, died suddenly of heart disease at his home on December 17. Dr. Gluck was born in Budapest, Hungary, in 1845, and studied medicine at the University of Vienna, graduating in 1871. The following year he came to this country. He was a member of the German Medical Society, and was at one time connected with the Mt. Sinai Hospital.

Correspondence.

ANTI-ALCOHOL MOVEMENT AMONG GERMAN PHYSICIANS.

To the Editor of the Medical Record:

Sir:—At the meeting at Basle of the V. International Congress to Combat the Abuse of Alcoholic Beverages, Drs. Gaule, A. Smith, Fürer, Legrain, and Bleuler delivered powerful addresses in favor of abstinence from alcohol. These addresses aroused great enthusiasm, and induced twenty-six men present at the meeting to form an organization of medical men for the promotion of scientific investigation of the effects of alcohol, and for the dissemination in medical circles of a clearer knowledge of the alcohol question. It is not known who was the father of the idea to form this organization, in noble-minded modesty he has not made any claim of priority; we may assume, however, that he was one of the pupils of Kraepelin.

The meeting was held on August 21, 1895, and this day is the real birthday of the Society of German Physicians for Abstinence, or, as it is called in German, "Verein abstinenter Aerzte des deutschen Sprachgebietes."

On September 20, 1896, in connection with the sixty-eighth Congress of Natural Scientists at Frankfort-on-Main, the constituting meeting took place in which the society elected its officers and adopted a constitution. The number of members on that day was seventy. More and more since its foundation this German society assumes a leading position in the temperance movement, because

this organization is working more than any other on a scientific basis; its labors have accomplished that the position of the medical profession at large toward the alcohol question has gradually changed, and that the appreciation of the temperance movement among physicians is increasing from year to year. The names of the illustrious men who during the twelve years of the existence of the society have been its presidents are: Forel, Kraepelin, Aschaffenburg Delbrück, and Bleuler. Physicians reading these names will appreciate their significance in the battle against alcohol and for the good of the society of which they have been presidents.

The development of the organization can best be judged by the increase in the number of its members.

As mentioned, there were 70 members at the time of the first official meeting in the year 1896;

in the year	1897	the society had			94	members.
" " "	1899	" " "	125	"
" " "	1900	" " "	159	"
" " "	1901	" " "	170	"
" " "	1902	" " "	192	"
" " "	1903	" " "	213	"
" " "	1904	" " "	237	"
" " "	1905	" " "	247	"
" " "	1906	" " "	300	"
" " "	1908	" " "	350	"

The activity of the society during the first year of its existence was restricted on account of limited means at its disposal, but the yearly gatherings alone which took place in connection with the meetings of the congresses of the Natural Scientists were the means for agitation; the highly valuable papers read and the truly earnest scientific discussions of these papers secured esteem for the name of the society and directed the attention of the medical profession to its aims.

Of significance are the following four theses which were discussed at the first official meeting:

1. No vocation is more able, more called for, more under obligation, than the medical profession, to conduct the much-needed combat against the drinking habit.

2. To a great extent physicians are to be blamed for the increase in the consumption of alcohol as a beverage.

3. The present methods of treatment of drinkers in the phrenocomeia are inadequate in many directions.

4. The laws concerning drinkers must be considered as impractical and insufficient.

The second annual meeting took place in Brunswick. The subject for discussion was "The Therapeutical Indications for Alcohol," by Dr. A. K. Beer of Munich, now in Milwaukee, Wis. In the discussion participated: Kantorowicz, Colla, Smith, and Hoppe, in favor of abstinence, and Schmitz (of Bonn) and Kugelmann (of Hanover), against abstinence. Three more papers were read, one by Forel, "Is the Mentally Stimulating or Exhilarating Effect of Alcohol on Sociability Commendable from the Point of View of the Physician?" and one by Hirschfeld on "Prevention of the Drinking Habit."

At the third annual meeting (1898, at Düsseldorf) Bonne spoke "On the Alcohol Question and Medical Practice," Fürer on "Neurasthenic Attacks of Precordial Oppression and Alcohol Therapy," Jordy on "Non-alcoholic Medical Wines." The last paper brought out a very long discussion.

Not without interest is the fact that two motions presented at this meeting are still under discussion at present: Legrain proposed the internationalization of the society and Kantorowicz, negotiations with life insurance companies for reduction of premiums in the case of abstainers.

The fourth annual meeting, held at Munich, presided over by Kraepelin, was especially well attended. Papers were read by the president on "The Psychical Effects of Alcohol"; by Colla, "New Clinical Experience Concerning the Effect of Alcohol," and by v. Bunge, "On the Increasing Inability of Mothers to Nurse Their Children and Its Relation to Alcoholism."

Much attention was shown at the seventh annual meeting, held in Carlsbad, by the Natural Scientists, who attended the session in large numbers. Kassowitz spoke on "Food and Poison," and his paper elicited a lively discussion. The second paper, read by Frick, was "On the Treatment of Febrile Diseases without Alcohol."

Rosemann, who had opposed some views of Kantorowitz as pronounced at the meeting in Carlsbad, spoke on invitation by the executive committee at the eighth annual meeting, held in Cassel, "On Alcohol as Food," and excited opposition on the part of some of the members. Then followed a paper by Keferstein, "The Influence of Large Amounts of Liquids on the Heart." At this meeting a prize of 300 marks was offered for the best treatise on the influence of alcohol.

At the annual meeting of 1904, in Breslau, Holitscher spoke on "Alcohol and Opium Habits"; Rösler, "On the Paramount Aims and Tasks of the Abstinent Physician."

The annual meeting of 1905 took place in Vienna. It was an exceptional success, the attendance was very great. Forel, Kassowitz, Bleuler, and Mathews read highly interesting papers, and elicited lively and valuable discussions.

I have no details of the meetings since 1905 because the history of the society written by Dr. A. Holitscher, who for several years was the general secretary of the society, and of which history I have availed myself, comprises only the first ten years. Dr. A. Holitscher has had the kindness to lend me the only copy he possesses.

From the information which I have gathered about these latest meetings I learn that they were characterized, as well as the preceding ones, by their scientific character. The principle of abstinence upheld by the members of the society is based on well-founded, indisputable, scientific investigations. The society has succeeded in gradually reducing the number of those physicians who still assume the ungrateful task of defending the use of alcohol. The society is endeavoring to furnish evidence that even the smallest doses of alcohol are injurious to the organism. They are guided by Kraepelin and his school upholding that it has been proven that alcohol injures the psychic functions and have come to the conclusion that there is more than ethical foundation for abstinence. Of especial importance are the experiments of Laitinen discussed by the society, which show that a small amount of alcohol, corresponding with the smallest amount of alcohol taken by men who are moderate drinkers, regularly administered to animals, reduces the power of resistance to infection and has a decidedly injurious influence on the descendants. Among other papers read at the meetings since 1905 were those of Delbrück and Vogt, who expressed their opinion that the administration of alcohol as a therapeutic agent was almost entirely unnecessary, and that the prescription by physicians of alcohol is furthering its use and conducive to establishing the habit. Hence if there is in existence a substitute of equal value—which is the case in nearly every instance—this should be given the preference. Vogt spoke about the firmly established facts of the physiological effects of alcohol and deduced from these the uncertainty and the falsity of most indications which to-day are deciding for the administration of alcohol.

A. Rose, M.D.
126 East Thirty-fourth Street, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

A NEW DEPARTURE IN HOSPITAL WORK—MEDICAL COUNCIL—IDIOPATHIC DILATATION OF THE BLADDER—CANCER OF CERVIX UTERI—THE WESTMINSTER HEALTH SOCIETY—OBITUARY.

London, December 4, 1908.

A somewhat novel departure has been instituted through the generosity of Lady Campbell Clarke at the Westminster Hospital. Out-patients who in the opinion of the staff need nutriment as much or more than medicine are to be provided with meals in the hospital. Such necessaries, as milk, which are to be taken at frequent intervals, will also in certain cases be supplied by the "Lady Campbell Clarke Fund." The beneficence of her ladyship will no doubt be wisely administered under the direction of the visiting members of the staff, to whom it will prove of great value in their treatment and will further relieve many cases of great distress due to illness.

On Monday the Council of the Hospital Sunday Fund met, the Lord Mayor presiding. The report which was adopted stated the total of the year's collections as £80,181. The amount collected in places of worship was £40,239, being £2,547 less than in the previous year. The decrease was attributed to the simultaneous collection for the "Pan-Anglican Congress," a suggestion which the Bishop of London hoped was not the true reason. The Council viewed with apprehension extensions contemplated by certain hospitals and institutions, whose income by no means met their expenditure, and where a considerable number of beds were empty for want of funds. The Council considered that in the present state of hospital finances such extensions should be discouraged by the fund, unless the hospital could show that it had the means to provide and maintain them. The report was adopted without discussion and it was resolved that the annual meeting of the constituents should take place on the 16th inst.

I am pretty sure the view of the Council as to extensions and enlargements will be strongly upheld. At any rate, there has been a feeling on the part of the public for some time past to condemn the extravagance of hospital managers and the absurdity of appealing for help to enlarge hospitals and other charities

which are not working at their full strength. A subscriber who is asked for money to provide more beds for a hospital with twenty or more unoccupied, if he thinks about the matter at all, may give an unexpected but fruitful response.

The autumn session of the Medical Council is for the most part devoted to penal proceedings and this year the sittings continued throughout the week. The cases which were tried were certainly considered by the Council with the greatest care and patience and I have no intention of calling in question any of the verdicts; but I think that some of the proceedings show that this body is not well adapted for judicial proceedings. That all the members are anxious to maintain the purity of the profession goes without saying, but it is just as clear that they are reluctant to pronounce a man guilty of conduct "infamous in a professional respect" without the most ample proof, for that is the only verdict they can find. It appears that the words "in a professional respect" are so restrictive that a person may well escape condemnation for a heinous offense against society, as the Council can only punish if the offense is in the course of professional duty. For this reason I am inclined to think that some of the cases brought before the Council would have been more appropriate for investigation by a court of law. Further, it seems a clumsy arrangement to bring together two dozen distinguished professional men to consider cases which a common jury would be equally capable of trying—not to say even more so. Unqualified practice and other irregularities could also be more rapidly and more effectively dealt with by a smaller body, but the duty has been laid on the Council by the Legislature and has been discharged as well as might have been anticipated with its imperfect authority. The dental department has been more successful because the dental act is a better instrument than the medical acts. The dental societies, too, have given more assistance to the Council than the medical associations. A recent decision of the law courts in a dental case supports the view expressed above and shows, too, that if the Council would suppress quackery it should seek further powers from the legislature. This seems obvious from the proceeding of the last day. A report of a committee was brought up on unqualified practice and contained information as to the provisions for dealing with it in the colonies and foreign countries. It suggested a Royal Commission to inquire into the subject. On the same day the opinion of the Council was said to have been asked by the Privy Council on the anesthetics bill. This bill had been approved by a committee as prohibiting any one who is not a qualified practitioner from administering general anesthetics in medical, surgical, or midwifery cases. These reports were adopted and the president requested to inform the Privy Council of both decisions.

The president of the Pathological Section (R. M. S.), Mr. Shattock, exhibited on the 17th ult. a dilated and hypertrophied bladder with double hydronephrosis from a man who had never had urinary trouble. There was no enlargement of the prostate and a catheter passed easily. He called the case idiopathic in the way we speak of the colon, esophagus, or stomach with similar conditions. He remarked that in the pelvic colon the dilatation usually began soon after birth. In the bladder dilatation had been observed in infancy and in the newly born—an example being in the Hunterian Museum. He spoke only of dilatation without recognizable cause. He suggested that it might be due to incoordination between the contraction of the detrusor and the dilatation of the sphincter. It was also possible that a hypoesthetic state of the mucosa delayed the reflex of micturition until the bladder had become abnormally full. Dr. T. G. Brodie and himself had experimented on a cat and when the mucosa was anesthetized with cocaine, on the bladder being filled with warm salt solution micturition was inhibited and the bladder became markedly distended. This indicates that the reflex of micturition is initiated by the tension of the vesical mucosa, *i.e.* the contraction of the detrusor and the associated dilatation of the sphincter. Whether anesthesia or hypoesthesia of mucous membranes occurred as a hysterical phenomenon might repay investigation.

Professor C. E. Purslow of Birmingham communicated to the obstetrical and gynecological section a case of cancer of the cervix uteri with unusual microscopical appearances. The patient, aged 21, had had one child. She applied with pink vaginal discharge and occasional pains in the back. On examination a fungating growth was detected. It extended more than half round the vaginal portion of the cervix on the right side, was friable, and bled freely when touched. Uterus mobile vaginal hysterectomy was performed. The patient recovered and seemed perfectly well for three months. Then she began to lose weight, gradually got worse, and died thirteen months after the operation. Masses of growth could be felt in the pelvis, but no post mortem was permitted. The microscopic preparations which were made indicated carcinoma.

Yesterday afternoon the War Minister, Mr. Haldane, attended the Westminster Health Society's annual meeting and moved the report. Comparing his own work with the society's, he said the latter did not follow the example of general staff work. People had been asleep as to prevention of disease, though it was more important than cure, but this society was awake and an admirable example of the beginning of wisdom in this region. A notable feature of its wisdom was that its work was undertaken in consultation with and under the direction of the Medical Officer of Health. That marked it out as true public health work. In the second place it limited its object; it aimed at getting into contact with cases before they needed cure; its visiting was directed to the ascertainment of definite conditions, which, if continued, must end in disaster to those concerned. These conditions were observed, reported on, and an organized effort made to remove them. Much more would be heard of these things in the future. The great commission on the Poor Law was coming to a conclusion and their report was looked forward to for guiding legislation. This society was doing what the report might lead to being done on the largest scale by government. It did not send its members to distribute money, but to find out what was necessary. Last year 11,000 visits were paid and in many cases provision made which meant the difference between health and sickness.

The subject of medical inspection of school children has been discussed in the House of Lords, chiefly from its financial aspect. It was pointed out that the act of 1907 laid the duty on the local authorities. The Board of Education issued regulations requiring the Medical Officer to report if the schedules were not properly carried out. It was understood that a substantial grant would be made toward the expenses and the adequacy of the inspection was to be a factor in determining the efficiency of the school and so the amount of its grant. Such a regulation was said to have been *ultra vires*. Moreover, no provision has been made for the cost, which would therefore fall on the rates. For the government it was replied that no special grants were advisable, indeed multiple grants are being done away with as fast as possible. Therefore, the cost must come out of the education rate. The burden on the local authorities had been exaggerated. This seems to imply that the medical inspectors will be squeezed by the local authorities after their usual custom.

Dr. W. A. Elliston, J. P., consulting surgeon to the Ipswich and East Suffolk Hospital, died on the 27th ult. Born in 1840, he qualified in 1862 and took the M.D., Lt. Andrews, in the same year. He was on the active staff of his hospital for about thirty years, retiring as consulting surgeon in 1900. Throughout East Anglia he enjoyed the confidence of his profession and was in constant request as a consultant. He took part in the development of Felixstowe. He also interested himself in medical politics and social reforms. He was for a long time president of the Medical Defense Union and a supporter of the claims of members of the College of Surgeons. In 1890 he was president of the British Medical Association. He delivered addresses on alcohol and on milk and occasionally contributed cases to the journals.

Indications for Radiotherapeutics.—Th. Nogier gives a careful résumé of those cases that may be expected to be relieved or cured by the use of the *x*-rays, and the technique of their use. Among the skin diseases cured are hypertrichosis, trychophytosis, favus, acne, prurigenous dermatoses, eczema when local, and lupus vulgaris. Of neoformations keloids are cured. Sarcomata should be first operated on and then rayed to prevent recurrences. Lymphadeny and leucemia are benefited Cutaneous epithelioma is cured. Deeper cancers may be first operated on and then rayed. Even internal cancers are benefited in relief of pain and inflammatory symptoms. Adenitis of tubercular nature is cured. Neuralgias are relieved. Hemorrhagic fibromata are cured by the production of the premature menopause. Dangers are radiodermatitis, sterilization of ovaries and testicles, and eczematous eruptions in the distribution a nerve that has been too strongly irradiated.—*Lyons Médical.*

Progress of Medical Science.

Boston Medical and Surgical Journal, December 10, 1908.

Use of Tuberculin in Diagnosis.—F. T. Lord concludes that reactions with any one of the three tests, when properly performed, indicate tuberculosis somewhere in the body. It may not be where our clinical data lead us to suspect it, and reactions may occur in the presence of latent, inactive as well as active, foci. This must be constantly in mind in applying the results of the test to individual cases. In patients suspected of tuberculosis, a positive test is only one more factor to be considered in establishing the diagnosis, while a negative test is of much greater value and goes far toward disproving the tuberculous character of the disease in question. Of the three tests, von Pirquet's cutaneous method appears to be quite harmless and reliable. It is probably more delicate than the conjunctival and subcutaneous tests and hence more often responds to latent, inactive and unimportant fooci. So far as can now be judged, the writer holds, there need be no hesitation in its application, but he is personally disinclined to the use of the conjunctival test.

A Clinical Study of the Transmission and Progress of Tuberculosis in Children Through Family Association.—The paper of C. Floyd and H. I. Bowditch is a practical exposition of one of its most significant topics growing out of the modern propaganda against tuberculosis. They discuss influences favoring infection, mode of infection, incidence, other factors influencing infection, infantile and adult types of the disease. Signs and symptoms, various diagnostic means and their relative value and treatment. As their study is based on 1,000 cases, its statistical value is thrown into strong relief and their findings are logically summarized. In order to properly protect the rising generation, the following measures are necessary: (1) Early notification of all births. (2) Better inspection and control of the cities' milk supply. (3) Systematic school inspection. (4) Housing reform. (5) Segregation of advanced cases. (6) Required notification of the disease. (7) Provision for the care of pulmonary tuberculosis in children. (8) Education of all school children on matters of general hygiene.

New York Medical Journal, December 12, 1908.

A New Operation for Hemorrhoids.—C. W. Heitzman reviews the various current operative methods and then describes the following procedure: After the usual preparation of the patient, the tumors are exposed successively and held between the thumb and the finger or with forceps. An incision is then carried in the long axis of the bowel through the mucous membrane, care being taken so as not to wound the blood vessels. The blood vessels being now exposed, they are grasped with forceps and traction applied. This, as a rule, will liberate the vessels, if not, the use of a small, blunt spoon or currette will materially assist in breaking up inflammatory adhesions of the connective tissue. When by this method the hemorrhoidal vessels are thoroughly exposed through the cut in the mucous membrane, a ligature of small-sized catgut is applied above and below. Now the vessels are extirpated with scissors or knife. The incision in the mucous membrane is closed with like suture material. It is found, however, that unless the incision is large it heals just as readily without suturing, being hermetically sealed with blood clot. Should too much redundant tissue remain, it may be removed, carrying the incision in the form of an ellipse and closed as before. It is surprising, however, how much the mucous membrane will shrink after removal of the vessels. The only dressing used is a sterile pad over the anal region. The operation is best performed without the use of sponging, a drip of boric acid solution being employed to keep the field clean. The operation is not applicable to the friable or capillary form, nor to the so-called connective tissue or cutaneous hemorrhoids. It is at once thoroughly surgical as well as simple. Little hemorrhage during the operation and the danger of secondary hemorrhage are reduced to a minimum. It is a comfortable operation for the patient; there is practically no pain. The edges of the wound are thoroughly coaptated, causing prompt healing and the absence of a cicatrix. The cause is removed, not merely a bunch of mucous membrance, as is often the case with other operations.

Sarcoma of the Small Intestines.—J. A. McGlinn has found forty-one cases of intestinal sarcoma on record and gives a comprehensive analysis of them. He adds one personal case; that of an Italian male of 18 years, with the history of gastrointestinal symptoms of one month's duration. In one week the abdomen began to enlarge. A diagnosis of ascitis from tuberculous peritonitis was made and a quart of yellowish white turbid fluid, considered pus, was withdrawn by paracentesis, but the abdominal cavity quickly refilled. At this time he came under the author's care, who performed abdominal secion. A considerable quantity of fluid, probably chylous ascitis escaped. The great omentum hung over the bowel like a red curtain. All the organs seemed symmetrically thickened except the liver, spleen and stomach. The bladder was as large as a seven months' uterus. After the operation the abdomen rapidly refilled and the patient died from asthenia on the tenth day. Microscopical examination of a small bit of tissue removed at the time of operation led to the diagnosis of large, round cell sarcoma. The author has been unable to find a similar case the counterpart of his own.

The Application of Rest and Exercise in the Treatment of Tuberculosis.—This subject is sensibly discussed by F. M. Poltenger. He lays special stress on the necessity of particularizing each case with reference to advice in the matters of rest and exercise, just as much as we would particularize in any disease with powerful drugs. He calls attention to instability of the heart as an early sign of tuberculosis. While at rest, the pulse may not be any quicker than normal, while upon exertion it is markedly accelerated and this feature continues through the disease. In health the pulmonary and systemic circulation balance each other, and the heart works without strain. In pulmonary tuberculosis, on the other hand, an inflammatory process is present, and, according to the extent and the nature of the pathological condition present, the pulmonary circulation is impeded or cut off, and to this extent the right heart is subjected to a greater or lesser strain. At the same time, the heart is incapacitated for withstanding this extra strain by the degeneration which occurs in the heart muscle consequent upon the toxemia and general muscle atrophy, as well as the interference in the nervous mechanism of the organ through the binding down of the vagus in adhesions and in masses of enlarged glands. The heart, then, must always be carefully considered in tuberculosis. It must be spared and strengthened for the great strain to which it is subjected. Early in the disease this care should be instituted, so that the patient may recover, if recovery is possible, with a sound heart. Late in the disease such care is imperative, that the patient may recover at all.

Journal of the American Medical Association, December 12, 1908.

Primary and Secondary Syphilis.—A. Ravogli has found in his treatment of syphilis, that in the malignant forms of primary syphilis, the symptoms are much more precocious, the period of incubation is shortened and the constitutional manifestations are hastened. This he explains by the power of the organism to produce antibodies opposing the invading germs. That this occurs in syphilis has been lately demonstrated; in the serum of syphilitics, products are present which are not found in normal serum. A lack of antibodies prevents a pronounced primary reaction and the unimpeded spirochetes are the more free to invade the whole organism. The idea that syphilis constantly follows the lymphatics to invade the system is no longer tenable, for there are many cases in which the infection is very rapid and can be traced to the extension of the virus through the blood vessels. Ravogli refers to several cases illustrating and confirming his views. The treponema, as Hallopeau and Gaston believe, undergoes changes in the organisms in the different stages of the disease, thus accounting for the different symptoms. The germs can also spread through the tissues by continuity, and this may be facilitated by increased virulence, or accounted for by a lack of resistance in debilitated conditions of the system. If the defensive glands have been injured by previous disease, the infection becomes the more dangerous. On the enfeebled condition of the system, the inability of the organism to produce antigens, and the passive condition of the leucocytes depends the factor of malignant syphilis. External injuries and irritations favor the local lesions in this way. According to the views of Hallopeau and Gaston, the persistency and stubbornness of the papulosquamous syphilides of the palms and soles must be due to the hard, thick skin of the part in the interstices of which the germs propagate, and are in a measure protected from the action of remedial agents in the circulation. It is difficult to foresee whether we will ever find an antisyphilitic vaccine, but in mercury we have a remedy that directly attacks the spirochete, and the recent discovery of the specific action of atoxyl on the disease, has, he believes, added another valuable remedy. Whether it is to replace mercury, or be used in conjunction with it, or whether mercury will still be our main resource, only time and experience will tell.

The Spirocheta and the Treatment of Syphilis.—J. F. Breakey finds a partial answer to the question: What advantage is the discovery of the spirochete to the treat-

ment of syphilis? in the recent work of Metchnikoff showing the prophylactic value of calomel ointment inunctions and atoxyl. If further work demonstrates the truth of the claims of the French investigators as to the prophylactic power of atoxyl, given soon after inoculation, such a fact can be made of practical use in one way at least. If all persons who have been exposed to a possible syphilitic infection were to submit themselves for treatment by prophylactic doses of atoxyl, it would be possible to wipe out the disease. The treatment would have to be instituted, however, before the infection had been generally disseminated and before the finding of the spirochete. In general practice, therefore, all suspicious cases would have to be treated alike, but the treatment with the proper dose of atoxyl is harmless. In case of the established disease, the only change in treatment which could be wrought by the discovery of the infecting organism would be to cause an earlier beginning of constitutional treatment, and this would still be open to the objection of possibly causing an early disappearance of symptoms and the production of a false sense of security, leading the patient to abandon the treatment too soon. Breakey quotes, with approval, the conclusions of Paul Salmon, that arsenic is as much a specific as mercury in syphilis, and more reliable as an abortive. As a remedy it is preferable in all stages, and is of special value in the graver and more malignant forms of the disease. It is not contraindicated in the parasyphilitic manifestations, but even ameliorates many symptoms. Syphilis may be aborted by toxyl administered as late as from one to two weeks afeer inoculation. Small doses are ineffective and useless and too large ones cause toxic symptoms. The ordinary dose should be 50 centigrams (7½ grains), which should be given hypodermically at intervals of one or two days and repeated from four to eight or ten times, after which an interval of rest should be taken, or the treatment continued with mercury or iodine.

Hemolysis and Cancer.—G. W. Crile describes the technique used by him for the determination of hemolysis of normal blood corpuscles by the serum of diseased conditions and *vice versa*. The method is somewhat elaborate, great care being taken to avoid injury to the red corpuscles and properly to control temperature. The normal bloods from several individuals are obtained and tested against each other, as well as against the blood of the patient, to avoid error from any possible abnormality, and all the tubes of the entire test are made up in duplicate and one set subjected to a temperature of 55 C., by which the possibility of error from the presence of inorganic hemolysins can be excluded. Inorganic hemolysins, not being influenced by heat, will thus reveal their presence. The test is made by noting the result of suspending the normal red cells in the patient's serum and suspending the patient's cells in normal serum. The results of a study of nearly six hundred cases are given, attention being directed especially toward the reaction in the normal state, in pyogenic infections, in malignant tumors, in benign tumors and in tuberculosis. No hemolysis was observed in normal cases or in cases of benign tumors. Besides a few reactions in miscellaneous cases, apparently not included in the series, hemolysis occurred seven times in 71 cases of pyogenic infections, 130 times in 153 cancer cases, and 48 times in 52 cases of tuberculosis. It appeared, in all of 11 postoperative cancer cases with clinical recurrence, and in none of 37 cases without clinical recurrence. Extracts of malignant tumors uniformly caused total hemolysis, and the reverse was the case with extracts of benign tumors. All cases of tuberculosis showed reverse hemolysis; that is, normal serum hemolyzed the patients' corpuscles. In all cases, serum heated to 55 C. for ten minutes prevented hemolysis. Sudden chilling of the blood, according to the method of Hoover and Stone, caused a marked increase in the hemolytic action. Plasma, obtained by immediately centrifugalizing the serum, caused little or no hemolysis in hemolytic cases. The hemolytic property reaches its maximum about 24 hours after the blood has been drawn. In the cancer group the patients in whom the disease was entirely removed lost their hemolytic property in from twelve to twenty-one days after operation; in those with incomplete removal it continued indefinitely. Crile concludes that hemolysis occurs in a number of diseases. It occurs with great frequency in cancer and tuberculosis, and its action in tuberculosis is the reverse of that in cancer. Clinically it affords evidence that may be used in the diagnosis of these two diseases, but the evidence is not as yet specific.

Air Infection.—C. V. Chapin questions the importance of air infection as a cause of disease. Bacteria are not readily given off from moist surfaces, and the evidence in regard to their retaining their virulence in a dry state, in the form of air-borne dust, is conflicting and difficult to analyze. Spores, of course, retain their virulence, but it is a fact that our most common spore-bearing pathogenic organism, that of anthrax, seems not to be air-borne. There is no theoretical reason why certain germs known to be resistant to drying, like those of tuberculosis, typhoid and diphtheria, may not be air-borne, but the evidence that they can be carried any distance is not conclusive. Some authorities have maintained the possibility of the air connection of smallpox, but this is contrary to facts as observed in this country. The history of surgery is significant as regards this question; at first, air-borne infection was carefully guarded against by the use of the spray, but later experience has taught surgeons to dispense with this safeguard. A number of facts are given in support of his position and his conclusions are summed up substantially as follows: 1. The theory of transmission of disease was developed as a reasonable way of accounting for the propagation of disease. 2. We now have other and more probable explanations. 3. The best medical thought has been steadily restricting the supposed sphere of aerial transmission. 4. Only a few authorities now claim that disease can be carried by the atmosphere outside of dwellings, and this is asserted only of smallpox. 5. Modern bacteriology teaches that most diseases are not likely to be dust-borne, and that they are spray-borne only for two or three feet, a phenomenon that resembles contact infection more than air infection as ordinarily understood. Tuberculosis is the disease most likely to be thus air-borne. 6. Animal experimentation indicates that tuberculosis may be thus conveyed. 7. Pathology does not assume, as is sometimes alleged, that tuberculosis is an air-borne disease. 8. There is no good clinical evidence that the common diseases are transmitted through the air. 9. There is considerable clinical evidence that scarlet fever, diphtheria, smallpox, measles, whooping cough, typhoid, and plague are not easily transmissible through the atmosphere. If these conclusions are correct, we should, he thinks, abandon aerial transmission as a working hypothesis and give more attention to strict medical asepsis. This he has learned by experience we cannot teach people as long as they believe air to be the chief vehicle of infection. Paris hospital experience has shown that there is little danger in neglecting the aerial factor.

The Lancet, December 5, 1908.

Bacterial Contamination of Milk as Illustrating the Connection Between Flies and Epidemic Diarrhea.—J. T. C. Nash exposed some saucers of milk to flies while other saucers were kept under the same conditions, except that they were covered. Analysis of both five hours later showed that the exposed saucer, in which were found the bodies of two flies, contained millions more of gas-forming bacteria than did the covered specimen. General results thus obtained were confirmed in further experiments. The importance of protecting milk from flies is illustrated by these experiments. It can readily be understood that the larger the number of flies the greater would be the pollution. It is not difficult to realize how in a fly-ridden district diarrheal diseases may be in excess unless care is taken to see that food supplies (especially milk) are protected from the contaminating attentions of flies. The experiments were undertaken on the lines of natural conditions obtaining in houses, so as to include the natural factors of symbiosis or antagonism of bacteria already existing in an ordinary milk supply. The number of putrefactive bacteria in milk is of great importance. The chemical changes produced in milk by, say, thousands of putrefactive bacteria may perhaps not be sufficient to cause serious diarrhea, while the chemical changes produced by millions of such bacteria may conceivably be very prejudicial and excite acute diarrhea. The author says that, as to treatment, the foregoing facts indicate the wisdom of early expulsion of the bacteria and their toxic products by a large dose of castor oil which should, in his judgment, be followed by small doses—say, ten grains—of sulphate of soda every two hours dissolved in sterilized (boiled) water. No food should be given for six or eight hours, and then only sterilized whey, commencing with small quantities, gradually increasing same. The utmost care should be taken that all milk used for artificially fed infants should at all times be scrupulously protected from fly contamination, especially in dealing with an infant suffering from or convalescent from epidemic diarrhea.

Prophylaxis of Acidosis Following Anesthesia.—F. H. Wallace and E. Gillespie analyze the phenomenon occurring in connection with three sets of anesthelized patients. In class 1 (127 cases), 32 showed acetone in the urine before operation and 60 after; 69 had primary vomiting and 49 secondary. In class 2, half-dram doses of sodium bicarbonate were given at four hourly intervals (in all, half an ounce), the last dose four hours before operation. Of the 73 cases thus treated, 15 had acetone before operation and 39 after. Primary vomiting occurred in 49 and secondary in 25. In class 3 the bicarbonate was re-

placed by half an ounce of glucose every four hours for six doses; the last, four hours before operation. Of 100 cases, 3 had acetone before and 22 after operation. There were 53 cases of primary and 21 of secondary vomiting. The anesthetics given during these three series were, with few exceptions, either chloroform or C.E. mixture given on a Skinner's mask, or $CHCl_3$ by Junker's inhaler; 32 per cent. were induced by ethyl chloride. The percentage of acetone after the various anesthetics showed very little change. The author could not determine that the time in hospital previous to operation had any bearing on the subject. The average duration of stay was four days previous to operation. The following previous observations were noted and confirmed: (1) the greater liability of children to symptoms; (2) the frequency in which septic cases, especially abdominal, showed symptoms of acidosis, and (3) the length of anesthesia was not a great factor in the production of acetone. General conclusions are (1) that so far as prophylaxis by drugs, glucose has a much greater power in controlling the acetonuria than sodium bicarbonate; (2) that the secondary vomiting is in direct relation to the amount of acetone produced; (3) anesthetics should be given by an open method; (4) that in all cases of vomiting lasting over 12 hours the stomach should be washed out with a solution of sodium bicarbonate, leaving some fluid in that organ.

Latent Persistence and the Reactivation of Pathogenic Bacteria in the Body.—This is the Horace Dobell lecture for 1908, delivered by L. S. Dudgeon, who considers particularly the pneumococcus gonococcus, Klebs-Loeffler bacillus, *B. proteus, B. coli,* and *B. typhosus.* He refers to recent literature on the bacteriology of normal organs and records certain observations in connection with aseptic wounds in one of the London hospitals. Here antiseptics are not included in the surgical technique, and thus bacteriological investigation can be completed under the most favorable conditions. In these observations of 45 cases treated without chemicals the wound surface was sterile on only 26 occasions and in 15 instances the *staphylococcus albus* was cultivated. The skin cut from the edge of the wound at the conclusion of the operation was found to be sterile six times in the first 45 cases, while on 30 occasions the *Staphylococcus albus* was found to be present. The suture, removed at intervals varying from 24 hours to six days after operation, was found to give a growth of the *Staphylococcus albus* on 30 occasions out of a series of 45. The exudate at the time of the removal of the suture gave a growth of the *Staphylococcus albus* on 18 occasions. There was only one case of suppuration in the whole of this series. We thus see that organisms belonging to the staphylococcic group are of frequent occurrence in wounds which heal without suppuration; their presence, however, but for bacteriological investigations would be unknown. It is more than probable that the existence of these organisms in normal tissues is an important source of suppurative inflammation in the healing of wounds. In regard to the pneumococcus, the cells of the upper air passage form the first line of defense and the pulmonary tissues the second. It may enter through the alimentary canal. It is found in the saliva, nose and tonsillar crypts. The gonococcus may remain in the tissues for an indefinite period without apparently producing any ill effect. The persistence of the Klebs-Loeffler bacillus in apparently healthy throats is well known. The proteus group may remain indefinitely without causing tissue change. Wound infection by it may cause gangrene. The *Bacillus coli* is a normal inhabitant of the intestinal tract. It is often found in the urine without symptoms. Its exact relation to typhoid we do not know. It often causes an acute febrile attack indistinguishable from typhoid except by bacteriological observation. In regard to the *B. typhosus*, it is generally now agreed that by the term "typhoid fever" we are to understand certain chemical phenomena which are due to infection with various microorganisms belonging to the typhoid coli group and not necessarily to the specific microorganism, the typhoid bacillus. This fact serves to explain why acute diseases, regarded as typhoid fever on their clinical manifestations, have failed to give a positive typhoid agglutination reaction at any period of the disease, quite apart from those rare instances of true infection by means of the *Bacillus Typhosus* which also fail to give this reaction.

British Medical Journal, November 28 and December 5, 1908.

Pelvic "Blotches" and the Roentgen Rays.—L. H. Harris refers to certain areas which he has frequently noted in pelvic radiograms, referring to them as "blotches." In his experience they have occurred only in males and they always occupy the same area—namely, a line drawn from the spine of the ischium to the symphysis pubis. They may be bilateral or unilateral, and vary in size from a hempseed to a broad bean. It seems most probable that these shadows are cast by calcareous deposits in the vesiculæ seminales, and in a recent case such deposits could be distinctly palpated on making a rectal examination on a case in which these pelvic "blotches" appeared. Frequently such deposits have been found post mortem in the vesiculæ seminales surrounding a cystic dilatation. These shadows might easily be mistaken for vesical calculi, and no doubt have very often been interpreted as such. Such a mistake may be avoided by remembering the constant position of these "blotches," and also the fact that generally vesical calculi occupy a central position.

Rheumatic Origin of Certain Serous Inflammations.—Eustace Smith denies that rheumatic lesions are limited to the pericardium alone, among the serous membranes. He relates the history of appendicitis in a child, with an intercurrent heat murmur. Salicylates promptly cleaned up the abdominal symptoms though the murmur continued. Abdominal illnesses of rheumatic origin may take the shape of a severe general peritonitis and the history of one case is given in which the cause was considered to be rheumatic. A young man with an attack of general peritonitis of apparently the most virulent character was given the salicylates and the whole aspect of the case changed with unlooked-for rapidity. To the author's mind these cases (of which we have mentioned the bare outlines) furnish evidence which cannot be lightly dismissed as to the nature of some attacks of serous inflammation in the abdomen, and suggest, at any rate, the possibility that these may at times have a rheumatic origin. If this be granted, it is advisable, he says, in all cases of appendicitis to begin the treatment with a few substantial doses of the salicylate of sodium, for the rheumatic element cannot be excluded until the result of treatment by this remedy has been ascertained. He has seen many cases of appendicitis in which the question of operation was being considered which underwent such rapid improvement under antirheumatic treatment that all idea of surgical interference was quickly set aside. If the treatment fail—that is, if no improvement be noticed within thirty-six hours of taking the first dose of the salicylate (which should be of substantial quantity and given every three hours)—the assumption of a rheumatic origin for the inflammation may be definitely abandoned.

Abdominal Auscultation as an Aid in Diagnosis.—A. F. Hertz claims that we have in abdominal auscultation a means by which the rate of passage of the contents of the small intestine from the stomach to the cecum can be measured and describes his experience in listening over the cecum while at the same time an *x*-ray examination (the patient having taken bismuth) was made of the abdomen. It was found that the appearance of a shadow in the cecum immediately followed the occurrence of the earliest sounds in the right iliac fossa. In those investigations in which auscultation was practiced without skiagraphy, the first cecal sounds were always heard at about the time that *x*-ray observations had previously shown that the first traces of the food would reach the cecum. Auscultation may therefore take the place of skiagraphy when the latter cannot for any reason be used, in the diagnosis of the rare cases in which constipation is due in part to the slow passage of food through the small intestine. The sounds heard over the cecum are in all probability due to the actual entry of the fluid contents of the ileum into the gas-containing cecum. Their loudness varies considerably in different individuals. When, five or six hours after a meal, the gas is largely replaced by fecal material, the sounds diminish in intensity and become less continuous. At all times they are louder in the upright than in the horizontal position, but for the first few seconds after lying down the sounds are generally loud and almost continuous, owing probably to the movements of the fluid contents produced by the action of gravity.

Bee Stings and Rheumatism.—E. T. Burton presents another letter on this subject and gives the histories of four cases, all of which showed distinct improvement under the stinging treatment. He adds certain practical points regarding the management of the bees, and has even devised a spring forceps with which to hold the insect while it is stinging. The insect is held close to the affected area and a very little pressure will make it sting. In spite of some ridicule, which has been thrown on the procedure, the author declares that every day impresses him more and more with the practical value of this therapy.

A Case of Osteitis Deformans.—S. White reports the case, an excellent photograph of which is added. The patient was a man 59 years of age and of good habits. He denied specific disease. Symptoms apparently began soon after his twentieth year. A full anatomical description of the patient is given and the author passes on to a general discussion of the malady. Very little information

concerning it has appeared since the original description by Paget (after whom the disease is sometimes named) in 1877. This authority regarded it as first, a rarefying osteitis, particularly of the compact bone, and second, the formation of new bone from the periosteum. Paget thought there might be some relationship between this disease and cancer, but analysis of recorded cases does not support this view. Some 100 cases have been reported in the last thirty years. The course is slow, and in the majority of recorded cases the disease does not seem to have shortened life materially. There is no evidence that any plan of treatment hitherto followed has been of any avail.

Some of the Effects of Excessive Smoking.—Nothing new is presented in the paper of J. D. Mann, whose statements are temperate and based on accurate clinical investigation. He describes the familiar cardiac disorders following tobacco excess. He says that it is obvious that with all physiologically active substances the qestion of degree is largely determinative of the results produced by any agency that is capable of affecting the health. Most men, if they choose to smoke, can do so within certain limits without injuring their health; some men can exceed such limits with apparent impunity. The extent of the limitation must be determined by each man for himself, and if he is wise he well keep well within the border-line and will hold to his resolution. Here lies the difficulty; the growth of a habit overrides discretion. The habit of excessive smoking is more insidious in its development than that of excessive drinking, for the results are much less obvious. An alcoholic may be appealed to by his friends or admonished by those in authority; this rarely happens to the adult smoker, unless he consults his doctor about "indigestion and palpitation" and admits that he smokes to excess; then probably the necessary warning will be given.

Physiology of the Fallopian Tube.—J. T. Shirlan says that there are no glands as such in the tube, but glands are, after all, but involutions of a secreting surface in order to increase that surface, and the remarkable foldings of the tubal mucosa may be looked upon as glands, the increased surface of the membrane being brought about by elevation instead of depression. We cannot draw any certain distinction between the epithelial cells of mucous membranes and so-called gland cells. As covering surfaces, they might all be called epithelial cells, and they all probably separate definite materials from the blood. Experiments on rabbits and guinea-pigs have, the author thinks, proved conclusively that there is tubal secretion. No mucus has ever been found in either menstrual or non-menstrual tubes. In studying the act of secretion, one finds that in some cases the cells give up the substances they have eliminated by rupture or deliquescence; while in others there are no signs whatsoever of any changes in the cells, and it is then that the secretion is more liquid, containing very little solid matter, or having it in a state of such perfect solution as to be capable of easy transudation. It appears to the author that the Fallopian secretion is of this second variety, the fluid being clear and watery. The fluid contains albumen, considerable sodium chloride with traces of calcium, phosphorus, and potassium, and is faintly alkaline. Such conditions favor the vigor of the spermatozoa and ova. It is exceedingly probable that the tubal mucosa is continuously moistened by a small quantity of fluid which is poured forth more abundantly during physiological excitement such as the passage of the ovum. The ampulla is the widest part of the tube and its plicæ are more numerous and more folded than in any other part. There is thus a "well" of saline fluid ready to receive the ovum, which in passing through the ostium abdominale sets up a peristaltic contraction of the muscular coat, and closes this orifice. A current is created in the fluid by ciliary motion, and the ovum is swirled along like a cork in a stream towards the uterus. It is absurd to imagine that delicate protoplasmic processes like cilia propel the ovum by direct contact—the cilia of other mucous membranes propel fluids—not bodies. The probability is that when a pregnant ovum remains in the tube, this occurrence is due to one of two things or to a combination of the two: either there has been too little secretion, or there has been a diminution in the lashing movements of the cilia, from a previous salpingitis.

Berliner klinische Wochenschrift, November 30, 1908.

Gastric Ulcer.—Klapp reports a case of ulcer situated in the posterior wall of the stomach and perforated into the pancreas. Clinically, the picture was that of carcinoma, the patient being cachectic and the stomach contents alkaline; no vomiting of blood had occurred. The ulcer was reached from the left outer side, the spleen being removed to allow free access. The operation resulted in the loss of some pancreatic substance and the gland had to be sutured. The ulcer itself was excised. The patient recovered completely though slowly. Klapp thinks this is the first case in which extirpation of the spleen was necessary to reach a gastric ulcer and considers that the loss of this organ is fully repaid by the access to the operative field thus obtained.

Paralysis of Crural Nerves After Operation.—Kurt Mendel and Wolff call attention to the fact that paralysis of the nerves of the lower extremities because of prolonged pressure or stretching during an operation is very much rarer than the same accident with the nerves of the brachial plexus. Only four cases of such paralysis of the crural nerve have been described. They report another case, bilateral paralysis of both nerves having followed a gynecological operation that lasted an hour and a half; the patient's thighs were flexed and abducted during this time. The authors think that the possibility of such an accident should lead to as much care in protecting the nerves of the lower extremities during an operation as is usually exercised in regard to the brachial plexus and its branches.

Deutsche medizinische Wochenschrift, November 26, 1908.

Treatment of General Burns.—Pels-Leusden says that the general symptoms are the most important in burns of any extent. Such symptoms may originate in the brain, in the heart, or in the kidneys. It is possible that the effect of heat upon the skin results in the development of toxins, which affect the general system of the patient. The heart is usually weak and fast, the vessel tone diminished, the temperature may fall and hemolysis may take place. To meet these conditions intravenous injections of heart stimulants may have to be used, and much fluid should be administered to the patients by the mouth and per rectum. There is no contraindication to the use of opiates, for the intense suffering of the patient has a very bad effect upon his condition and must be relieved. The best treatment for the local lesion is that of Tschmarke and consists of cleaning the burned areas as thoroughly as is done for a surgical operation. As a rule either local or general anesthesia is required to accomplish this, the pain being intense. The surface is then covered with abundant layer of gauze, the upper layers of which have to be frequently changed because of the secretion from the wounds. Such cleaning of the burned surface prevents the death of small portions of epithelium lining the glands because infection is prevented and these islands of epithelium become the starting points for the growth of new skin. If infection of burned areas has occurred alcohol compresses and then incision and evacution of pus is indicated. The contractures that often remain after severe burns must he treated by plastic surgical procedures.

Phonometry.—Schlesinger describes under this name a new method of determining the borders of organs. He makes use of a phonendoscope and a tuning fork. The results are exact enough to give very well the differences of heart limits in the various phases of respiration, röntgenological examination showing the same results. The method, too, allows of exact determination of the limits of the lung apices, and may be used to show the presence of very small subpleural foci of tubercular infiltration. The upper border of liver dullness is very exactly determined by the use of the same appliances.

Inflammatory Tumors of the Mesentery.—Haberern says that such tumors usually appear from several weeks to several years after laparotomies and are very difficult to differentiate from real neoplasms. Being inflammatory in character they become quickly adherent to the surrounding structures and are difficult to remove on this account. Haberern reports a case of such a tumor, which proved inaccessible to operative removal, but suppurated in its interior and gradually disappeared after drainage was instituted. Histological examination showed granulation and scar tissue without any sign of malignancy. Such tumors most often follow operations for hernia, the mesentery being exposed to much trauma or infection in these procedures. Operative treatment is but rarely necessary, as resorption of the granulation tissue takes place under usual antiphlogistic measures with the internal administration of potassium iodide. The prophylaxis consists in careful asepsis and in putting any sutures or ligatures necessary in operations for hernia into healthy mesentery and not into inflamed portions of it.

Elimination of Uric Acid in Children.—E. Modigliani gives the results of his estimations of the elimination of uric acid in well and sick children, fed on a diet of milk and bread, and kept in bed during the time of estimation. The elimination varies with body weight in well children, the limits being from 0.61 to 0.168 gr. in children from two to six years of age. In sick children it varies between 0.062 and 0.300.—*Rivista di Clinica Pediatrica.*

Book Reviews.

Genitourinary Diseases and Syphilis. By Edgar G. Ballenger, M.D., Lecturer on Genitourinary Diseases, Syphilis and Uranalysis, Atlanta School of Medicine; Surgeon to Presbyterian Hospital, Atlanta, Ga. Atlanta, Ga.: E. W. Allen & Co., 1908.

The author asserts that this book is for the medical student, and thinks it "may prove of value to the general practitioner." In reality the genitourinary specialist can read it with pleasure and profit. True, it here and there contains a point to which exception might be taken, but considering that in 259 pages the author condenses the essentials of urogenital affections and syphilis, they cannot be covered otherwise than in a somewhat conspectus-like manner. It is regrettable that many of the 86 illustrations are rather crude. The text certainly warrants better drawings. Nevertheless, the very crudities of some of the pictures serve to assist the student, especially in differentiation, as, for instance, between gonococcus and pseudogonococcus. The index of 12 pages could most satisfactorily be elaborated to the advantage of the book and the convenience of the reader. The author describes a method of aborting gonorrhea which consists of injecting an organic silver preparation, which he causes to be retained from two to four hours, by sealing the meatus with zinc oxide adhesive plaster. It is singular that a writer so precise as Ballenger should attribute an old form of the Valentine urethroscope to Fowler. In a short, admirable chapter on bacterins, the author gives a conspectus of the present knowledge regarding the treatment of gonorrhea with opsonins; he is in advance of many in having obtained success therewith in acute gonorrhea, although he recommends daily irrigations, etc., to supplement the vaccine treatment. Barely a page of the work can be read without finding at least one instructive and interesting point. The experienced teacher, the skilled genitourologist, and the learned syphilographer is revealed in every line.

Lehrbuch der Specifischen Diagnostik und Therapie der Tuberculose. Für Ärzte und Studierende. Von Dr. Bandelier, Oberarzt der Dr. Weickerschen Lungenheilanstalt in Görbersdorf; und Dr. Roepke, Dirigierendem Ärzte der Eisenbahnheilstätte in Melsungen. Zweite erweiterte und verbesserte Auflage. Mit 19 Temperaturkurven auf 5 lithographischen Tafeln, 1 farb. lith. Tafel und 4 Textabbildungen. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1908.

The renewed interest in the treatment of tuberculosis by means of the various tuberculins is shown by the demand for a new edition of this monograph within nine months after its first appearance. The book has been improved by the addition of much matter dealing with the recently introduced local tests for tuberculosis and of a colored plate giving the results of positive cutaneous and ophthalmic reactions in tuberculosis. Questions of technique are considered at length and the volume is in general well adapted to the practical needs of physicians. American readers who do not read German are informed that an English translation has been prepared.

Chronischer Magenkatarrh. Von Hofrath Dr. F. Crämer. Munich: J. F. Lehmann, 1908.

The present monograph on chronic gastric catarrh gives a detailed description of this prevalent malady. The acid gastric catarrh met with especially in people using tobacco and alcohol is fully discussed. In the way of treatment the author recommends lavage, a prolonged, strict diet, and a hygienic mode of living. The practitioner will derive much profit from the perusal of the book.

Modern Medicine. Its Theory and Practice. In original Contributions by American and Foreign Authors. Edited by William Osler, M.D., Regius Professor of Medicine in Oxford University, England; formerly Professor of Medicine in Johns Hopkins University, Baltimore; in the University of Pennsylvania, Philadelphia, and in McGill University, Montreal. Assisted by Thomas McCrea, M.D., Associate Professor of Medicine and Clinical Therapeutics in Johns Hopkins University, Baltimore. In seven octavo volumes of about 900 pages each, illustrated. Volume IV. Philadelphia and New York: Lea & Febiger, 1908.

This fourth volume of Modern Medicine treats of diseases of the circulatory system, of the blood, and of the spleen, thymus, and lymph glands. The senior editor contributes the chapters on Acute Endocarditis, Diseases of the Valves of the Heart (with Dr. A. G. Gibson); Diseases of the Arteries and Aneurysm. Diseases of the Lymphatic Vessels and Glands, and of the Thymus constitute three excellent chapters from the pen of Dr. Alfred Scott Warthin of Ann Arbor. Dr. Alexander G. Gibson writes on Hypertrophy of the Heart, Insufficiency and Dilatation, and (with Dr. Osler) Diseases of the Valves of the Heart. Dr. Charles F. Hoover contributes a chapter on General Considerations in Cardiovascular Disease, and on Functional Diseases of the Heart. Dr. A. McPhedran writes on Diseases of the Pericardium, and Dr. Robert H. Babcock on Diseases of the Myocardium. The other contributors are Dr. Maude E. Abbott, on Congenital Cardiac Disease; Dr. George Blumer, on Thrombosis, Embolism, Phlebitis; Dr. Richard C. Cabot, on General Pathology of Blood-Forming Organs and Pernicious and Secondary Anemia, Chlorosis, and Leukemia; Dr. Joseph H. Pratt, on Purpura and Hemophilia, and Dr. Irving Phillips Lyon, on Diseases of the Spleen. This is one of the most interesting volumes of the series thus far published, not only because of the importance of the subjects treated, but also by reason of the excellent manner in which the subjects have been handled by the contributors. As a treatise on diseases of the heart and vessels and of the blood this volume will compare most favorably with any published.

Die Lehre von der Kongenitalen Tuberculose. Mit besonderer Berücksichtigung der Placentartuberculose. Von Dr. Anton Sitzenfrey, I. Assistenten der Universitätsfrauenklinik und Privatdozenten für Geburtshilfe und Gynäkologie an der Universität in Giessen. Mit 28 in den Text gedruckten Abbildungen. Berlin: Verlag von S. Karger, 1908.

The author had an exceptional opportunity of observing a number of cases of childbirth in tuberculous women, to examine the placentæ and to follow the fate of many of the children. This has enabled him to present a very interesting study of congenital tuberculosis, illustrated by fine pictures of tuberculous infection of the placental and uterine tissues. He has rounded out his own observations by the consideration of the theories and the experimental work done by other workers on the subject; in addition, he gives a selected bibliography of 190 numbers. The book is well worth the attention of pathologists as well as of practising physicians.

Die Placenta Marginata und Ihre Enstehung. Von Dr. P. Sfameni, Professor und Director der Universitätsfrauenklinik in Perugia. Mit 11 Abbildungen im Text. Berlin: Verlag von S. Karger, 1908.

This monograph considers the anatomy of the placenta marginata, its clinical features and the various theories proposed for the explanation of its formation. The author then states his own view of the matter, according to which the anomaly is caused by disturbed relation between the forces exerted by the growing ovum and the growing uterus. A bibliography of the subject accompanies the volume.

The Handy Reference Handbook of the Diseases of the Skin. By George Thomas Jackson, M.D., Professor of Dermatology, College of Physicians and Surgeons, New York: Consulting Dermatologist to the Presbyterian Hospital, New York, and to the New York Infirmary for Women and Children; Member of the American Dermatological Association and of the New York Dermatological Society. With 99 illustrations and 4 plates. Sixth edition, thoroughly revised. New York and Philadelphia: Lea & Febiger, 1908.

The new edition of this well-known textbook is increased in size by the addition of articles upon several rare lesions of the skin and by the revision of the sections on pathology in the older articles. The alphabetical arrangement has been retained, each name being followed by an extensive list of synonyms that enhance the value of the book for reference purposes and, at the same time, give evidence of the sad lack of uniformity in the nomenclature of the diseases of the skin. The individual articles are surprisingly complete for the size of the book; comparison with more pretentious volumes on dermatology shows that nothing essential has been left out. The book is heartily recommended to students of medicine as well as to practitioners.

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Second Series. Vol. XIII. Periodicity, Prussia. Washington: Government Printing Office, 1908.

Among the important titles in this volume are Peritonitis, Pharmacy, Physiology, Pleurisy, Pneumonia, Pregnancy, and Prostate. Besides the catalogue the volume contains a supplementary list of abbreviations of titles of medical periodicals, the original list having appeared in Vol. IX, additions to the same being published in each volume since. This volume includes 7,678 subject-titles of separate books and pamphlets and 40,221 titles of articles in periodicals, in addition to 5,566 author titles. The entire library contains 165,342 bound volumes and 291,346 pamphlets. The catalogue is edited by Major W. D. McCaw, U.S.A.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 3, 1908.

DR. JOHN A. WYETH IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Ophthalmology. The topic for discussion was "The Diseases of the Eye and Orbit Depending on Diseases of the Accessory Sinuses."

The Anatomical Relations of the Orbit to the Accessory Sinuses of the Nose.—Dr. GEORGE S. DIXON read this paper, illustrating it with lantern slides. The bony cavities of the orbits, he said, were somewhat pyramidal in form with their apices behind. The inner walls were approximately parallel, but the others diverged so that the orbital axes were separated in front by about 60 mm. while they coverged to about 35 mm. behind. The depth from base to apex was about 47 mm. in the average adult. The base or outer margins measured about 35 mm. in diameter, and were somewhat quadrilateral in form. The capacity of each orbit was about 24 cc. The roof was arched, and presented the optic foramen behind, the fossa for the lacrymal gland in front, the supraorbital notch or foramen, and a depression for the attachment of the pulley for the superior oblique muscle. The lower wall or floor was directed downward and outward, and presented a groove behind converted into a canal in front for the passage of the infraorbital nerve and artery. The inner wall presented anteriorly the lacrymal groove for the lacrymal sac. The lacrymal sac was continuous with the nasal duct and communicated with the inferior meatus of the nose. The anterior and posterior ethmoidal foramina were found in the upper margin of the inner wall. Surgically the outer wall was least important of all. The orbit with its contents was in close relation with the frontal sinus above, the ethmoidal cells and sphenoidal sinus internally, the maxillary antrum below, and was in communication with the inferior meatus of the nose through the nasal duct, and that inflammation and suppuration in any of these cavities were liable to involve the orbital contents. The maxillary antrum, or antrum of Highmore, was the largest of all the accessory sinuses of the nose, and it might be described as the triangular, pyramidal cavity in each superior maxillary bone, with its base directed toward the nose and its apex toward the malar bone. It varied greatly in size and form in different individuals; the ordinary capacity of each cavity in the dried bone was about 16 cc. The walls were thin, especially the inner or nasal. As the size of the cavity increased the thickness of the walls decreased. Not infrequently thin vertical plates of bone crossed the sinus below and interfered with drainage. So-called dental cysts might protrude into the cavity, with which they might or might not communicate, and one or more bicuspid or molar teeth were likely to enter the sinus. The roof of the antrum was very thin. The ethmoidal cells were composed of a mass of thin-walled cavities. The anterior and middle set of cells drained into the middle meatus, and the posterior set into the superior meatus of the nose. The sphenoidal sinus varied greatly in size and form, and in the dried bone it had a capacity of about 13 c.c. The frontal sinus had the distinction of being even more erratic than the others, and it had been impossible to reach anything like the limit of size, form, and location. All of these cells or sinuses were lined with mucous membrane continuous with that of the nose. The orbital contents received their blood supply through twelve branches from the ophthalmic branch of the internal carotid, and from the infraorbital branch of the internal maxillary artery. The frontal sinus received its supply from the anterior ethmoidal and supraorbital branches of the ophthalmic artery. The maxillary antrum was supplied by branches given off from the infraorbital artery, and sphenopalatine branches of the internal maxillary artery. The sphenoidal sinus was supplied by the external branch of the sphenopalatine. The venous circulation was through the vessels returning principally in the course of arteries supplying the parts. There was no direct communication between the orbit and accessory sinuses of the nose if one made an exception of the lacrymonasal duct. Indirect communication occurred between the orbit and ethmoidal cells through the anterior and posterior vessels, and between the orbit and the maxillary antrum by way of vessels passing between these two cavities through the floor of the orbit. A limited amount of tissue separated the accessory sinuses from the orbital contents. Nature was inclined to be protective always and in the majority of cases barred progress in the direction of the orbit by inflammatory thickening until pressure and necrosis overcame the temporarily increased resistance.

Ocular Complications of Nasal Sinus Disease.—Dr. ARNOLD KNAPP said that the most striking and probably the best known orbital complication of nasal sinus disease was the one due to a dilatation of the sinus without inflammatory signs, the so-called mucocele, which caused a mechanical displacement of the orbital contents. The eyeball was generally involved. The distention which the sinus underwent was associated with a rarefaction of the bone. The only treatment was operation; this was usually simple, consisting in the removal of the lower wall of the frontal sinus and of the entire ethmoidal labyrinth, thus permitting free drainage into the nose. Inflammation of the sinuses was associated with external or orbital inflammatory signs whenever the inflammation invaded the intervening bony wall. In mild cases there was no macroscopic change in the bone but a periostitis was present over the floor of the frontal sinus with swelling and redness of the eyelid or over the ethmoidal os planum, causing exophthalmos. This condition might resolve of itself or yield to intranasal treatment. The orbital contents were generally not involved in these cases beyond slight venous congestion at the optic disc. Subperiosteal abscesses were not infrequent in children, the infection being transmitted by the ethmoid labyrinth. In operating on these cases a curved incision was made along the inner orbital margin and on retracting the periosteum the small collection of pus would be encountered between the periosteum and the bone and usually a small irregular defect in the os planum. The opening in the bone should be slightly enlarged and the contiguous ethmoidal cells curetted. If the orbital periosteum was invaded involvement of the orbital structures resulted, either cellulitis or abscess. The important part played by nasal sinusitis in producing orbital cellulitis and abscess had only been recognized within the last few years. Under these circumstances the usually practiced blind incisions into the orbital cavity were not surgical; treatment should be based on the lines of the orbital operation for nasal sinus empyema. There should be broad exposure by an incision along the orbital margin, careful inspection of the orbital walls, and proper drainage according to the individual case. The reader of the paper was of the opinion that the importance of the maxillary antrum in causing orbital complications had been exaggerated. An important group of ocular complications of nasal sinus disease was that involving the optic nerve. The recent investigations of Onodi had shown that the optic nerve was frequently in close relation to the posterior ethmoidal cells and that the extreme thinness of the intervening wall made the involvement more likely than in the case of the sphenoid. It was of special interest that the optic nerve was involved in the form known as retrobulbar neuritis in which a central scotoma was the charactertistic functional defect. The prognosis of these cases was excellent and now that ophthalmological attention had been focused on this interdependence of the nose and eye, some of the hitherto obscure cases of acute retrobulbar neuritis would be recognized and nasal treatment promptly instituted. Ocular paralyses were not infrequently the only manifestations of

orbital complications. Neuralgia, especially ciliary and retrobulbar, was frequently due to sinus affections and asthenopia was a common symptom. According to Kuhnt muscular asthenopia, accommodative asthenopia, and contractions of the visual field were the functional disturbances observed in nasal empyema in the order of their frequency. There was a group of eye affections comprising iridochoroiditis, glaucoma, and detachment of the retina, with which certain authors had brought sinus disease in etiological relation. This was a subject upon which we required additional information. Kuhnt had stated that he had never seen a case of iritis or choroditis caused by sinus disease, but thought that cyclitis, especially the form chiefly characterized by opacities of the vitreous, could depend on this cause. He had never observed glaucoma to be caused by nasal disease, but believed that in predisposed eyes an attack might be brought on by a sinus affection. The reported cases of detachment of the retina associated with nasal sinus disease were not convincing. He felt sure that the list of ocular disturbances which could be produced by sinus affections was not exhausted and that there was a great deal of careful work still to be done.

The Diseases of the Eye and Orbit Depending on Diseases of the Accessory Nasal Sinuses.—Dr. C. G. Coakley presented this paper in which he discussed the diseases involving each of the sinuses and the diseases of the orbit liable to be produced by them. He first took up the maxillary sinus and discussed suppurative inflammation. He said that infections that caused suppuration reached this sinus through the nose, the ethmoidal cells, and as a result of dental or periodental suppurations. Orbital disease as the result of disease of the maxillary sinus was rather rare. He thought that this was accounted for from the fact that in the neighborhood of the ostium maxillare the nasoantral wall was extremely thin and oftentimes for an area of a cm. was void of any bony support. Consequently secretions from the antrum when held under moderate tension and pressure found their way into the nasal cavity through this thin wall. If this outlet was obstructed by deflected septum, polypi, or other neoplasms the secretion from the antrum might rupture through into the floor of the orbit, thus causing an infective orbital cellulitis. Dentigerous cysts might grow to enormous size and by pressure absorb the bony walls of the antrum, not only the anterior but also the superior, producing a displacement of the orbital contents upward, outward, or forward, according to the portion of the floor of the orbit that was absorbed. When small, these cysts might give rise to neuralgic pains, but when they grew larger there was also a bulging of the anterior wall of the maxillary sinus or the displacement of the globe of the eye in addition to the neuralgia. The contents of the cyst were invariably sterile while the cyst wall was intact. If the cyst became infected either as the result of spontaneous rupture or surgical interference serious orbital cellulitis might arise. Malignant disease of the antrum, although rather rare, might extend to and involve the contents of the orbit either directly from the antrum or indirectly through the ethmoidal labyrinth. Secondly, in disease of the frontal sinus the relation to the orbit was one which resulted in more frequent complications to the orbital contents. If there was suppurative inflammation of the frontal sinus and, for any reason the nasofrontal duct was obstructed, either from tortuosities or enormous swelling of the lining membrance of the canal, or from the presence within the nose of the various pathological conditions such as were mentioned as causing obstruction to the ostium maxillare the secretion under pressure sought an outlet along the lines of least resistance. In case of perforation of the floor of the frontal sinus, two classes of phenomena might be observed. In acute cases, the infected pus might burst through the bone and periosteum and infect the loose cellular tissue of the orbit and a general orbital cellulitis, with sudden oedema and redness of the lids would ensue in the course of a few hours with complete inability to separate the lids, and displacement of the globe of the eye. In the less acute type there was a gradual and progressive bulging of the floor of the orbit with less acute ocular symptoms. The bulging and fistula might occur anywhere along the entire orbital arch from the inner to the outer end. The globe might consequently be displaced in various directions. The diagnosis of acute or chronic involvement of the frontal sinus was comparatively easy with the aids of modern diagnosis available. In a large proportion of the cases the nasofrontal duct was partially patent and the presence of a certain amount of pus in the nose directed the attention of the rhinologist to suppuration in some of the accessory sinuses. In the acute cases the extreme tenderness of the bone of the affected side and the appearance of swelling below the supraorbital arch made it probable that the frontal sinus was affected. In these cases a good skiagraph was a most valuable aid. He had seen some cases, however, where there was such evident involvement of the frontal sinus, accompanied by such manifest orbital cellulitis, that it did not seem advisable to delay operating until a skiagraph could be made. Thirdly, he considered the ethmoidal cells. This region, if diseased, was much more liable to involve the orbit than either the maxillary or the frontal sinuses. Orbital cellulitis occurred more frequently as a result of ethmoidal disease than it did from disease of the frontal sinus. It was very difficult in some instances to differentiate the source of an orbital cellulitis, whether from the frontal, ethmoidal or sphenoidal sinuses. In the severer types of involvement it was seldom that one group of sinuses alone was involved, there was usually a combination and sometimes all of them were involved. The surgeon in operating should invariably investigate all three sinuses, and if they were found diseased, perform a radical operation. Cysts of the ethmoidal region were not uncommon and might result in tumor-like masses which invaded the orbit in various places. Fourthly, Dr. Coakley considered thrombosis of the orbital veins. This thrombosis might involve only a portion of the veins of the orbit or it might involve all the veins and extend backward into the circular sinus. If the thrombus was an infected one a portion might get into the general circulation and all of the symptoms of pyemia develop. If the thrombus was not infected, organization of the clot might occur and the circulation be reestablished. Fifthly, the sphenoidal sinus was considered. This sinus varied greatly in its position in reference to the apex of the orbit. If the sinus was large it might partially or completely encircle the optic nerve as it passed through the foramen. There was a large class of cases of ethmoidal and sphenoidal disease falling under the observation of the rhinologist without any involvement of the optic nerve. In the absence of any visible secretion or any appearance of local inflammatory in the posterior portion of the nares as compared with the anterior portion, the diagnosis of sphenoethmoiditis was difficult. There was no way of satisfactorily detecting the condition of the sphenoid and posterior ethmoid cells without, in a large proportion of cases, removing the entire middle turbinate. Then unless the septum was very markedly deflected the anterior wall of the body of the sphenoid came into view and one might enlarge considerably the sphenoidal opening and the posterior ethmoids so as to inspect the interior. In operating there were two difficulties to contend with, first, the fact that many patients complained of considerable pain even when thoroughly cocainized, so that it was impossible at a single sitting to do all that was necessary and secondly, that in spite of the use of suprarenal extracts the bleeding was often so great as to prevent one getting a proper view of the operative field. If this happened the surgeon would find it impracticable to perform any further surgical work on the patient for a period of about two weeks. From a study of nineteen cases referred to him for retrobulbar neuritis he found that only three of them showed any condition as a result of nasal examination that would make

one suspect any disease of the sphenoid or ethmoid. When operated upon these cases had large sphenoid and ethmoid cavities, the mucous membrane was edematous and considerable secretion existed in the cavities. One case was totally blind in one eye and within a few weeks after operation recovered almost perfect sight. A second case that could barely distinguish light made an almost perfect recovery. A third case was totally blind and had made a perfect recovery. Ten patients with retrobulbar neuritis had their middle turbinates removed and their sphenoidal and ethmoidal cavities opened without finding any disease.

Dr. William C. Posey of Philadelphia said that in recent years an ocular symptomatology of sinusitis had been evolved, which was incomplete by reason of the lack, in nearly all instances, of pathological evidence to prove the dependence of diseases of the eye and orbit upon conditions within the sinuses; nevertheless the changes in the eye caused by sinusitis had been observed by so many writers that it might be said to be now fairly well established. Ophthalmologists realized that the treatment of abscess of the orbit demanded that not only should the pus be liberated from the orbit, but that the origin of the abscess be detected and if possible removed. The question had arisen as to whether this field belonged to the ophthalmologist or to the rhinologist. The proper person was one who combined both ophthalmology and rhinology in his practice, but this association was falling into disuse. He urged upon the ophthalmologist the desirability of a more intimate knowledge of the anatomy and diseases of the sinuses and insisted upon the treatment of these complications by ophthalmologists, or at least in their presence and with their counsel. He did not intend, however, that the rhinologist should be supplanted in the general treatment of sinsusitis. The interest of the ophthalmic surgeon in this branch of surgery had already borne fruit, for the operation devised by Knapp for opening the frontal sinus accomplished all that the Killian procedure designed with less deformity and with conservation of the function of the superior oblique muscle. The involvement of the optic nerve as a consequence of ethmoidal and sphenoidal sinusitis might vary in degree from a simple edema to an active retrobulbar inflammation. As a rule the patient complained of some dimness of vision in one eye, at times of vertigo, headache, and other head symptoms. The ophthalmoscope usually showed the unaffected eye to be normal, while in the fellow eye a slight veiling of the nerves at the edges was seen, with a dilatation of the retinal veins and a choking of the lymphatics around the central vessels. In cases of only slight involvement the patient was usually conscious of dimness in the affected eye. There was a normal vision for form, but a diminution of the light sense. A chief characteristic of neuritis due solely to sinus inflammation was its unilateral character, for although both nerves might be affected in the optic canal by inflammation of both sphenoidal sinuses, such cases were very rare. He referred at length to the changes in the optic nerve from sinusitis as set forth by Birch-Hirschfeld. The speaker and Dr. Packard had treated a number of cases in common and Dr. Packard had summarized his observations from the standpoint of the rhinologist as follows: There were several classes into which cases of ophthalmic disease, resulting from intranasal trouble or disease of the accessory sinuses, might be divided. (1.) Cases of direct extension of suppuration. These cases generally had a long history of intranasal or sinus trouble, as the escape of pus into the orbit was due to necrosis of the bony wall of the involved sinus. (2.) There was a large class of cases in which eye symptoms occurred, and upon rhinological examination there was nothing to account for them except congestion of the sinuses, or possibly an accumulation of nonpurulent secretion within them. (3.) There was a very large class of cases which presented ophthalmic symptoms which were undoubtedly due to old sinus trouble, but in which no pus could be found at the time they were examined by the rhinologist. The history of these cases usually pointed to old catarrhal trouble. (4.) There was a class of cases in which a septal spur or deflection, upon which the swollen turbinate impinged and in which intraocular pains or other symptoms might result which were relieved by a measure directed to enlarging the space between the turbinates and the septum. As indicating the frequency with which orbital inflammation was dependent upon disease of the accessory sinuses Birch-Hirschfeld found that of 684 cases of the former at least 409 depended upon one of the sinuses. In almost all cases the condition was chronic or acute purulent sinusitis which followed rhinitis, influenza, pneumonia, scarlet fever, and diphtheria, or after traumatism. The bacteriology of the eye was practically that of the accessory sinuses of the nose. An original sinusitis might heal while the orbital condition to which it gave rise was progressive, as it could not find drainage.

Dr. Emil Gruening said that the relations between the eyes and the nose had interested him for a long time because he often encountered cases showing ocular symptoms such as lacrymation and photophohia, in which local treatment of the eye and general treatment proved ineffective, while nasal treatment was beneficial. He had read a paper on this subject in 1886 which had been published in the Medical Record. The diseases of the accessory sinuses of the nose causing complications in the orbit came frequently under the observation of the ophthalmic surgeon. He was of the opinion that in many of these cases the intranasal treatment should be supplanted by operations from the orbit. In 1895 and 1896 he had written two articles on "Empyema of the Ethmoidal Cells and Its Operation from the Orbit" and on "Orbital Fistulæ Due to Ethmoidal Disease." At that time he wrote that the good results obtained by surgical procedures from the orbit were so gratifying that it seemed advisable to substitute more frequently the orbital for the intranasal operations. The advantages of the orbital operation over the intranasal were the following: 1. The possibility of more direct inspection and exploration of the ethmoidal spaces. 2. The greater facility of removing granulations and polypi and carious bone. 3. The better chance of securing drainage by a counter opening, *i.e.*, by perforating the floor of the ethmoidal body from above. The resulting scar was hardly visible and did not disfigure the face.

Dr. Robb of Boston and Dr. Robert C. Myles also discussed the papers.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held November 17, 1908.

Dr. Onslow Allen Gordon in the Chair.

The Treatment of Lacerated and Contused Wounds and Compound Fractures.—Dr. Martin B. Tinker of Ithaca, N. Y., read this paper. He said that it was the prevailing practice for the attending surgeon to relegate the treatment of these severe injuries in most cases to the house surgeon. There was a tendency to scarcely appreciate the importance of the careful and skilled treatment of the grave injuries to the limbs. As the result of this neglect, these traumata frequently resulted in death tetanus, malignant edema, spreading gangrene, streptococcus infection, and infection with the bacillus capsulatus ærogenes. To the workingman the mere loss of a finger was a matter of considerable importance, and it was the duty of the surgeon, in the presence of a crushing injury to a finger, to seek to prevent the loss of permanent injury to the member from an osteomyelitis, etc. There was a general dislike for accident surgery. But it was just as creditable to save an arm as to remove a tumor. It was noted that to-day, in spite of the advances of surgery, there was no essential difference in the mthod of handling these cases to the practice that prevailed fourteen years ago. The usual treatment was the scrubbing up of the parts, the irrigation with antiseptics, the institution of

free drainage, and the application of antiseptic dressings. In the process of scrubbing, however, infectious material was frequently rubbed into the wound. Moreover, irrigation did not suffice, for the fluid rarely penetrated into the deeper parts. Bichloride or carbolic solutions, if strong enough to kill bacteria, were likewise effective in destroying the tissues. These when dead were a perfect nidus for the further growth of bacteria. The speaker suggested a modification of the older methods and did not claim originality. He admitted that his methods also had their disadvantages. Before scrubbing up the damaged limb, he covered the lacerated parts with cotton soaked in sterilized oil. This was done with the object of preventing any further infection of the lacerated tissues. It was impossible to remove all the dirt from the latter. The application to the surface of powerful antiseptics like Harrington's solution, pure carbolic acid, or strong formalin solution was permissible. It was necessary to get relatively healthy tissues before closing the wound. After the application of a tourniquet it was advisable to pare off the superficial torn and damaged tissues by means of a sharp curved scalpel. The tendons and nerves were to be spared. After this the wound was to be sutured loosely, with or without drainage, as circumstances dictated. Then abundant and loose dressings were to be applied, so as not to impair the circulation. For wounds in which the dirt was ground in, and in case of badly damaged or crushed parts, swabbing instead of pareing off the surface was to be the procedure. It was then necessary to wait until the line of demarcation appeared. The speaker cited a case in which the toes were mashed to a pulp, and the plantar surfaces of the metatarsal bones were exposed. The parts were swabbed and placed in a bichloride bath. At the end of two weeks the line of demarcation had formed. The two middle toes were dead; the metatarsal bones were shelled out of the outer toes, and the soft parts of the latter were used as flaps in forming a serviceable stump of the foot. By this conservative method of dealing with an injury for which a Syme or a Pirogoff operation was usually performed, it was possible to get a stump capable of bearing the weight of the body. In the processes of swabbing, disinfecting and pareing an anesthetic was necessary. In the presence of profound shock, local anesthesia was preferable. In combating shock the speaker had found morphine invaluable. In combination with a good preparation of myoscine it was most effective. Then cocaine was injected locally. This was best injected in such a manner as to cause a ring of infiltration anesthesia about the main nerve trunk, or if possible, the cocaine was to be injected directly into the nerve itself. Novocaine was better than cocaine. In a solution of 1-500 it was as effective as cocaine, and five times less toxic. This procedure reduced the tendency to shock. Crile had shown that when the main nerve trunk was infiltrated with cocaine, the shock of amputation was markedly diminished. On account of the frequency of death from tetanus following severe injuries, the speaker adopted the additional precaution of giving an immunizing dose of tetanus antitoxin. This was of no avail if injected when the disease was fully developed. For shock the speaker administered one pint of coffee per rectum, and an intravenous saline infusion with adrenalin added to it. The pulse usually flagged as soon as the stimulation was removed. The other aids to the successful tiding over of the dangerous period, as the warmed operating table, etc., were also resorted to. To hold broken bones in place plaster-of-Paris was used. Windows in the east were not necessary in a clean case. The cast was removed at the earliest possible moment. The *x*-rays were to be employed in order to recognize if the fragments were in proper alignment. The patient was to get up early, with the aid of crutches. In the severe injuries it was necessary to suture the tendons and nerves. Primary nerve suture was attended with satisfactory results, while secondary suture was usually unsatisfactory. If necessary, secondary bone suture was to be resorted to. The transplantation of bone from animal to man was not usually successful. It was well to leave all fragments of bone that were still attached to periosteum. Skin grafting and blood-vessel anastomosis were occasionally necessary. The man who could save the blood supply was the one who could save limbs that were usually amputated. In all injuries of the lower extremities, if the blood-vessels were intact, the limbs could be saved. By such conservative methods, which entailed a great deal of care and labor on the part of the surgeon, the results were infinitely more satisfactory.

The Ethics of Our Profession.—Dr. A. Vander Veer of Albany, N. Y., read this paper. He commented on various definitions of ethics, and said that it was not his intention to discuss the codes, but to discuss ethics from the viewpoint of scientific medicine. In particular, his object was to discuss in its ethical relations the attitude of the profession toward its students. He gave an historical résumé of the development of medical education in New York State during the past century, and of the development of legislation relating to it. The tendency of to-day was to demand from the student a preparatory education that was too elaborate for the needs of the majority of practitioners. If the college degree was to be demanded from prospective students of medicine, and if the latter were to spend four years in the study of medicine with the subsequent one or two years of hospital or laboratory work, then the practitioner would not be able to begin his bread-winning until the age of twenty-eight. For the majority of practitioners, particularly those of rural communities, the limited remunerative returns from his practice made this demand for elaborate preliminary preparation too exacting. The combination course of six years of study, as advocated by President Butler and others, which would lead to both of the degrees of of A.B. and M.D., was endorsed by the speaker as the ideal curriculum.

Philadelphia County Medical Society.

At a stated meeting held November 25 a symposium was held on the subject of vaccination. Dr. Alexander C. Abbott presented a communication dealing with "The Rôle of the Bureau of Health in Public Vaccination." He pointed out that outbreaks of smallpox can be prevented by proper enforcement of the law and the universal practice of vaccination. Dr. Jay F. Schamberg read a paper entitled "Smallpox Before and Since the Discovery of Vaccination." He referred to the terrible plagues of smallpox that devastated Europe and England between the fifteenth and eighteenth centuries, when from 85 to 95 per cent. of the population were afflicted with the disease. A remarkable decrease in the prevalence of the disease has been noted in every country in which vaccination has been made compulsory. It has been contended by the opponents of vaccination that the improvement is due to better sanitary conditions, but a like improvement has not been noted with respect to other transmissible diseases. Dr. Wm. M. Welch read a paper entitled "Remarks on the So-called Dangers of Vaccination." He showed that the number of cases in which bad results attend vaccination is small in relation to the large number of persons vaccinated. Complications are almost invariably due to carelessness or want of cleanliness on the part of the physician or the patient. Disease is at the present day rarely if ever transmitted by vaccination. Hampton L. Carson, Esq., submitted a communication entitled "The Legal Aspects of Vaccination." He cited opinions of the Pennsylvania Supreme Court to show that the Legislature in the exercise of the police power of the State has the right to enforce any regulation calculated to conserve the public health. The vaccination law he contended came within the exercise of that right.

INDEX.

A.

Abbe, Robert, anesthesia at St. Luke's Hospital, 263.
Abdomen, support of, after laparotomy, 775.
Abdominal auscultation, 1103; and pelvic operations, convalescence in, 814; conditions, diagnosis of certain chronic, 551; incisions, direction of, 671; operation, remote pain following, 81; surgery, leucocyte count in, 628.
Abortion, indications for, 32; tubal, progressing, 900.
Abscess of lung, from ascending infection from appendicitis, 665; pelvic, 39, 892; prevesical, 204; ovarian, drainage after rupture of, 899; subdiaphragmatic, 774; tropical, of the liver, 338, 340, 341.
Absinthe tabooed, 151.
Abuse of a calling, 845.
Accidents, hysterical and neurasthenic conditions in, 857.
Acetonemia, periodic, in older children, 241.
Achrondroplasia, 72.
Acid-fast bacilli, comparative examinations of the, 594.
Acidosis, classification of, 245; following anesthesia, prophylaxis of, 1102.
Acne, pustular, treated with staphylococcus vaccine, 239.
Actinomycosis of the ribs and vertebræ, 776.
Adams-Stokes disease, autopsy in a case of, 199.
Adenoids, pneumonia associated with, 629.
Adenoma of cervix uteri, 937.
Adiposis dolorosa, 934; with involvment of large nerve trunks, 1018.
Adrenalin glycosuria, effect of pancreatic extract on, 542; influence of, in causation of arteriosclerosis, 464.
Adrenals, relation of, to kidneys, 374; tumors of, and hypernephroma of kidney, 722.
Adulteration, to stop, 65.
Agnosia, significance of, in interpretation of air infection, 1102; psychoses, 1053.
Alaska, disease among the aborigines of, 368.
Albuminuria, intermittent, relation of, to hereditary tuberculosis, 603; orthostatic, and lordosis, 928.
Alcohol in treatment of children's disease, 281; injection of, in trigeminal neuralgia, 628; movement against, by German physicians, 1098; problem, recent medical discussions of the, 193; question, relation of the medical profession to, 934; use of, in Berlin, 495.
Alcoholic psychoses, 806.
Allergy, 188.
Alvarenga prize, 801.
Amblyopia in children, 241.
Ambulance service in New York City, 365.
Amebiasis, intestinal, 340.
American Academy of Medicine, president's address, 293.
American Association of Railway Surgeons, 718.
American Dermatological Association, 577.
American Electro-Therapeutic Association, 577; advancement of, 1023.
American Hospital Association, 65.
American Surgical Association, early days of, 34; reminiscences of the, 189.
Amputation, court orders, 535.
Analgesia, nasal, 457; spinal, clinical experiences with, 503.
Anastomosis, intestinal, 373; vessel, by means of rubber tubing, 671.
Anderson, J. F., differentiation of outbreaks of typhoid fever due to infection by water, milk, flies, and contacts, 909.
Anemia, fibroid and, 806; in children, 247; of hepatic cirrhosis, 681; pernicious, in pregnancy, 467; pernicious, remissions in, 282; secondary, of tuberculosis, treatment of, with hypodermics of iron, 620; splenic, splenectomy, recovery, 248.
Anesthesia at hospitals, symposium on, 295; at St. Luke's Hospital, 263; blood changes in, 889; by means of chloroform and ether, 271; chloroform, 322; chloroform, fatal toxemia after, 583; improvement of general, 261; in ophthalmology, 1020; inhalation, in "healed" pulmonary tuberculosis, 927; local, 889; local, in major surgery, 1037; local, in operations for hernia, 458; lumbar, 272; nitrous oxide, 889; prophylaxis of acidosis following, 1102; scopolamine-morphine, in obstetrics, 32.
Anesthetics, administration of, at Mt. Sinai Hospital, 264; at the Hospital for Ruptured and Crippled, 266.
Anesthetist, professional, the hospital and the, 260.
Aneurysm, large, pulsation of, 974; of the heart, 282; popliteal, treatment of, 165.
Angina in scarlatina, necrotic or ulcerative, 631.
Animal experimentation, 414.
Ankle drainage, 491; sprains of the, 417.
Ankylosis, fibrous, of the knee, 777.
Ankylostoma in Australia, 383.
Ankylostomiasis, blood changes in, 332; in British Guiana, 379; in South Africa, 379; sanitation in reference to, 378.
Anthrax, external, treatment of, 367.
Antitrypsin in the blood, 630.
Antrum, maxillary, methods of opening the, 506.
Anuria, calculous, treatment of, 200.
Aorta, etiology of degenerative changes of the, 376.
Aphasia during whooping-cough, 283; relation of auditory area to, 248; two cases of, relieved by operation, 421.
Apoplexy, delayed, 425; in the classification of diseases, 680; its causes and treatment, 680.
Appendicectomy, lumbar, 1019.
Appendicitis, acute, in children, 679; acute, treatment of, 808; acute, value of a differential leucocyte count in, 63; and movable cecum, 851; and rheumatism, 1056; blood analysis in, 158; chronic, in children, 117; chronic, in women, 187; diagnostic methods in, 925; differentiation between, and diseases of the uterine adnexa, 200; leucocytosis in, 808; medical treatment of, 307; obstruction of the bowel, simulating, 400; perforative, early symptom of, 674; perforative in pregnancy, 768; peritonitis, due to, 1059; rectal drainage in pelvic abscess due to, 283; three unusual cases of, 879.
Appendix, abscess of the, treatment of, 373; carcinoma of, 38; carcinoma of, primary, 539; necessity for removal of, after perityphlitic abscess, 198; separate from colon, 38.
Appetite in children, loss of, 1060.
Army test ride in Philippines, 407.
Arrhythmia, cardiac, some forms of, 682.
Arsenic in treatment of diseases of skin, 815.
Arteries, cerebellar, occlusion of the posterior inferior, 423; cerebellar, thrombosis of the, 424; cerebral, distribution of, 421; coronary, result of ligation of, in dogs, 244; degeneration of, in the rabbit, 629; experimental disease of, 621; normal and pathological, 976.
Arteriosclerosis, 894; and hypertension, treatment of, 1024; cerebral, artificial hyperemia in, 416; influence of adrenalin in causation of, 464; of uterus, 771; premonitory signs of, 198.
Artery, innominate, legation of, 935.
Arthritis deformans of hip, 777; gonorrheal, hyperemia in, 106; gonorrheal, improved treatment of, 143; non-tuberculous, 540; septic, 1026; some types of rheumatoid, 775; tuberculous, of hip joint, 645, 646.
Arthropathy in rötheln, 187.
Ascites in new born, 240.
Asepsis in childbirth, 672.
Ash-free diet, 245.
Association des médicins de langue Française de l'Amerique du Nord, 25.
Association of Military Surgeons of Illinois, 844.
Asthenia universalis and tuberculosis of the lungs, 596.
Astragalus, fracture of, 856.
Ataxia, locomotor, 163.
Asthma, thymic, 31.
Atonia gastrica, remarks on, 453.
Atrioventricular bundle, study of, 247.
Atrophic infants, dealing with, 548.

Atropine and slow pulse, 32.

B.

Babies, help for the, 150.
Baby foods, 110.
Bacillus, a new pathogenic, 150.
Bacteria, latent persistence and reactivation of, 1103.
Bacteriology of bed-stuffing, 212; of the common cold, 1052.
Bad Nauheim, the cardiac atmosphere of, 369; treatment, 1068.
Baltimore Medical College, 111.
Barker, Milton R., abnormal motility of the stomach a valuable factor in the diagnosis of gastric lesions, 442; pancreatitis, with illustration of crystals of pancreatic reaction, according to Cammidge's test, 875.
Barney, C. N., the ophthalmo-reaction to tuberculin, 96.
Basedow's disease, leucocytes in, 674.
Bassler, A., early diagnosis of gastric carcinoma, 1088; significance of wash water examinations for gastric cells in the diagnosis of atrophic gastritis; report of two cases, 51.
Baths and exercise in heart disease, 895; Mount Clemens mineral, 227; public, 110.
Beale, H., hexamethylenamine as a specific in typhoid fever, 157.
Beck, Dr. Carl, honored, 25.
Becquerel, Antoine Henri, death of, 411.
Bee stings and rheumatism, 769, 891, 1103.
Bellevue, larger, opposed, 24.
Beraneck's tuberculin, 641.
Berkeley, W. N., some notes on the medical treatment of inflammations of the biliary tract, 831.
Berlin, letters from, 412, 933.
Bettmann, H. W., cholecystitis, with suggestions for the prevention of gallstones, 923.
Bier's hyperemia, 106, 115.
Bile duct, common, melanotic sarcoma of the, 37; passages, surgery of, 1026; tract, medical treatment of inflammations of, 831.
Bilharziasis, 385; of the gastric mucous membrane, 503.
Biliary disease, treatment of, 1027.
Binghamton Academy of Medicine, 677.
Birkett, H. T., a brief account of the history of medicine in the Province of Quebec, from 1535 to 1838, 129.
Birth rate, our falling, 970.
Births and deaths, registration of, 730; in England and Wales, 29.

Ellis, R., unusual cardiac murmurs, 145.
Elmer, W. P., the action and dosage of phenolphthalein, 838.
Embolism, pulmonary, operation for, 190; pulmonary, operative treatment of, 494.
Embryonal tissues, transplantation of, 190.
Emmanuel movement, 884.
Emotions, physiology and pathology of, 310.
Emphysema, surgical, 160.
Empyema, chronic, treatment of, by hyperemia and hypertransudation, 503; surgical treatment of, 253.
Encephalitis, types of, 425.
Endoaneurysmorrhapy, 935.
Endocarditis, management of chronic, 158; ulcerative, cerebral complications of, 945.
Endoscopy, uterine, after abortion, 571.
Endothelioma of pleura, 78, 867.
English, international, 882.
Enterectomy for gangrene, extensive, 541.
Enterostomy: its value in intestinal obstruction, 854.
Enuresis after prostatic abscess, 203.
Enzymes in tuberculous lesions, part of, 902.
Epididymitis, gonorrheal, acute, 974.
Epiglottis, cysts, abscesses and edema of, 510; syphilis of the, 509.
Epilepsy and dementia præcox, diagnosis of, 423; in private practice, 186; lumbar puncture in the treatment of, 624; voice in, 752.
Epithelial tumors, cutaneous, 807.
Epithelioma and syphilis of the tongue, 208; of pharynx, 888; Roentgen rays in, 975.
Ergograph in fatigue tests, 251.
Ergot, hypodermatic injections of, in cases other than obstetrical, 60.
Erysipelas, bacterial treatment of, 580; in the new-born, 583; treatment of, 157; 332; treatment of, by bacterial vaccines, 1031.
Erythema multiforme with visceral lesions, 501.
Erythromelalgia, and allied conditions, 248.
Esophagoscope, the, as a diagnostic

and therapeutic aid in esophageal obstruction, 179.
Esophagoscopy, direct, dangers of, 841.
Esophagus, congenital obliteration of, 733; dilatation of the dietetic treatment in, 16; stricture of, spasmodic, in an infant, 733; stricture of, x-ray diagnosis of, 855; surgery of, 502.
Esperanto, a plea for, 538; Congress, 65.
Ether, administration of, by open method, 283; administration of, per rectum, 853; anesthesia, diuresis following, 64; as an anesthetic, new method of administering, 1050; induction, new wrinkle, 1012; new, simple, and ready method of dropping, from the can, 712.
Eucalyptus in hemorrhage, 199.
Eupyrexia, 705.
Evans, Dr. W. A., appointment of, 110.
Ewald, Dr. C. A., honors for, 323.
Exercise, surgical injuries brought on by, 159.
Expert testimony and the alienist, 239; testimony and the medical witness, 857.
Eye and autointoxication, 30; and diseases of nasal sinuses, 1106; and orbit, diseases of, depending on nasal sinuses, 1107; deep lesions of, associated with gout, 1033; diseases of, relation of disease of accessory nasal sinuses to, 681; foreign bodies in, 966; in multiple sclerosis, 159; lesions of, demanding immediate treatment, 372; serum therapy in diseases of the, 200.
Eyelid, everting the upper, 417.

F.

Factory ventilation, cash value of, 691.
Fallopian tube, physiology of the, 1104.
Fatigue, tests with ergograph, 251.
Fauna of Croton water supply, 534.
Feces, hard curds of infants', 549; ova of parasites in, 542.
Federal health departments, need of, 818.
Feeble-minded, care and control of in Great Britain, 493; children, deformities in, 775; education of, 993.
Fee, division of, 903.
Feeding, modern laboratory, 548; of the soldier, the, 622.
Femur, neck of, fracture of, 776.
Ferris, A. W., Italian immigration and insanity, 1082.
Fetus, death of, in utero, 896; generalized edema of the, 457; maceration of, in relation to legal medicine, 333.
Fever, in infancy and early childhood, 157; relapsing, 248; spotted, 913.
Fibroid, symptomless, 582.
Fibroids and anemia, 806; intraligamentous, 774; uterine, complicating pregnancy, 774.
Fibrotuberculoma of pleura, 903.
Filtering beds, properly constructed, 456.
Fishberg, Maurice, tuberculosis among the Jews, 1077.
Fistula, fecal, two cases of, 898; rectal, bismuth paste in, 853; ureterovaginal, following hysterectomy, 937.
Flannelette, 797.
Flat-foot, correction of, 1025; important facts, 796.
Flies and disease, 576; as agents of dissemination of Koch's bacillus, 635; danger from, 109; epidemic diarrhea spread by, 1102.
Food values in nutrition of children, 894.
Foot and mouth disease, outbreak of, 884; flat, correction of, 1025; flat, important facts, 796; lipoma of, diffuse painful, 723.
Foote, E. M., early diagnosis of carcinoma of the sigmoid, 254.
Forest fires, 760.
Formalin as a urinary preservative, 409.
Fourth of July, the, 21; toll of the, 64.
Fowler, H. A., autochthonous urethral calculi; report of a case, 174.
Fractures and wounds, treatment of, 1108; some lessons from ancient, 503; treatment of, by mobilization and massage, 378.
Fresh air for children, 850; in treatment of disease, 732.
Fulguration, 374; treatment of malignant tumors, 892.
Funiculitis, endemic, 159.

G.

Gaertner's canal, abscess of, 773.
Gallant, A. E., vaginoureterostomy after nephrectomy for pyonephrosis due to a "sigmate" constriction of the ureter, 529.
Gall-bladder trouble in gastric ulcer, 855.
Gallstone ileus, two cases of, 583.
Gallstones, etiology of, 819; prevention of, 923; removal of, weighing two pounds, 283; symptomatology and diagnosis of, 820.
Ganglia, the nature of, 840.
Ganglion, Gasserian, surgery of the, 34.
Gangrene, angiosclerotic, reversal of circulation in the prevention of, 231; diabetic, amputation in, 267; in strangulated hernia, treatment of, 31; of skin in scarlet fever, 283.
Gasserian ganglion, surgery of the, 34.
Gaston, J. McF., case of obstruction of the bowels, simulating appendicitis, 400.
Gastric and duodenal ulcers, perforated, 1044; cells, significance of wash water examinations for, 51; pains, differentiation of, 856; symptoms, reflex, 81; ulcer, acute perforating, 80; ulcer and cancer, 372; ulcer, diagnosis of, 657; ulcer, management of, 942; ulcer, perforated, 31; ulcer, treatment of, 377; ulcer, with reference to precancerous influence, 856.
Gastric atonia, remarks on, 453.
Gastritis, atrophic, significance of wash water examinations for gastric cells in the diagnosis of, 51.
Gastroenterostomy, intestinal occlusion after, 416.
Gastromyxorrhea, 456.
Gastroptosis, a new corset for, 197.
Gastrostomy 378; indications for temporary, 365.
Generative organs female, tuberculosis of, 648; repair rather than removal, 775.
Genital tuberculosis, 581.
Genitalia, female, development and malformation of, 900.
Genitourinary, diagnosis, preparation for a, 445.
Germs in cracked dishes, 152.
Gibbs memorial prize, 24, 121.

Lymphangiectasis, case of, 206.
Lymphatic organs, effect of repeated injections of tuberculin on, 501.
Lymphoid tissue, hypertrophy of, relation of, to tuberculosis, 684.

M.

McCosh, Andrew J., observations on the treatment of exophthalmic goiter, 476.
McLaughlin, W. B., a new and efficient method of room disinfection, 104.
Magruder, W. E., congenital umbilical hernia, with report of case, 393.
Maher, S. J., tuberculosis in Connecticut, especially in rural Connecticut, 169.
Malaria and tuberculosis, differentiation of early, 567; in young children, 624; latent, diagnosis of, 381; on the Isthmus of Panama, 880; pernicious, pathogenesis of, 140.
Malignant disease, enigma of, 1095.
Malingering, new sign of, 457.
Malnutrition and society, 525; of infants, kefir in, 968.
Manila, letters from, 112, 280, 455, 538, 579.
Manitoba Medical Association, 718.
Manson, L. S., a case of syringomyelia, 925.
Maragliano's serum, untoward effect following use of, 642.
Maritime Medical Association, 192.
Marmorek's serum, 283, 883, 891.
Marriage and gonorrhea, 1060; from a medical point of view, 314; licenses, 66.
Mastoid, dermoid cyst over the, 116; meato-, operation, 629; operation for the cure of chronic purulent otitis media, 608.
Mastoiditis, case of, 208; prevention and preoperative treatment of, 981.
Matsui, S., Imperial Institute for the Study of Infectious Diseases, Tokyo, Japan, 584.
Measles, effect of, in cutireaction with tuberculin, 332; in utero, 679; treatment of, 839.
Meatomastoid operation, 629.
Mechanicobiological standpoint in medical problems, 722.
Medical advance, currents and counter-currents in, 854; colleges raise entrance requirements, 24; day in Eastern Pennsylvania, 191; directory, want to discontinue, 1030; education, 292; education of general public, 292; education, the standard of, 85; expert testimony, 78; fees, 368; inspection in Chicago, 495; library, and its contents, 550; practice law, 410; practice in New York, 1012; profession, duties of, to the public, 605; schools merge, 233; schools, early, and legal regulation, 707; service in a modern army in war, 1028; society, right to resign from, 24.
Medical Association of the Southwest, 763.
Medical Club of Philadelphia, 25.
Medical profession, ethics of, 1109.
Medical Society of the County of New York, 931.
Medicine and surgery in the Orient, 30; human element in, 857; in Venice, 719; in the province of Quebec, 129; losses and gains in, 928; modern, 286; preventive, school of, 151; public, and its relation to society, 230.
"Ménière's disease," the myth and the mystery of, 745.
Meningitis, anti- serum, 115, 674, 768; anti- serum, method of administering, 1059; cerebrospinal, case of, treated with antimeningitis serum, 19; cerebrospinal, serum treatment and prognosis of, 557; cerebrospinal, serum treatment of, 769; epidemic cerebrospinal, serum treatment of, 544, 545, 546; examination of cerebrospinal fluid in, 545; tuberculous, a case of apparently, 735; tuberculous, clinical manifestations of, 602; tuberculous, diagnostic value of lumbar puncture in, 651; tuberculous, surgical possibilities in, 645; tuberculous, with miliary tuberculosis in an infant, 602.

Meningococcus, anti-, serum, 115, 674, 768; method of culturing, 333.
Mental defectives, high-grade, 413; disorder, special provisions for management of certain forms of, 964.
Mercury and tuberculosis, 72; in tuberculosis, 1018.
Mesentery, inflammatory tumors of the, 1104.
Metabolism, salt, and diabetes, 456; sugar, catarrhal jaundice and, 575.
Metal, dermatitis due to, 539.
Meyer, N., Royal Institute for Infectious Diseases in Berlin, 861.
Meyer, Willy, the improvement of general anesthesia, 261; the possibility of avoiding conspicuous scar formation in softened tuberculosis of the cervical glands, 865.
Mice, cancer in, action of two sera upon, 583.
Migraine an occupation neurosis, 198.
Milk and infections, 849; breast, feeding, 723; clean exhibit of, 192; commercial pasteurization of, 729; cows', obtaining sterile, 979; diet in diarrheas of infancy, 416; diet in obesity, 332; pasteurization of, in Great Britain, 274; pasteurized, and infant death rate, 410; problem, present status of the, 78; pure, crusade in Great Britain, 927; soured, use of, in chronic ill-health, 373; top, fat and protein content of, 549; tubercle bacilli in, 1066.
Mines, sanitation of, 713.
Minot, Dr. C. S., appointment of, 110.
Miracles at the tomb of B. Francois de Pâris, 1.
Mississippi Valley Medical Association, 763.
Missouri Valley Medical Association, 535.
Mitchell, Dr. S. Weir, election of, 451.
Moeller, H. N., an unusual case of cerebrospinal meningitis treated with antimeningitis serum, 19.
Morphine, China bars, 151; derivations in ocular therapeutics, 815.
Morphinism and the opium habit, 621; the narcotic method of treating, 404.
Morris, R. T., doctors *versus* new ideas, 679.
Mosquito marshes, drainage, 65.
Mothers of infants, caring for, 531.
Mount Clemens mineral baths, 227.
Mouth, cancer of, 942; care of, during infancy and childhood, 959; pigmentation of, 935; sepsis of, 629.
Muscular coordination, 158.
Myasthenia gravis, case of, 425.
Mycosis fungoides, relation of, to infection and malignancy, 447.
Myeloma in myelogenous leukemia, 31.
Myer, J. L., the esophagoscope as a diagnostic and therapeutic aid in esophageal obstruction; report of cases, 179.
Myocarditis, clinical features of, 945.
Myopia and its prevention, 799.
Myositis ossificans, 776

N.

Narcosis and immunity, 492.
Nasal analgesia, 457; duct strictures, 722; sinuses, disease of, relation of, to diseases of eye, 681.
National Association for the Study and Prevention of Tuberculosis, 26.
National Institute of Homeopathy, 111.
National Volunteer Emergency Service, 625.
Naval Medical Corps, work and needs of, 1051.
N. B., a Mexican labor, 329.
Neck, fracture and dislocation of the, 795; glandular tumors of, treated with *x*-ray and high frequency currents, 983.
Neoplasms, prognosis of, 540.
Nephritis, acute syphilitic, 72; chronic, blood-pressure in, 891; chronic, orrhotherapy in, 842; chronic, pathology of, 320; experimental, lesions of, 244; hemorrhagic, 806; in children, unusual type of, 731.
Nephrotomy and nephrectomy, indications for the performance of, 337.
Nerve anastomosis in infantile paralysis, 54; area, mental, and relation to gray hair, 160; auditory, division of, 769; circumflex, inflammation of, 18; suturing, 321.
Nerves, motor peripheral, surgery of, 778; plastic operations upon, 200.
Nervous system, diseases of heredity in, 1019; early diagnosis of organic disease of, 1020; influence of, infective processes, 977.
Nervousness in children, dietetic causes of, 724.
Nesbitt, C. T., a contribution to the study of the diathetic states, 615.
Neuralgia, chronic, its cause and cure, 815; trigeminal, injection of alcohol in, 628.
Neurasthenia, blood pressure in, 241; etiology, pathology, and course of, 983; treatment of, by static electricity, 984; true, its nature and treatment, 955; ultraviolet ray and high frequency currents in, 957; ventriculi and gastroptosis, 539.
Neuritis, occupation, of branch of ulnar nerve, 425.
Neurological Society, report of, 676.
Neurologist, letters to a, 66, 153, 234, 324, 496.
Neurologists and electrotherapy, 115.
Neuromuscular coordinations having educational value, 767.
Neuroses of nose, 1008; pharyngeal, 715; reflex, arising from ocular and nasal abnormalities, 888; spirit and drug, 857; vasomotor trophic, 937.
Newborn, ascites in, 240; deafness of, 229; erysipelas in the, 583; hemophilia in, 240; icterus gravis of, 882; inguinal hernia in, 417; insufflation in, 936.
New Hampshire Medical Society, 26.
New York, death rate in, 191, 233, 323, 495, 534, 576, 717, 762, 843, 884, 970, 1055; health conditions in, 23; healthy year in, 64; hospital system, 151; medical practice in, 1012.
New York and New England Association of Railway Surgeons, 577.
New York Department of Health, 495.
New York Pathological Society, 717.
New York State Board of Medical Examiners, 883.

Picayune cup, award of, 411.
Placenta, functions of, 883.
Placental extract, hemolytic power of, 1050; transmission of paratyphoid infection, 23.
Plague, bubonic, treatment of, 503; cats as preventers of, 851; in San Francisco, 762; in Trinidad, 24; in Venezuela, 65, 151; mode of dissemination and methods for control, 345.
Playground Association of America, 495.
Pleura, endothelioma of, 78, 867; fibrotuberculoma of, 903.
Pleural adhesions, prevention of, 377; reflexes, further observations on, 251.
Pleurisy, purulent, of the apex, 147.
Pneumatosis cystoides intestinorum, 32.
Pneumonia and weather, 415; associated with inflammation of adenoid growths, 629; broncho-, in children, recurrences of, 1021; diagnosis in infancy, 240; family, 724; fresh air in, 239; in children, 415, 858; lobar, serum treatment of, 715; on the Isthmus of Panama, 563; one method of treatment, 372; specific skin eruption in, 1020; treatment of, 804; treatment of, etiological indications in, 1042.
Pneumothorax, 377; pure, in pulmonary tuberculosis, 688.
Pogue, G. R., tuberculosis other than pulmonary treated with tuberculin, 352.
Poker-back, 331.
Police power for protection of health, 691, 692.
Poliomyelitis, acute anterior, 482; acute anterior, in the adult, 331; acute, following tonsilitis, 766; anterior, 1025; anterior acuta, 980; anterior acuta, an epidemic of, 735; anterior, case of, 207; anterior, in Massachusetts in 1907, 779; early orthopedic treatment of, 779; early symptoms of the recent epidemic of, 736.
Polk, C. G., epilepsy in private practice, especially that from reflex causes, 186.
Polycythemia and blood pressure, 937.
Pott's disease, early diagnosis of, 208; jacket for correction of deformity in, 207.
Powers, W. H., tetanus; with a report of a case treated by intraspinal injections of magnesium sulphate, 146.
Pregnancy, ectopic, 772, 897; effect of cholesterin on, 1061; pernicious anemia in, 467; toxemia, 899; tubal, 900; tubal, hemorrhage due to, 465; tubal, ruptured, 975; tubal, vaginal operation in, 117; tuberculo-opsonic index in, 232.
Primary union, factors in addition to asepsis necessary to secure healing by, 755.
Professional intolerance, 881.
Prophylaxis *vs.* treatment, or prevention rather than cure, 833.
Prostate, conservative treatment of, 331; enlarged, treatment by high frequency current, 1024; gland, when should it be removed?, 856; hypertrophy of, 1061.
Prostatectomy by combined routes, 378.
Prostitution, relation of, to tuberculosis, 694.
Pseudometastases in case of ovarian dermoid, 541.
Psoitis, puerperal, 75.
Psoriasis, pathogenesis of, 740.
Psychiatric prognosis, 158.
Psychical end results in surgical operations, 37.
Psychic element in medical practice, 82.
Psychology of success, 448.
Psychoses, alcoholic, 806; significance of agnosia in interpretation of, 1053.
Psychotherapeutics, 250.
Psychotherapy, 580; of hysteria, 894; rest treatment in relation to, 424.
Pubiotomy, is it a justifiable operation? 505.
Public Health and Marine-Hospital Service, 150; enlarging the powers of the, 730.
Public Health Bureau, 624.
Public health exhibits, 716.
Public school education, 731.
Puerperal infection, lactic acid bacillus in treatment of, 200.
Pump, suction bell, Dr. Fowler's, 206.
Purin-free diet, limitations of, 891.
Pyelitis, 374; terminating in suppurative nephritis, 735.
Pyelonephritis, gravidic, nonexistence of, 200.
Pyemia sinusitis, 462.
Pylorus, congenital hypertrophic stenosis of the, 457; congenital narrowness of the, 199; infantile hypertrophic stenosis of the, 35; permeability of, estimating the, 939; stenosis of, chronic hypertrophic, in an infant, 1021.
Pyocyanase in throat affections, 583.
Pyometra in cancer of the uterus, 696.
Pyonephrosis and renal calculi in a pregnant woman, 805.

Q.

Quebec, the history of medicine in the province of, 129.
Query, a, 845.
Quinine poisoning, 976.
Quinsy, hemorrhage following, 511.

R.

Rabies, animal inoculation in, 729; diagnosis of, 239; diagnosis of, standard methods for the, 729; outbreak of, 23; provision for treatment of, 152.
Race suicide in France, 762.
Radiographer, general practitioner his own, 1025.
Radium salts for cancer, 540.
Ranula, 582.
Rat leprosy, 723.
Rats defy poison, 191; to go, 65.
Raynaud's disease, painful feet of, 780.
Rectum, cancer of, operation for, 378; disease of, posture in treatment of, 681; nonabsorption of antitoxin from, 416; prolapse of, 680; rupture of, 807; spontaneous rupture of the, 74; surgery of venereal stricture of, 853.
Recumbency in convalescence, 502.
Red Cross, American, 1015; emblem, misuse of, 150; New York, 1014; tuberculosis camps, 409.
Reed, Dr. C. A. L., appointment of, 192.
Reed, Dr. Walter, memorial to, 24.
Reese, F. DeW., operative and nonoperative fibroid tumors of the uterus, 788.
Reflex, a new, 1021.
Reflex phenomena, influence of exercise and habit on, 1094.

594; on clothing of tuberculous patients, 366; transformation of human and other types of, 1018; variations of the, 594, 636; viability of the, 592.
Tuberculids, toxic, 450.
Tuberculin an adjunct to home treatment of tuberculosis, 501; Beraneck's, 641; effect of repeated injections of, on lymphatic organs, 501; effect of, upon healthy persons, 23; fat-free, use of, 542; inunction, 72; measure of activity of, 901; treatment, immunization in, 642; treatment in cases of tuberculosis, other than pulmonary, 352; treatment of tuberculosis by, 641.
Tuberculin-reaction and the nervous system, 761; clinical value of, 251; conclusions from tests of, 640; cutaneous, 117; cutaneous, application of, 641; cutaneous, effect of measles on, 332; cutaneous, in children, 161, 640, 650; diagnostic use of, 1101; ophthalmo, 96, 160, 640, 684, 1020; ophthalmo, Calmette's, 650; ophthalmo, cytodiagnosis in, 409; ophthalmo, dangers of, 374, 892; ophthalmo, in typhoid fever, 149.
Tuberculosis, abdominal, relative frequency of, 603; and its treatment, 1025; among the Jews, 1077; and malaria, differentiation of early, 567; and mental defect, relation between, 690; and public schools, 695; and syphilis, 696; animal inoculation in, 729; anti-, International Association, 692; anti-, new law, 897; apex, chondrotomy in, 107; body or the bacillus? 694; bovine, bacilli of, in human beings, 533; calcium metabolism in, 902; campaign, 109, 494; campaign against, 979; campaign against and proposed national department of health, 819; campaign against, in Sweden, 531; campaign, posters, in, 66; camps, day, 275, 687; camps, night, 687; cause of failure in treatment of, 856; channels of entrance of, 595; children of parents with, 649; class system in home treatment of, 377; condition of teeth in, in relation to prognosis, 688; congress, 572; lessons of the recent, 1065; contributions from orthopedic surgery to the study of, 684; cost of, 690; creosote inhalations in, 492; crusade against in New York City, 700; Cuguillère's serum in the treatment of, 520; diagnosis and treatment of early cases of, 638; diet in, 639; difficulties of early recognition of, 694; dispensaries in cities and towns, 686, 687; dispensary, 897; dispensary in Lyons, 693; duration of the actively infectious stage of, 597; duties of general government in restriction of, 692; economic aspects of, 690, 691; electrotherapeutics in treatment of, 1059; employment for patients in, 628; enzymes in, 902; exhibit prizes, 716; exhibition, 969; family, 849; farm colonies for, 694; genital, 581; "healed" lesions in, 968; hemoptysis as a symptom of early, 638; hemoptysis in, temporary hypertension as a cause of, 642; hereditary, relation of, to intermittent albuminuria of childhood, 603; heredity in, influence of, 1019; high altitude treatment of, 639; high altitudes in, 688; home treatment of, 628; hospital for, 233, 576; hospitals for, construction of, 599; housing of patients in, 687; human, notification in, 818; hygienic instruction in schools, 694, 695; hypertrophy of lymphoid tissue in, 684; immune bodies in, 631; immunity in, 901; immunization against, 901; importance of treatment in sanatoria in, 637; in Cuba, 692; in lime workers, 977; in hospitals for insane, 687; in hospitals for the insane, 1040; in New York, control of, 817; in Philippine Islands, 692; infection from table utensils at sanatoria, 635; institutional care of cases of, 694; instruction, elementary, as to, 694; intertransmissibility of human and bovine, resolutions on, 633, 637; intestinal infection and immunity in, 741; joint, 775; joint, treatment of, 896; joint, vaccine therapy in, 645; lack of accommodation for cases of, 121; latent, 595; lesions of, 902; lesions of, in infants and young children, 603; Maragliano's serum in, 642; medicinal treatment of, 684; mercurial treatment of, 688; mercury and, 72; mercury in, 1018; miliary, in a child, 602; miliary, with tuberculous meningitis in an infant, 602; mixed infections in, 597; nurse in, work, 695; occupation, for convalescents from, 813; open-air treatment in, 436; opportunities for infection in, 635; opsonic index in, 639; other than pulmonary, treated with tuberculin, 352; overwork and nervous strain in, 691; para-, 450; patients, governmental control of, 818; percutaneous infection in, 634; placental transmission of, 649; preaching the crusade against, 151; predisposition of, overcoming, 919; predisposition to, overcoming the, during childhood, 651; prevention of, 693; problem, 694; problem in the Philippines, 1006; prophylaxis of, 1020; prostitution, relation of, to, 694; relation of air to the contagion of, 634; relation of ear lobule to, 149; relation to crime and the criminal, 693; relation to tuberculin reactions, 903; relief agencies in, 693; Roentgen rays in, 596; routes of infection in, 595; sanatoria for well-to-do patients, 687; sanatorium treatment of, 685; secondary anemia of, treatment of, with hypodermics of iron, 620; sources and ways of infection in, 595; sources of infection in, 634; surgical, 689; surgical bone, in adults, 689; surgical, iodine therapy in, 690; surgical, outdoor treatment of, 646; tests for, value of recent, 650; transcutaneous inoculation of, 634; transmissibility of, by means of dried sputum, 533; treatment of, 813; treatment of, by administration of mercury, 456; treatment of, by filtered bouillon of tubercle bacillus, 641; treatment of, by tuberculin, 641, 642; treatment of outside of sanatoria, 687; treatment of, sinuses, 775; trypsin and amylopsin in, 282; tuberculin an adjunct to home treatment of, 501; university bars, 151; unteachable patient in, 693; Wall street tackles, 151; *x*-ray examinations in diagnosis of early, 687; *x*-ray treatment of glands in, 816.
Tuberculosis, human and animal, relation between, 1018; human and bovine, 377; human and bovine, relations of, 635; human and bovine, treatment by different kinds of tuberculin, 636; human and bovine, treatment of, by tuberculin, 641; human and cattle, 373.
Tuberculosis in children, 601, 602, 603; frequency of, 651; human contagion as a factor in, 649; obstructions of the oro-nasopharynx, as a factor in, 649; primary localization of, 603; prophylaxis of, 652; relation of infectious diseases to, 602; school, method for detection of, 651.
Tuberculosis of bladder, 647; of bones, joints and glands in children, treatment of, 684, 689; of breast, 645; of cornea, 599; of ear, 513, 599; of female generative organs, 648; of foot, operative treatment of, 333; of glands, cervical, avoiding scar formation, 865; of glands, cervical, scar formation in, 684; of glands, mesenteric, healed, 902; of glands, relation to spinal symptoms, 642; of hip, treatment of, 645, 646; of kidney, 689; of larynx, 598; of lungs and pleura, surgical aspects of, 643; of mammals and birds, 275; of nose, mouth and pharynx, 598; of pericardium in children, 603; of peritoneum, 648; of sinuses, treatment of, 689; of upper air passages, 115; of vas, epididymis and testicle, 688.
Tuberculosis, pulmonary, among printers, 691; and asthenia universalis, 596; and ozonated air, 332; apical, chrondrotomy in, 937; cardiac complications in, 944; care of patients in advanced stages of, 687; coagulability of the blood in, 688; comparative value of treatment of, 1018; early diagnosis of, 479; effect of exercise on opsonic index in, 685; effects of pleuritic exudate upon, 928; etiology of, 199; expectant treatment of, 849; graduated labor in, 685; healed, inhalation anesthesia in, 927; hemoptysis in, 642; hemoptysis as a sympton of early, 639; in Connecticut, 169; opsonic index in, 1031; pneumonic process in, 903; pneumothorax in, 688; predisposition of the apices of the lungs to, 596; prognosis of, in children, 684; rest and exercise in, 686; treatment of, with tuberculinum purum, 902; tuberculo-opsonic index in, 640; *x*-ray examinations in, 638.
Tuberculous, care of, in homes, 819; children of the, 807; sinuses and fistulæ, treatment of, 896.
Tumors, heteroplastic, appearance of, in transplantations of new growths of animals, 301; malignant, pathology of, 407; malignant, prognosis of, 540.
Turbinals, morphology of the, 509.
Twenty-first French Congress of Surgery, 887.
Typhlitis, 775.
Typhobacillosis, 597, 1053.
Typhoid bacillus, carrier, 582, 717, 762; carrier, fifty-two years after recovery, 239; "carriers," effective periods of, 1061.
Typhoid fever and descending infection of the biliary passages, 61; ascitic exudate in, 251; diagnostic value of enlarged spleen in, 75; differentiation of outbreaks of, 909; direct contagion of, 761; epidemics, origin of, 542; epidemiology of, 728; fasting in, 197; hexamethylenamine in, 278; hexamethylenamine as a specific in, 157; in Manitoba, 728; in Richmond, Va., 728; in New York, 121; lumbar puncture in meningeal forms of, 75; milk-borne outbreak of, 114; ophthalmoreaction in, 149; perforation, treatment of, 774; prevention of, 849; reduction, pure water and, 65.
Typhoid spine, 780.

U.

Ulcer, duodenal, in children, 977; peptic, diagnosis of, 657; perforating, of the alimentary canal, 361.
Ulcers, gastric and duodenal, 1044.
Ultramicroscopic examinations, 532.
Ultraviolet ray and high-frequency currents in neurasthenia, 957; high-frequency currents and tubes, 942.
Uncinariasis, fight against, in Porto Rico, 62.
Uremia, decompression of, 881.
Ureters in children, catheterization of, 937.
Urethra, fragmented filiform removed from, 1070; length of, some observations on, 490; primary carcinoma of the female, 37; rupture of, 1019.
Urethritis, chronic, zinc ionization in, 416.
Urethrotomy, internal; its indications and technique, 855.
Uric acid in children, elimination of, 1081.
Uric-acid-free diet, some mistakes which may prevent the best results of the, 560.
Urine, acidity of the, 74; blood in, 241; findings in infants suffering from intestinal infection, 549.
Urobilinuria, relations of, to bile pigment in the blood, 248; significance of, 199.
Uronephrosis, subcapsular, case of, 204.
Uterus, adenoma of cervix of, 937; arteriosclerosis of, 771; cancer of body of, relation of, to fibroids, 722; cancer of the, pyometra in, 696; displacement of, 540; displacement of, in pelvic tumor, 291; examination of, with endoscope, after abortion, 571; fibroid tumors of, operative and non-operative, 788; posterior displacements of the, 82; mixed tumors of the, 117; treatment of displacements of the, 290; vertical and horizontal amputation of the, 505.

V.

Vaccination with humanized lymph, 726.
Vaccine, gonococcus, 807; gonorrhea, 768; infection with, 503; therapy, a defense and an estimate of, 22; therapy in general practice, 723; therapy in joint tuberculosis, 645; therapy, some cases of, 682; therapy, value of, in surgical infections, 853.
Vaccines, autogenous bacterial, 856; bacterial, the use of, 229; bacterial, treatment of erysipelas by, 1031; in gonococcus and streptococcus infections, 1031; stock, therapeutic value of, in treatment of bacterial infections, 723.
Vacuum tube discharges, physiological action and therapeutic effect of, 1025.
Vaginoureterostomy after nephrectomy for pyonephrosis, 529.
Valentine, J. J., preparation for a genitourinary diagnosis, 445.
Varicocele, 417.
Vasomotor tropic neuroses, 937.
Vegetable, diet, 780.
Venereal diseases, the conquest of the, 45.
Venesection, 457; and cardiovascular affections, 812.
Venice, medicine in, 719.
Ventricles, hemorrhage into the, 198.
Vermont State Medical Society, 802.
Vertebra, second cervical, fracture and dislocation of, 1059.
Vertigo and tinnitus, a severe case of, 630.
Vibration in the treatment of constipation and pelvic conditions, 224.
Vienna, letter from, 71, 196, 370.
Virginia State Medical Society, 802.
Viscera, abdominal, displacements of, 860; transposition of, 850.
Visceral disease, painful cutaneous zones in, 358.
Visceroptosis, rational treatment of, 815.
Viscosity of the blood, 934.
Vivisection, alleged professional opposition to, 191.
Voice production, essentials in, 508, 509.
Voice sign, the epileptic, 752.
Vomiting in childhood, diagnostic importance of, 78; obstinate, in a baby, 866.
Von Leyden, the appearance of heteroplastic tumors in the transplantations of the new growths of animals, 301.
Voorhees, I. W., pansinusitis dextra with paralysis of the right vocal cord, 1092.

W.

Wainwright, J. W., bituminous coal smoke: its chemistry and effects on the health of man and plants, works of art and commerce, 791.
Waite, Lucy, the surgical situation, 834.
Wakefield, Homer, the physiology and pathology of the emotions; the physical bases of mental etiology, 310.
